A woman's age when her first child is born affects her risk for developing breast cancer—the younger she is, the lower the risk. Overall, lifetime risk of breast cancer is reduced in parous women compared to nulliparous women, but pregnancy must occur at a young age.[194] A complete pregnancy before age 25 reduces the risk of breast cancer by about 36%, this protective effect is weakened in multiparous women if their age at first birth is greater than 30.[195,196] The protective factor is especially observed in the years of peak incidence, the postmenopausal years.[197] The risk reduction is limited to hormone receptor–positive breast cancer.[195] The influence of pregnancy on the risk of breast cancer also depends on family history, lactation postpartum, and overall parity.[196] Paradoxically, women of all ages have a transient *increase* in breast cancer risk with a recent pregnancy and after each subsequent pregnancy.[196,198] **Pregnancy-associated breast cancer (PABC)** is defined as breast cancers diagnosed up to 5 years after a completed pregnancy; however, risk may persist for a decade.[196,199] Delayed childbearing observed in the United States and all developing countries is expected to show a rise in diagnosed breast cancers.[196] The transient increase in breast cancer risk for all parous women includes events associated with pregnancy, including pregnancy-related hormones, such as estrogen, progesterone, and growth hormone, that promote or initiate cancer cells, immune suppressive effects of pregnancy, and breast tissue involution.[196] Breast gland *involution* after pregnancy and lactation uses some of the same tissue remodeling pathways activated during wound healing (i.e., proinflammatory pathways). The proinflammatory environment, although physiologically normal, promotes tumor progression. One mechanism identified links fibrillar collagen deposition, noted during normal involution, to high levels of COX-2 expression in tumor cells

TABLE 24-13 FACTORS ASSOCIATED WITH INCREASED RISK OF BREAST CANCER*

CATEGORY	RISK FACTOR	RELATIVE RISK†
Race	Blacks have higher incidence up to age 40 yr; whites have higher incidence after age 40	1.1-1.9
Family history	Breast cancer in first-degree relative before age 60	2-3
	Premenopausal or bilateral breast cancer	>4
	Postmenopausal in first-degree relative	≤2
	Breast cancer in two first-degree relatives	4-6
	BRCA1 or *BRCA2*	≤4
	TP53 (Li-Fraumeni syndrome)	≤4
Previous medical history	Moderate or florid mammary hyperplasia	1.5-2
	Mammary papilloma	1.5-2
	Atypical mammary hyperplasia	4-5
	DCIS, LCIS‡	8-10
Estrogen exposure	Early menarche (before age 12 yr)	1.1-1.9
	Late menopause (after age 55)	1.1-1.9
	Postmenopausal hormone therapy	1.4
	Oral contraceptive use	1.5
Pregnancy	Nulliparous or late first pregnancy (after age 35)	1.1-1.9
Radiation	Atomic bomb	3
	Repeated fluoroscopy	1.5-2§
Obesity and stature	Postmenopausal	1.2
	Tallness	≤2
Dietary/alcohol	High alcohol consumption	1.4-2
	High energy intake	≤2
	Advanced age	2-4
	Xenobiotics	≤2
Social	Smoking	2-4
	Higher socioeconomic status	≤2
	Low physical activity	≤2
Environmental	Excess radiation to breasts	??‡
	Chemical carcinogens	≤2-??
	Infectious agents	≤2-??

*Normal lifetime risk in white non-Hispanic women: 1 in 8.

DCIS, Ductal carcinoma in situ; *LCIS,* lobular carcinoma in situ.

and subsequent tumor cell metastasis.[194] This alteration provides support to the tissue change in stroma for driving carcinogenesis.[200] The presence of macrophages in the involuting mammary gland contributes to carcinogenesis.[198,201] Immature macrophages are capable of suppressing cytotoxic T-cell function causing an immunosuppressive stroma conducive to tumor cell promotion. Macrophage and T-cell abundance in breast cancer represent prognostic indicators for tumor recurrence and overall survival.[202] (Involution and pathophysiology are discussed on p. 845.)

The main mechanisms for the *protective* effect of pregnancy are controversial including: (1) induction of breast differentiation with lasting protective phenotypic (morphologic) changes; (2) altered cell fate with removal or modification of vulnerable cells, possibly stem cells; (3) enhancement of the ability for DNA repair or apoptosis, or both; (4) altered systemic hormonal regulation and possible persistent changes in intracellular pathways regulating proliferation; (5) decreased proliferation in the parous involuted gland; and (6) early-life hormonal and dietary exposures.[197] Longer duration of breast-feeding (at least 1 year) is associated with a decreased risk of both hormone receptor–positive and hormone receptor–negative breast cancer.[203] In older first-time mothers, there is theoretically a greater chance for precancerous breast lesions to continue to develop with pregnancy or with events related to pregnancy, for example, postpartum gland involution[196] (see p. 845).

Amphiregulin (AREG) was found to be a major paracrine mediator of ductal morphogenesis and plays an important role in mammary stem cell self-renewal and differentiation.[204] Recent studies show that AREG modulates WNT and NOTCH signaling and functions in regulating the invasive phenotype.[205] Investigators are focusing on the *TP53* tumor-suppressor gene, which has been demonstrated to be important in pregnancy-related hormone-induced protection. The function of *TP53* is required for hormone-mediated protection against the carcinogens dimethylbenz(*a*)anthracene (DMBA)-induced carcinogenesis in mice.[193] The functions of cadherins or adhesion molecules and p53 (protein) are closely linked. A pivotal role for p53 is the regulation of a balance between apoptosis and cell proliferation.[206] Russo and colleagues[207] have found that

the postpregnancy involuted mammary gland exhibits elevated expression of genes involved in DNA repair and apoptosis. Pregnancy may induce a protective mechanism at the post-transcriptional level (epigenetically) that maintains the faithfulness of the transcriptional process.[208]

Lobular Involution and Age and Postlactational Involution

Part of the uniqueness of the mammary gland is its profound physiologic changes throughout the phases of a woman's life: puberty, pregnancy, lactation, postlactational involution, and aging. The human breast is organized to 15 to 20 major lobes, each with lobules containing milk-forming acini (see Figure 23-19). With aging, breast lobules regress or involute with a decrease in the number and size of acini per lobule and replacement of the intralobular stroma with the more dense collagen of connective tissue.[209] Over time the glandular elements and collagen are replaced with fatty tissue. This process is called **lobular involution** whereby, over many years, the parenchymal elements progressively atrophy and disappear. A first study of its kind found lobular involution was associated with reduced risk of breast cancer. Breast cancer risk decreased with increasing extent of involution in both high- and low-risk subgroups defined by family history of breast cancer, epithelial atypia, reproductive history, and age. Based on histologic and epidemiologic factors, these investigators propose that delayed involution (persistent glandular epithelium) is a major risk factor for breast cancer.[209] Widely appreciated is that as women age, their risk of breast cancer increases. But the *rate* of increase of breast cancer *slows* at about 50 years of age.[210] This slowing has been attributed to a reduction in ovarian hormone production. Milanese and colleagues[209] observed a definite increase in the process of involution at about 50 years of age with complete involution present in 5.8% of women ages 40 to 49 years and 21.6% of women ages 50 to 59 years. Investigators propose that involution may contribute to this slowing in the rate of increase of breast cancer among women older than 50 years. Importantly, investigators found an inverse association between lobular involution and parity.[209] Other investigators have reported that the more children a woman has, the more likely she is to have persistent lobular tissue,[211] which Milanese and colleagues[209] found was associated with increased risk of breast cancer. However, multiparity also has been found to reduce risk of breast cancer.[212,213] This apparent contradiction may be explained by studies documenting that full-term pregnancies after 35 years of age are correlated with an increased risk of breast cancer.[214] In the Milanese study, age of the mother at each child's birth was unknown.

Henson and colleagues[215] propose that late pregnancy with its concomitant increase in the proliferation of the ductal-alveolar epithelium is likely to interrupt the process of involution, which typically begins between 30 and 40 years of age. The activated stromal environment in the process of involution is similar to that in invasive breast cancer. The long-term protective effects of pregnancy with hormones released during pregnancy affect remodeling of the stromal microenvironment by causing apoptosis and involution. However, an increase in

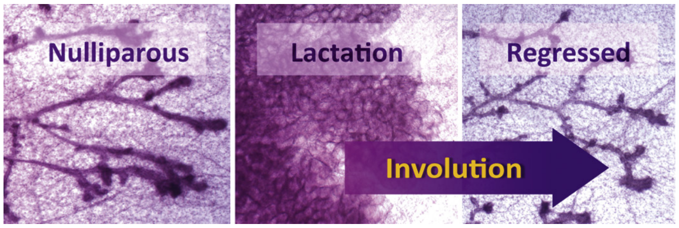

FIGURE 24-31 Extracellular Matrix (ECM) Is Different in Nulliparous, Lactating, and Involuting Glands. Several ECM differences between nulliparous, lactational, and involuting mammary glands are related to collagen-fiber organization, cell motility and attachment, and cytokine regulation in a rodent model. Many protumorigenic ECM proteins are mediators of breast cancer progression specific to the involutional window, and systemic ibuprofen experimental treatment during involution decreases its tumor promotional changes. (From O'Brien JH et al: *J Proteome Res* 11:4894–4905, 2012.)

breast cancer risk following pregnancy may be caused by the *process* of mammary gland involution, which returns the tissue back to its prepregnant state and is co-opted by processes of wound healing resulting in a proinflammatory environment that although physiologically normal can promote carcinogenesis.[201] Postpartum involution uses the biologically coordinated programs of epithelial cell death and stromal remodeling to change the gland back to its original nonsecretory state before the next pregnancy.[194] In a mouse model, human breast cancer cells exposed to the involuting mammary microenvironment form large tumors with abundant fibrillar collagen, high COX-2 expression, and further evidence of an invasive phenotype.[194] Additionally, macrophages, specifically M2-polarized macrophages, are necessary for the epithelial cell death during normal postpartum mammary gland involution.[216] Therefore, the re-emerging stroma and activated immune cells seem key for understanding the pathogenesis of pregnancy-associated breast cancer. An important transcriptional regulator of genes, **Stat3,** is associated with inflammation, wound healing, mammary macrophages, and mast cells. Stat3 appears to have an important role in modulating cell death and involution.[217] In postlactational involution the mammary gland regresses and remodels to its prepregnant state whereby fibroblasts secrete proteases that degrade the extracellular matrix proteins. Consequently, the increased release of bioactive matrix fragments can promote tumor growth, motility, and invasion.[199] The extracellular matrix (ECM) is very different between nulliparous, lactating, and involuting glands as shown in Figure 24-31 (see What's New? Breastfeeding and a New Emerging Target—NSAIDs for the Prevention of Pregnancy-Associated Breast Cancer).

Interestingly, oophorectomy, which is associated with a decrease in risk of breast cancer, leads to atrophy of breast parenchyma in young women as is noted in older women. Thus the risk reduction of oophorectomy may be caused by an accelerated involution.[215]

Hormonal Factors

The link between breast cancer and hormones is based on six factors that affect risk: (1) the protective effect of an early (i.e., in the 20s) first pregnancy; (2) the protective effect of removal of the ovaries and pituitary gland; (3) the increased risk associated

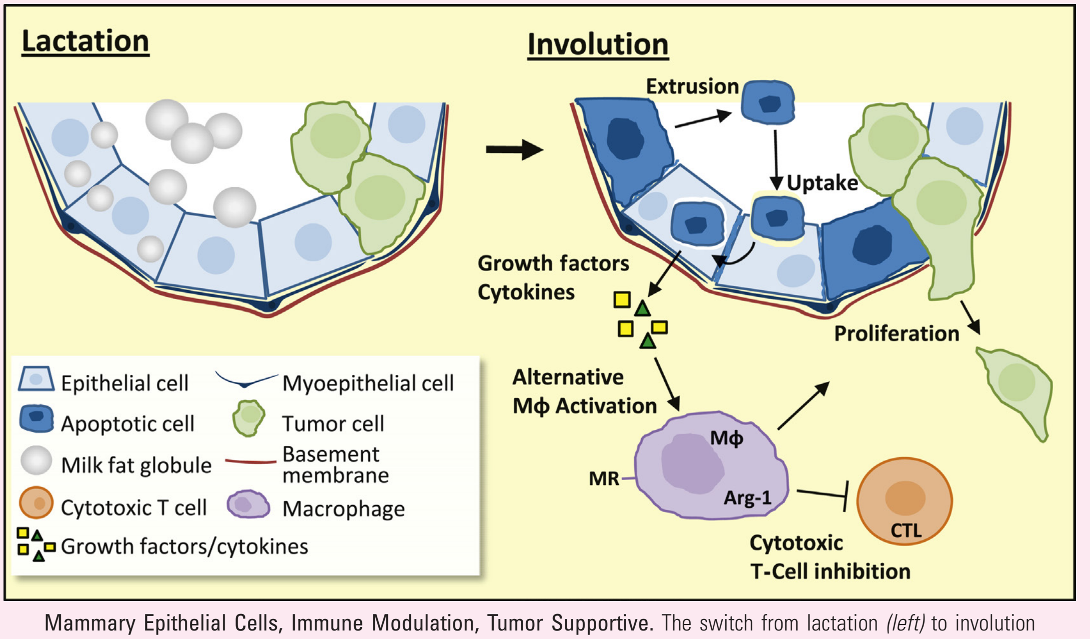
WHAT'S NEW?

Breastfeeding and a New Emerging Target—NSAIDs for the Prevention of Pregnancy-Associated Breast Cancer?

A longer duration of breast-feeding is correlated with a lower risk of breast cancer.[1] In reports of large sample sizes, the risk-reducing effect was observed for both pre-and postmenopausal women.[1,2] Longer duration of breast-feeding reduced the risk of triple-negative cancers but not for luminal cancers.[3] The longer the duration of breast-feeding per child was related to lowered risks of breast cancer.[4,5] Although it has not been adequately studied, one hypothesis for why longer duration of breast-feeding is protective against breast cancer is that a slow-paced weaning may decrease the stromal inflammatory reaction during the breast involution.[6] Pregnancy and postpartum involution both affect a woman's risk for breast cancer. The postpartum period is associated with a transient 5- to 10-year period of increased risk crossing over to a protective effect.[7-9] Recent pregnancy correlates with decreased survival for breast cancer patients compared with nonpregnancy-associated breast cancer.[10] Postpartum breast cancers are known as type II pregnancy-associated breast cancer (PABC). Mechanisms of postpartum mammary gland involution in which the physiologic programs similar to those involved in wound healing are activated to remodel the lactationally competent mammary gland back to a nonsecretory state likely account for the poorer prognosis of PABC.[11] Recently, having breast-fed and the total duration of breast-feeding conferred a substantial reduction in breast cancer risk among *BRCA1* but not *BRCA2* mutation carriers, of 32%.[12]

Investigators using the lactogenic microenvironment to discover new therapies that would promote breast differentiation (thus decrease the risk of cell transformation) developed a lactogenic mouse model. These investigators showed that the loss of a single gene, caveolin-3 (cav-3) expressed in myoepithelial cells within the mammary gland, conferred protection against mammary tumor formation.[13] These results support the fact that the lactogenic microenvironment is a critical factor in preventing mammary tumor onset, progression, and metastases.[13]

Investigators demonstrated that cyclo-oxygenase 2 (COX-2), an enzyme involved in initiating inflammatory responses, is up-regulated in the mammary gland during involution. COX-2 inhibition is considered an important target for prevention and treatment of several cancers.[14] NSAID treatment (ibuprofen) in animal models of PABC decreases tumor-promotional attributes of postpartum involution mammary extracellular matrix.[14] Treatment inhibited tumor progression, in part, by suppressing COX-2–dependent collagen deposition. Investigators assessed drug effects on the process of mammary gland involution. They demonstrated that COX-2 inhibition by NSAIDs can decrease COX-2 activity in the gland without interruption of involution.[14] NSAIDs suppress tenascin-C, a glycoprotein, expressed in mesenchymal tissues during development and re-expressed during carcinogenesis.[14] Studies investigating promotion of breast cancers that develop in the postpartum period have identified fibrillar collagen as an ECM mediator of progression that can be targeted by ibuprofen treatment.[15,16] Organization of collagen into radially aligned fibers, called tumor-associated collagen, predicts survival in women with breast cancer.[17] M2-polarized macrophages are necessary for epithelial cell death during normal postpartum mammary gland involution.[18] Macrophages and their monocytic precursors can change their functional state (e.g., exhibit plasticity) in response to cues from the microenvironment. For example, macrophages can be functionally polarized into M1 (proinflammatory) and M2 (alternatively activated),



Mammary Epithelial Cells, Immune Modulation, Tumor Supportive. The switch from lactation *(left)* to involution *(right)* promotes milk-producing epithelial cells to undergo apoptosis *(dark blue cells)* and then the cells extrude into the alveolar lumen. Other milk-producing cells are activated to become phagocytic cells *(light blue cells)* and engulf the shed apoptotic (dead) cells. Clearance by the immune system of apoptotic cells is thought to result in release of Th2 cytokines and growth factors from the phagocytic mammary cells. This changed cytokine environment is anticipated to promote alternative activation of macrophages (see text) and inhibition of a protective immune response or cytotoxic T lymphocyte (CTL) cells, resulting in an immunosuppressive environment and promoting a tumor microenvironment *(green cells)*. (From Fornetti J et al: *Cell Cycle* 11[4]:639–640, 2012.)

Breastfeeding and a New Emerging Target—NSAIDs for the Prevention of Pregnancy-Associated Breast Cancer?

called M2-polarized macrophages.[19] Interleukin-4 (IL-4) and IL-13, cytokines of the Th2 response, are the major inducers of the "alternative activation" of macrophages that play an important role in the immune response to parasites, in allergy, wound healing, and tissue remodeling.[19] The figure on p. 846 represents a recent model of phagocytic mammary epithelial cells and a protumorigenic microenvironment.

NSAIDs potentially represent a promising treatment for type II PABC without interrupting postpartum remodeling. Elucidation on the mechanisms of lobular involution is very important for understanding breast carcinogenesis and factors that reduce breast cancer risk. Factors related to the risk of breast cancer are diverse and not just limited to reproductive factors. However, with later age of first full-term birth around the world, concern is for increasing the baseline risk of breast cancers.

with early menarche, late menopause, and nulliparity; (4) the relationship between types of fat, free estrogen levels, and oxidative changes in estrogen metabolism; (5) the hormone-dependent development and differentiation of mammary gland structures; and (6) the efficacy of antihormone therapies for treatment and prevention of breast cancer. Throughout its existence, the mammary gland epithelium proceeds through critical "exposure periods" of rapid growth or cycles of proliferation, including neonatal growth, pubertal development, pregnancy, lactation, and involution (after pregnancy and postmenopause; see p. 845).[201,218]

Our understanding of the role of systemic hormones as powerful regulators of mammary gland development is shifting. Evidence is pointing to the wide-ranging effects of systemic hormones as possibly not due to their *direct* hormone action but rather their *induced* actions from multiple secondary paracrine effectors—thus the term *hierarchical*.[192] Unraveling is a complex model of hormone, paracrine, and adhesion molecule-signaling pathways affecting epithelial and stromal cell fate in development and cancer (Figure 24-32). Despite differences between the organized process of development and the less, even chaotic, environment of invasive cancer, both processes share many identical mechanisms and signaling pathways. Key is *tissue remodeling* that applies to pubertal growth, immediately after pregnancy and during involution (see previous section).[201,219,220]

The female reproductive hormones (estrogens, progesterone, and prolactin) have a major role and effect on mammary gland development and breast cancer (Figure 24-33).[219] A vast majority of breast cancers are *initially* hormone dependent (estrogen receptor positive [ER+] and/or progesterone receptor positive [PR+]), with estrogens playing a crucial role in their development.[221] Estrogens control processes critical for cellular functions by regulating activities and expression of key signaling molecules. These processes include regulation of receptor activity, its interaction with other intracellular proteins, and DNA.[221] Estrogens thus play prominent roles in cellular proliferation, differentiation, and apoptosis.[221-223] Estrogens affect microtubules that are essential for establishing cell shape and cell polarity, processes necessary for epithelial gland organization.[221]

Depending on the experimental model system used, progesterone in animal and in vitro studies show both an increase and decrease in breast cancer risk[224-226] (see following discussion). These data question the continuing view that PR is co-expressed in every ER+ luminal cell, highlighting the potential for ER and PR to *individually* contribute to the biology of normal breast development, function, and role in breast carcinogenesis[227] (Figure 24-34, and see p. 849). Additionally these data identify a novel cell population that may be very important in understanding the cancer-causing effects of synthetic progestins in hormone replacement therapy (HRT) (see p. 853).

Prolactin, produced by the pituitary gland, travels through the blood and exerts multiple metabolic and reproductive effects especially on the breast as the key regulator of lactation. Prolactin is also produced in other tissues, including the breast (known as extrapituitary prolactin).[228,229] Recently, investigators reported that autocrine prolactin is required for terminal mammary epithelial differentiation during pregnancy and production is regulated by the signaling pathway Pten-PI3K-Akt.[228] Although this finding is critical for normal breast development, differentiation, and lactation it may also be important in breast carcinogenesis because the PI3K-Akt signaling pathway is commonly activated in human cancers. This suggests the important possibility that autocrine prolactin may play a role in breast cancer.

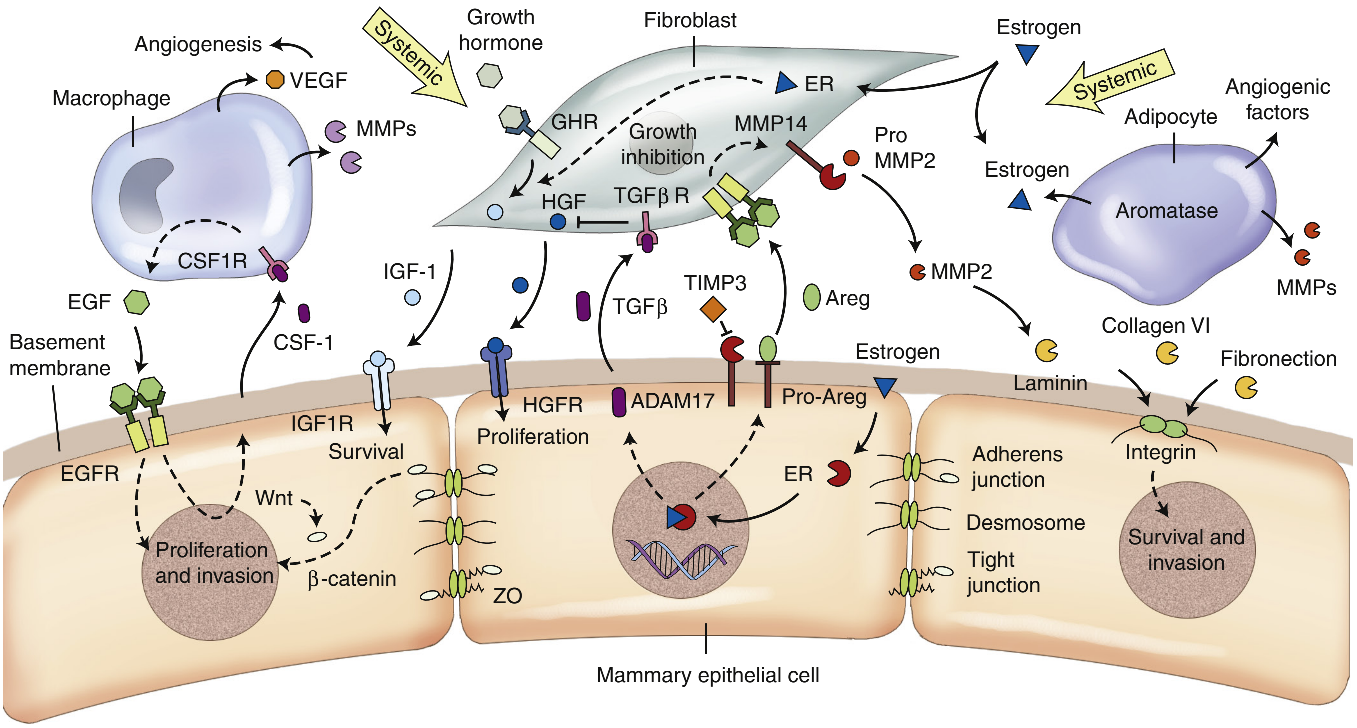

FIGURE 24-32 **Figure of the Current Hypothesis of Mammary Gland During Development and Cancer.** A tissue model of interacting endocrine, paracrine, and adhesion signaling pathways that modulate epithelial and stromal cell behavior. Some of the pathways depicted are not exclusive to one type of stromal cell. Dotted arrows indicate indirect interactions. (From Lanigan F et al: *Cell Mol Life Sci* 64:3165, 2007.)

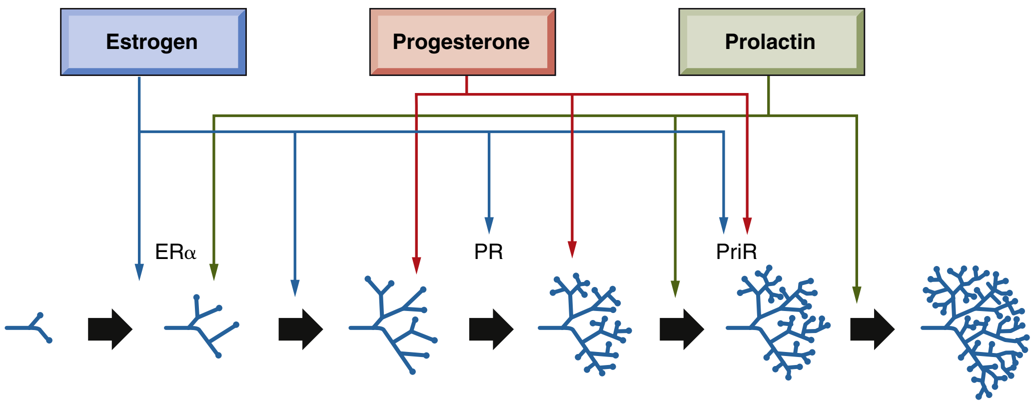

FIGURE 24-33 **Factors Involved in Mammary Gland Development.** Work of numerous laboratories led to the identification of many genes important in mammary gland development that are summarized in the scheme. It is possible to consider four major hormonal hypotheses for breast cancer: (1) ovarian androgen excess (testosterone, for example), (2) estrogens and progesterone levels (ovarian and hormonal replacement), (3) estrogens alone (ovarian and hormone replacement), and, (4) local biosynthesis of estrogens in breast tissue. These hypotheses, however, may not be mutually exclusive. HRT is discussed later in a separate section; the present discussion is concerned with endogenous levels of hormones.

The first hypothesis that breast cancer risk is increased among women who have ovarian androgen excess also includes chronic anovulation and reduction of luteal-phase (menstrual cycle) progesterone production. Therefore, it is also called the "ovarian hyperandrogenism/luteal inadequacy hypothesis." This hypothesis, proposed by Grattarola in the 1960s, was based on the observation that women with breast cancer also reveal hyperplasia of the endometrium—a common symptom of ovarian, androgen excess chronic anovulation, and progesterone deficiency.[219] These findings have been confirmed and extended[230] in several studies including prospective studies. From a pooled analysis of nine prospective studies of postmenopausal women, all the androgens were positively (significantly) associated with breast cancer risk.[231] The majority of data from this pooled analysis were for testosterone. Similar findings were

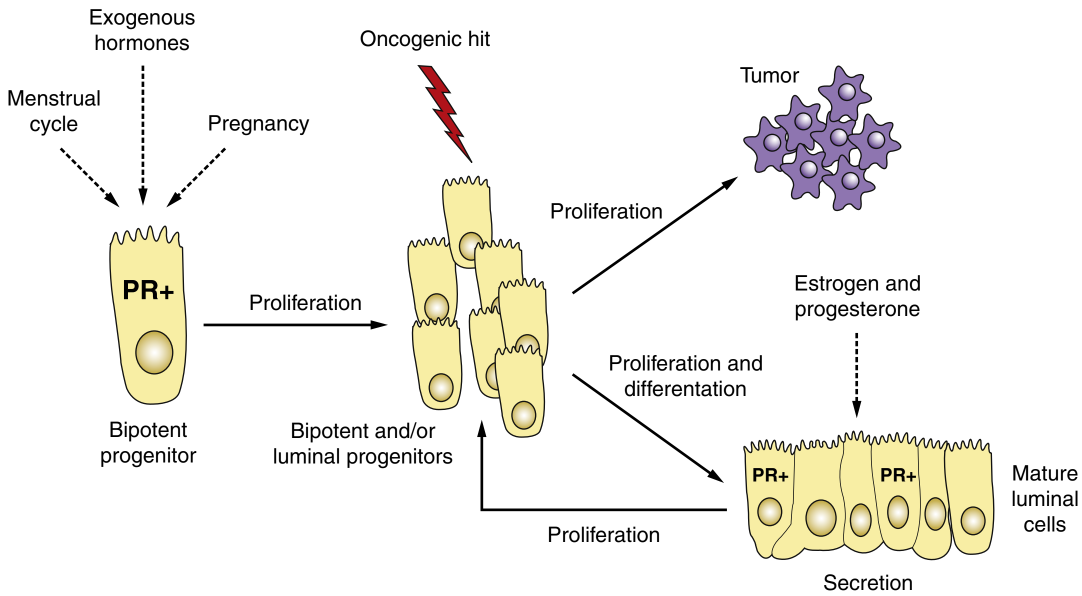

FIGURE 24-34 **Progesterone Progenitor Cells, a Working Model.** The fate of progesterone receptor–positive (PR+) progenitor cells is important to understand for normal breast development and breast carcinogenesis. When P levels peak during the second phase of the menstrual cycle and during pregnancy, a subset of PR+ bipotent (more than one type of cell) progenitor cells proliferate to expand the epithelial compartment providing a larger pool of cells susceptible to oncogenic mutation. These cells can then differentiate into mature luminal cells that can respond to the proliferative and secretory signals of both estrogen (E) and progesterone (P). This process is increased by the E induction of PR expression in this cell subtype. (Adapted from Hilton HN et al: *Mol Cell Endocrinol* 361:191–201, 2012.]

observed in the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort study.[232] Four prospective studies have reported a positive association for premenopausal women between testosterone and risk of breast cancer.[233] A prospective Italian study showed a significant increase in breast cancer risk for premenopausal women who had elevated levels of testosterone and lower levels of progesterone.[234] In a recent case-control study serum androgens were associated with both ER+, PR+ and ER–, PR– cancers.[235] A case-control study nested with the New York University Women's Health Study showed premenopausal serum testosterone and free testosterone concentrations were positively associated with breast cancer risk.[236] Unclear from studies is whether the association with testosterone is direct or indirect (i.e., enzyme conversion by tissue aromatase of testosterone to estradiol) (Figure 24-35). Overall, the association between circulating testosterone in postmenopausal women and subsequent risk of breast cancer is now well established.[237] Indeed some investigators propose increased androgenic activity is the principal endocrine abnormality of women with hormone-dependent breast cancer called the androgen-excess theory.[238] These investigators suggest that androgen excess is the main growth stimulator of ER+ tumors through testosterone conversion into estrogens through the aromatase enzyme in stromal tissue (see the fourth hypothesis in the following text). Studies have demonstrated a correlation between the androgen receptor (AR) and ER/PR pathways, a potential role for AR in prognosis, carcinoma proliferative responses to androgen in several AR expressing cell lines, and expression of an androgen-dependent cascade of intracellular signaling in AR expressing breast tumors. AR is reported to be expressed in 50% to 100% of breast cancers; however, controversy exists about the percentages because of study methods used.[239] A subset of individuals with triple negative breast cancer (TNBC) has been reported to express AR in carcinoma cells leading to the treatment proposal of manipulation of androgen signaling or AR targeted therapies. Further study is needed because of the reported proliferative and antiproliferative effects of AR in TNBC.[239] For those women with high testosterone/AR-negative tumors, androgen excess does not stimulate tumor growth directly through conversions to estrogens but can by increasing the production of epidermal growth factor (EGF) and EGF inhibitors may be indicated.[238]

The second hypothesis is increased breast cancer risk among women with blood elevations of both estrogens and androgens. These observations revealed increased proliferation rates of breast epithelium during the luteal phase of the menstrual cycle when the ovaries produce both estradiol and progesterone. A recent reanalysis of 13 prospective studies showed that circulating concentrations of sex hormones are associated with several of the established or suspected risk factors for breast cancer. The hormones were all positively correlated with each other, implying they are all part of the same metabolic pathway.[240] The strongest associations were with BMI and all the hormones were higher in obese women with breast cancer than in women with a low BMI. Analyses related to increasing age found large decreases in circulating DHEAS and androstenedione, small changes in estrogens and testosterone, and increases in SHBG (consistent with other previous reports). The smaller decrease in estrogen blood concentrations may be caused by increased synthesis of estrogen in tissue by aromatization in older women

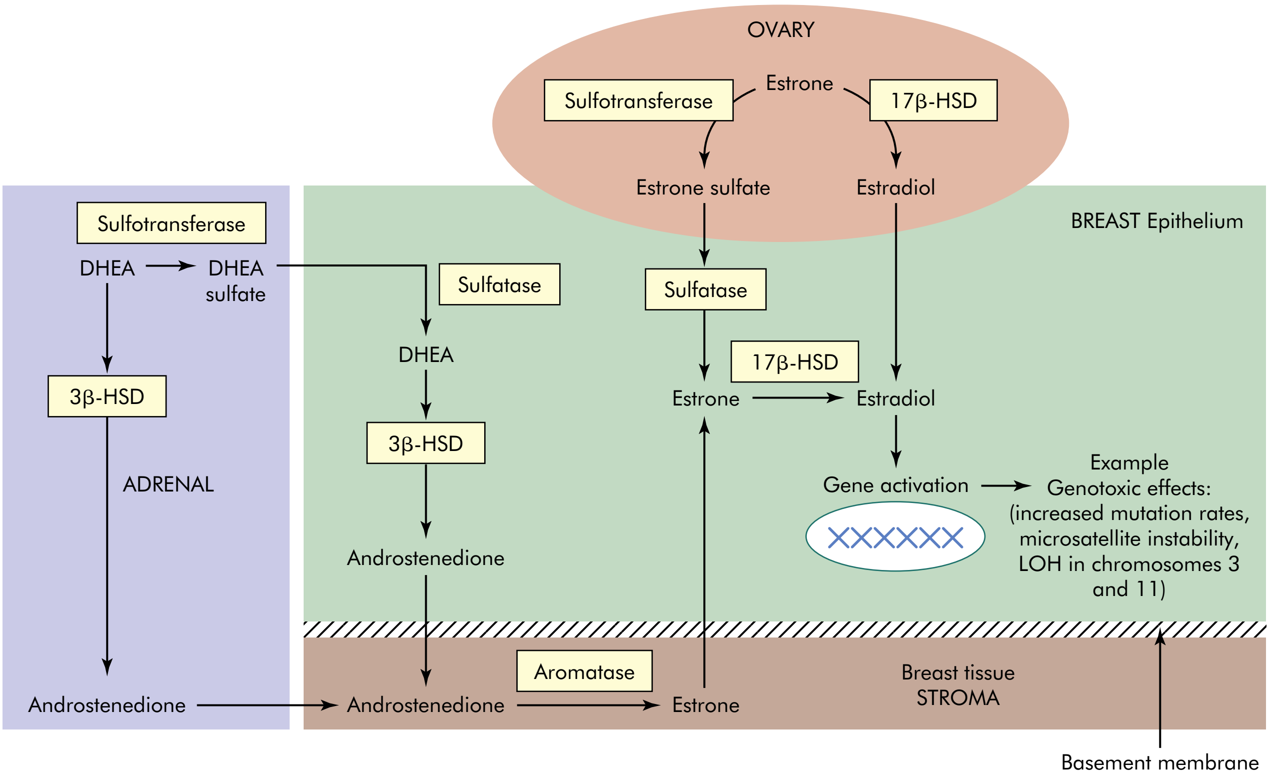

FIGURE 24-35 Local Biosynthesis of Estrogens. Three main enzyme complexes *(yellow)* involved in estrogen formation in breast tissue, including aromatase, sulfatase, and 17β-estradiol hydroxysteroid dehydrogenase (17β-HSD). Thus despite low levels of circulating estrogens in postmenopausal women with breast cancer, the tissue levels are several-fold higher than those in plasma, suggesting tumor accumulation of these estrogens. Data suggest that most abundant is sulfatase in both premenopausal and postmenopausal women with breast cancer. Numerous agents can block the aromatase action, exploration of progesterone, and various progestins to inhibit sulfatase and 17β-HSD or stimulate sulfotransferase (i.e., breast cancer cells cannot inactivate estrogens because they lack sulfotransferase) may provide new possibilities for treatment. *LOH,* Loss of heterozygosity (see Chapter 12). (Adapted from Russo J, Russo I: *Molecular basis of breast cancer: prevention and treatment,* Germany, 2004, Springer-Verlag, Berlin Heidelberg.)

or women with ovariectomy, or both.[240] Ovariectomy was associated with androgen levels about 30% lower than from women with natural menopause. Surprisingly, no significant differences in those women with ovariectomy were found for total estradiol or estrone (researchers excluded women using exogenous hormone therapies). Cigarette smoking and alcohol use were associated with moderate increases in all the hormones. Age at menarche, age at parity, age at first-term pregnancy, and family history of breast cancer were not strongly related to any of the hormones studies. From this study, type of hormone assay used affected some of the results and assays that used a purification step were more specific and sensitive.[240] Overall, older data are too few to draw any *firm* conclusions.[233] New data identify mammary stem cells (MaSCs) as critical targets for ovarian hormones, especially progesterone surges during the normal reproductive cycle and pregnancy increasing the proliferation of mammary stem cells.[241,242] Progesterone-expanded MaSC pools could accumulate mutations and acquire the properties of tumor-initiating cells. From these studies the progestin in HRT was proposed as a risk factor because of the presence of hidden or occult preinvasive breast cancer in postmenopausal women that contains ER–/PR–/CK5+ stem cells, which may be reactivated by progestins and function as tumor-initiating cells.[243] Overall, complex data indicate that progesterone as a proliferative hormone is a risk factor for breast cancer (promotes preneoplastic progression) and stimulates the normal breast epithelium through a complex paracrine mechanism (Figure 24-36, *A*). Paradoxically, however, in the more advanced stage of breast cancer, PR either independent of progesterone hormone or in response to progesterone is proposed to impede invasion and metastasis by maintaining epithelial cell differentiation and inhibiting epithelial-mesenchymal transition (EMT) a key developmental process often activated in cancer invasion and metastasis (see Figure 24-36, *B*, and Pathogenesis section). Dysregulation of the RANKL-RANK signaling pathway is implicated in both the initiation and progression of progesterone-dependent mammary carcinomas, and inhibitors of RANK or RANKL are suggested to have an effect on the development of breast cancer.[243]

The third hypothesis is often called the "estrogen-alone hypothesis." Substantial prospective data have accrued on circulating estrogens and breast cancer risk in postmenopausal women.[231,237,244] From the EPIC study,[232] increasing blood levels of estradiol also increased the risks for breast cancer (relative risks 1.4,1.2,1.8, 2). Updated analyses from two cohorts of the pooled analysis of nine prospective studies provide strong

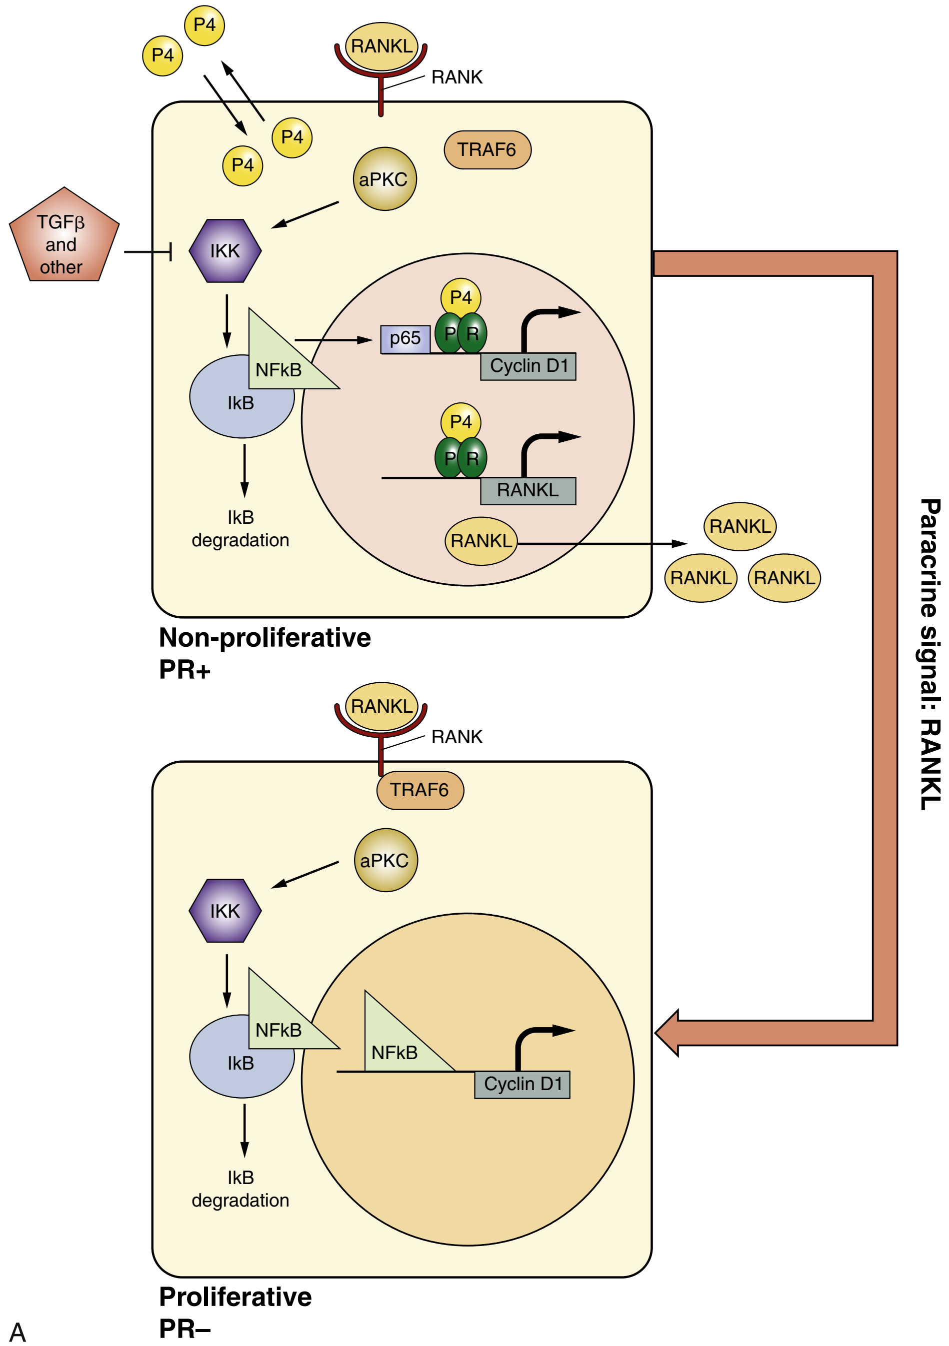

FIGURE 24-36 A Model of Progesterone Regulation of Mammary Cell Proliferation. **A,** Model for progesterone regulation of cell proliferation in the mammary epithelium mediated by the RANK-RANKL paracrine signaling pathway. This model is based on work with the mouse mammary gland; RANKL is a direct target of PR induced by progesterone (P4) and is then released to interact with the RANK receptor on either PR+ or PR– cells. In PR+ cells, RANKL activates the downstream IKK/IkB/NFkB/cyclin D1 signaling pathway to stimulate proliferation. RANKL does not generate a sustained activation of the NFkB/cyclin D1 proliferative pathway in PR+ cells because of the suppressive actions of TGF-β and/or other unknown mechanisms.

Continued

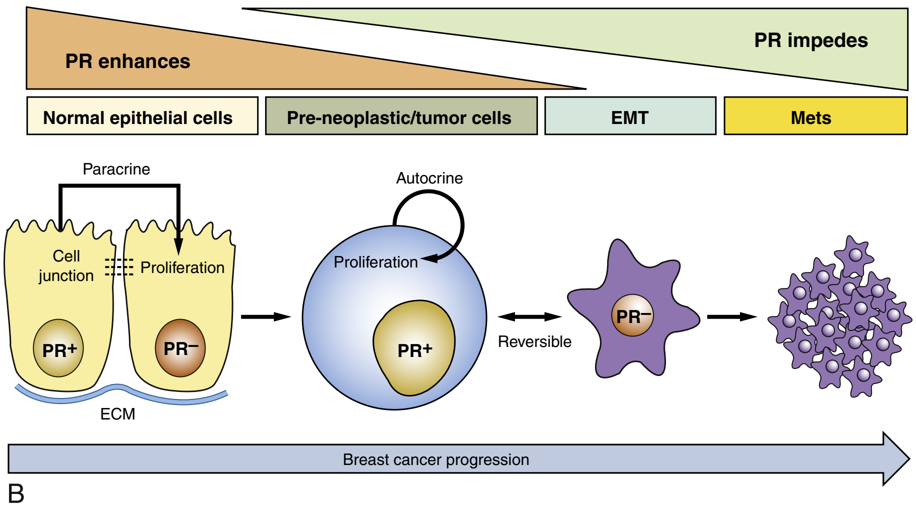

FIGURE 24-36, cont'd A Model of Progesterone Regulation of Mammary Cell Proliferation. **B,** Model for progesterone and PR action at stages of breast cancer progression. Progesterone is a risk factor for breast cancer and promotes preneoplastic progression by stimulating cyclic proliferation of the mature breast epithelium and by activating mammary stem cell pools or hidden tumor-initiating cells. Alterations in the progesterone/PR signaling axis, including a switch from a paracrine to an autocrine regulation of proliferation, contribute to progression. In more advanced stage breast cancer PR, either independent of P4 or in response to P4, suppresses tumor invasion and metastasis through maintaining epithelial cell phenotype and impeding the epithelial-mesenchymal transition (EMT). *TGF,* Tumor growth factor. (Adapted from Obr AE, Edwards DP: *Mol Cell Endocrinol* 357[1-2]:4–17, 2012.)

evidence that circulating hormones are an important marker of increased risk in postmenopausal women and not a result of the production of hormones by a tumor.[245] Positive associations with urinary estrogen levels also were similar from two prospective studies.[246,247] A recent large case-control study nested with the EPIC prospective cohort study showed that serum levels of total and bioavailable testosterone and estradiol are associated with risks of ER+, PR+, joint ER+PR+, and surprisingly, with ER–, PR–, and joint ER–PR– breast tumors. Estrogen binding to the receptor ER-alpha increases tumor growth and in clinical studies only individuals with ER+ tumors respond favorably to antiestrogenic therapy. It is, therefore, paradoxical that in this case-control study estrogens showed a direct association with ER–, PR–, and joint ER–PR– breast cancer and only moderately smaller (effect size) than seen for hormone receptor–positive disease.[235]

EPIC and other studies, however, observed no clear relationship between plasma estrogen levels and breast cancer risk in *premenopausal* women.[232] Yet investigators had little ability to evaluate hormonal levels with phases of the menstrual cycle. In premenopausal women, the NHS II found in the follicular phase of the menstrual cycle, but not the luteal phase, that circulating total and free estradiol was significantly associated with breast cancer risk.[248] Experimental studies have also provided strong and consistent evidence that estrogens can promote breast tumor development and growth[249] (see the Pathogenesis section).

Overall, the positive association between circulating estrogens in postmenopausal women and subsequent risk of breast cancer is well established. The association appears strongest for estrogen-positive tumors and is statistically robust across groups of women at varying risk of breast cancer.[237] Relatively few studies on circulating sex steroids and breast cancer have been conducted in premenopausal women, possibly because of the difficulty to accurately assess hormones levels over the menstrual cycle.

The fourth hypothesis suggests that *local* (in situ; paracrine) formation of estrogens in breast tumors may be more significant than circulating estrogens in *plasma* for the growth and survival of estrogen-dependent breast cancer in postmenopausal women. The rationale is based on the following evidence: (1) estradiol (E_2) levels in breast tumors are equivalent to those of premenopausal women, despite plasma E_2 levels being lower after menopause; (2) E_2 concentrations in breast tumors of postmenopausal women are at least 10 times higher than serum levels; and (3) biosynthesis of estrogens in breast tumors occurs through two different routes, the aromatase pathway and the steroid sulfate (STS) pathway[221] (see Figure 24-35).

Estrogens in normal breast tissue in pre- and postmenopausal women are comparable, reflecting other than ovarian biosynthesis of estrogens that occurs in several peripheral tissues including adipose, muscle, skin, bone, brain, aorta, and breast tissues.[250,251] A series of enzymes are involved in in situ production of estrogens in breast carcinoma tissues, but aromatase (member of the cytochrome P-450 family) is a key enzyme of estrogen production through conversion of adrenal androgens in estrogen-dependent postmenopausal breast cancer.[250] Breast tissue metabolism of estrogens through the aromatase-mediated pathway is correlated with the risk of breast carcinogenesis. Evidence suggests that the site of conversion of androgens to estrogens in breast cancer is the stroma and not the malignant

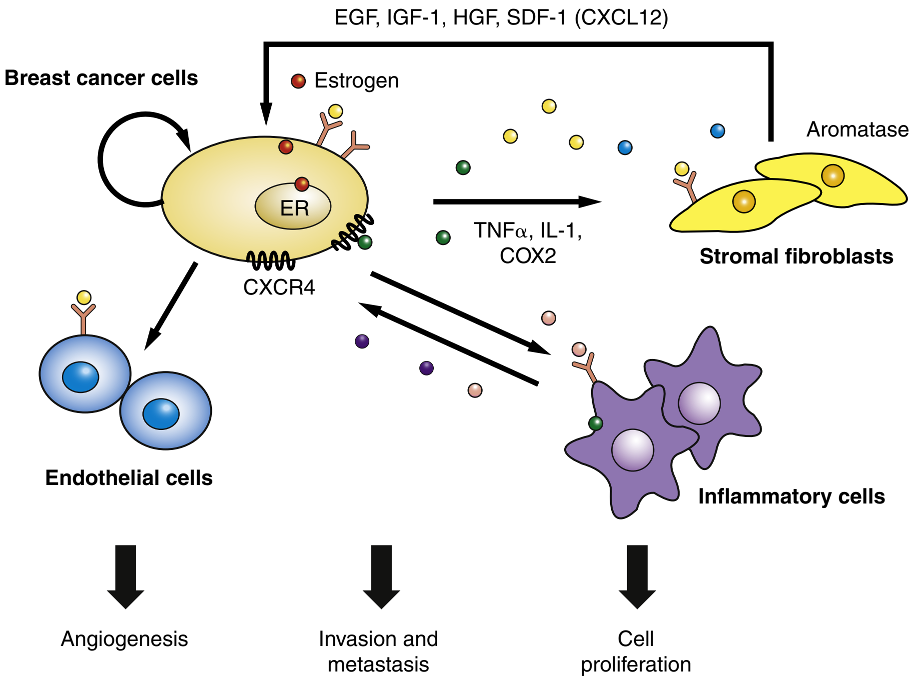

FIGURE 24-37 **Breast Cancer Cells and Stromal Fibroblasts Produce Estrogen.** In the microenvironment of breast carcinoma, breast cancer cells interact with different stromal cells through the secretion of growth factors and cytokines. Fibroblasts adjacent to cancer cells produce estrogen through the expression of the enzyme aromatase, which is induced by several factors including tumor necrosis factor alpha (TNF-α), interleukin 1 (IL-1), and cyclo-oxygenase 2 (COX-2). These interactions lead to cancer cell proliferation, angiogenesis, and metastasis. (Adapted from Yamaguchi Y, Hayashi S: *Endocr J* 56[1], 2009.)

epithelial cells.[252] Stromal fibroblasts adjacent to the tumor express aromatase and actively induce local estrogen production and signal crosstalk between estrogen and growth factors affecting the progression of breast carcinomas (Figure 24-37).

Investigators also have reported aromatase in adipocytes and carcinoma cells.[250] Stromal fibroblasts demonstrate multiple functions in the genesis and progression of breast cancers and carcinoma-associated fibroblast (CAFs) are potential therapeutic targets for many other cancers.

Breast tissue also contains high sulfatase activity and produces estrone through the hydrolysis of estrone sulfate[221] (see Figure 24-35). Thus quantitatively estrone sulfate may be the most important circulating estrogen in women; it increases the reservoir for the production of estrone and, ultimately, estradiol. It was found that E_2, itself, has antisulfatase action. This paradoxical effect of estradiol could be related to some studies that have found estrogen replacement therapy (ERT) to have either no effect or to decrease breast cancer mortality in postmenopausal women[253] (see p. 854). In summary, the blockage of estradiol through both the aromatase and sulfatase pathways, as well as the stimulation of sulfotransferase activity (i.e., sulfation is important to estrogens because the addition of the charged sulfonate group protects the hormones [estrogens] from binding to their receptors and, consequently, inhibiting cell growth) can provide new and potentially powerful applications in breast cancer.

Although experimental, clinical, and epidemiologic research have implicated endogenous estrogens in the etiology of breast and endometrial cancer and, possibly, ovarian cancer, the role of individual *patterns* of estrogen metabolism is a new focus, especially for epidemiology.[249] Estrogen metabolism from oxidation of the parent estrogens, estrone, and estradiol occurs at either the 2-, 4-, or 16-position of the carbon skeleton to yield 2-hydroxylated, 4-hydroxylated, or 16-hydroxylated estrogens, respectively. The 4- and 16-α-hydroxylated pathways are potentially tumor promoting; conversely, the 2-hydroxylated pathway has been demonstrated to be less tumor promoting and, possibly, inhibiting.[254] A recent prospective case-control study found nearly all estrogens, estrogen metabolites, and metabolic pathway groups were associated with an increased risk of breast cancer especially unconjugated estradiol. These investigators found more extensive 2-hydroxylation of estrogens is associated with lower risk and less methylation of potentially genotoxic 4-hydroxylation pathway with a higher risk of breast cancer in postmenopausal women.[255] Thus potential imbalances in estrogen metabolites in breast tissue correlate with the development of tumors and suggest possible biomarkers related to the risk of developing breast cancer.

Hormone Replacement Therapy (HRT) and Breast Cancer Risk: Estrogen Plus Progesterone and Estrogen Only (ERT). Most epidemiologic studies have found an increase in breast cancer risk related to HRT with combined estrogen and progestogens (HRT)[256,257] (Table 24-14). Evidence comes from observational studies and clinical trials and suggests an approximate 30% to 70% increase in breast cancer risk with HRT current use and

TABLE 24-14 HORMONAL TREATMENTS ASSESSED BY THE IARC MONOGRAPH WORKING GROUP

GROUP 1 AGENT	CANCER ON WHICH SUFFICIENT EVIDENCE IN HUMANS IS BASED	SITES WHERE CANCER RISK IS REDUCED	ESTABLISHED MECHANISTIC EVENTS	OTHER LIKELY MECHANISTIC EVENTS
Diethylstilbestrol	Breast (exposure during pregnancy), vagina and cervix (exposure in utero); limited evidence: testis (exposure in utero), endometrium	—	Estrogen receptor–mediated events (vagina, cervix), genotoxicity	Epigenetic programming
Estrogen-only menopausal therapy	Endometrium, ovary; limited evidence: breast	—	Estrogen receptor–mediated events	Genotoxicity
Combined estrogen-progestogen menopausal therapy	Endometrium (risk decreases with number days/month of progestogen use), breast	—	Receptor-mediated events	Estrogen genotoxicity
Combined estrogen-progestogen oral contraceptives	Breast, cervix, liver	Endometrium, ovary	Receptor-mediated events	Estrogen genotoxicity, hormone-stimulated expression of human papillomavirus genes
Tamoxifen	Endometrium	Breast	Estrogen receptor–mediated events, genotoxicity	—

From IARC Special Report: *Lancet* 10:13–14, 2009.

breast cancer risk disappearing a few years after treatment discontinuation.[258-260] Additional support for HRT to increase breast cancer risk was the *reduction* in risk reported by several countries with discontinuation of HRT use.[257,261]

Evidence on the route of administration of HRT, oral versus transdermal (gel or patch), and the risk of breast cancer has limited research. To date, epidemiologic data suggest the route has no effect on the risk of breast cancer and hip fracture.[262] Results on route of HRT on risk of coronary heart disease and colorectal cancer are inconsistent. Studies on the risks of diabetes and stroke are too few for clinical evidence. Additionally, there is a suggestion, that needs research confirmation, that oral route versus transdermal HRT may increase the risk of thromboembolism.[263]

HRT use has been associated with a greater breast cancer risk than ERT. Intense debate is whether ERT is associated with an increase in breast cancer risk compared with *never use* of hormone therapy. Use of ERT was associated with a *decreased* risk in the Women's Health Initiative (WHI) randomized trial even after cessation of treatment[264,265] but not in observational studies.[259,260,266,267] From the recent WHI report, women with a prior hysterectomy who were followed for 10.7 years and who used conjugated equine estrogen (CEE) for an average of 3.5 years (median of 5.9 years) were not associated with an increased or decreased risk of coronary heart disease (CHD), deep vein thrombosis, stroke, hip fracture, colorectal cancer, or total mortality, and the previous finding of a decrease in breast cancer risk persisted.[264] According to investigators, this decrease in risk is neither perplexing nor contradictory to other findings in which estrogen increases risk because of the underlying biology of breast cancer and estrogen. Laboratory data support a protective effect of estrogen under the right environment—that is, after a period of long-term natural (endogenous) estrogen deprivation. If this environment exists, then exogenous estrogen will induce apoptosis or cell death of the occult breast cancer cells.[225] The changing concepts in ERT are related to acquired resistance to long-term antihormonal therapy in breast cancer. This finding is the basis for the clinical use of estrogen to treat advanced antihormone-resistant breast cancer.[267,268] One hypothesis is long-term antiestrogen treatment or estrogen deprivation causes the development and progression of antihormone resistance (e.g., from tamoxifen).[267] Under these environments laboratory data support a mechanism of estrogen-induced apoptosis (estrogen E_2 suppressed ER alpha signaling) and produced stress responses, endoplasmic stress, and inflammatory stress responses, that led to apoptosis.[269] Other proposed causes of treatment resistance include the changes in the stroma with carcinomas (mesenchymal phenotype),[270] p53 status,[271] dysregulation of the estrogen receptor,[272] and low levels of nuclear Nu-Sta5a (signal transducer and activator of transcription-5a).[273] Nonetheless, careful debate has continued about ERT and breast cancer. Issues include: (1) a potential age effect (younger versus older women) on the risk-to-benefit profile of hormone therapy (HT), (2) overall duration and safety (short- and long-term) of HT use, (3) differential effects of HT in slender or overweight/obese women, and (4) estrogen decline or deprivation (menopause) for a specified time (length unknown) then followed by ERT replacement leads to apoptosis or cell killing of lingering breast cancer cells. Thus because the use of ERT in the WHI in 80% or greater (of study pills) was 3.5 years, longer use may still increase breast cancer risk. Longer use in animal studies has been linked with increasing cell proliferation, angiogenesis, and inhibiting apoptosis.[274] Longer use of ERT that may increase breast cancer risk was found in combined data of 16 studies and another analysis of 52,705 women with breast cancer.[267,268] In these studies and the Million Women Study, leaner women had an even higher risk of breast cancer.[275] Women in the WHI do

not represent the typical woman who might be prescribed HT for menopausal symptoms.[276] For example, 68% of the women in the WHI were older than age 60 when enrolled in the study, thus an older population than the average woman entering menopause.

Insulin and Insulin-Like Growth Factors. IGFs regulate cellular functions involving cell proliferation, migratory, differentiation, and apoptosis. IGF-1 is a protein hormone with a structure similar to insulin. The growth hormone–IGF-1 axis can stimulate proliferation of both breast cancer and normal breast epithelial cells.[277] A pooled analysis of 17 studies showed a significant association of IGF-1 with breast cancer risk.[278] Interestingly, no significant difference was found according to menopausal status. Joint associations of IGF-1 and estradiol together showed they were related to risk and those women in the top thirds of estradiol and IGF-1 levels had the highest risk. Estradiol increases IGF-1 activity in the breast.[279] Insulin and IGF-1 receptor family are now known to have a role in macronutrient intake and cancer, diabetes and cancer, and obesity and cancer.[280]

Light at night (LAT) can accelerate tumor growth (in vivo), and one mechanism proposed is continuous activation of IGF-1 receptor (IGF-1R) signaling.[281] A recent case-control study of 1679 women exposed to LAT during sleep was significantly associated with breast cancer risk.[281] This study was the first to identify bedroom light intensity and breast cancer risk. Although inconclusive, shift-work and its disruptive effects on circadian rhythms and sleep deprivation at night have been suggested as a risk factor for breast cancer.[282]

Prolactin and Growth Hormone. Grown hormone (GH) injected in mice acts on mammary stroma.[283] GH induces the production of IGFs in the liver; IGF signaling is important for breast development and is implicated in breast carcinogenesis. Two studies, however, have reported a link with GH and breast cancer risk.[284,285] In the largest prospective analysis of circulating prolactin and breast cancer risk, those with the highest levels had the highest risk.[286] (For more on prolactin see p. 847.)

Human Chorionic Gonadotropin. hCG increases during the first trimester and then rapidly declines to a steady state throughout pregnancy. Data from rat studies indicate that hCG may be useful in developing new therapies because it has antiproliferative and anti-invasive effects.[287] However, insufficient data exist on the safety of hCG; its role in carcinogenesis is complex and much research needs to be done.[288]

Oral Contraceptives. The International Agency for Research on Cancer (IARC) group confirmed that combined estrogen-progestogen OCs increase the risk for breast, cervix, and liver cancers.[257] A recent meta-analysis of 66 studies showed current use of oral contraceptives, nulliparity, and 30 years or older at first birth were associated with a 1- to 1.5-fold increased risk of breast cancer.[289] Hormones are discussed further in the Pathogenesis section.

Mammographic Breast Density

Mammographic breast density (MBD) is the radiologic appearance of the breast (largely stromal and epithelial tissues) reflecting variations in breast tissue composition (Figure 24-38). Mammographic breast density appears white or dense on a mammogram, is expressed as a percentage of the mammogram (percent mammographic density), and is a strong and consistent risk factor for breast cancer.[290,291] **Percent mammographic density (PMD)** estimates the proportion of stromal and epithelial tissues in relation to fat tissue in the breast. Internationally, studies done in the United States, Canada, and Europe all found that a significant increase in risk associated with more extensive PMD; risk persisted for 8 to 10 years from the date of the mammogram, and increased with increasing PMD. Extensive PMD is associated with a markedly increased risk of invasive breast cancer.[290] Thus extensive breast density is one of the strongest risk factors for developing breast cancer and second only to age and carrying a *BRCA1* or *BRCA2* mutation.[290,292] Lifestyle factors, including age, parity, BMI, and exogenous hormone levels, explain about 20% to 30% of the variation in PMD among women. The estimate of 61% to 67% of the variation could be caused by genetic factors; however, linkage and candidate gene association studies have not reproducibly identified loci related to MBD.[293] A recent meta-analysis of five genome-wide studies of PMD discovered an association between common variants in ZNF365 and breast cancer. DNA methylation or other epigenetic studies of breast density are commencing.

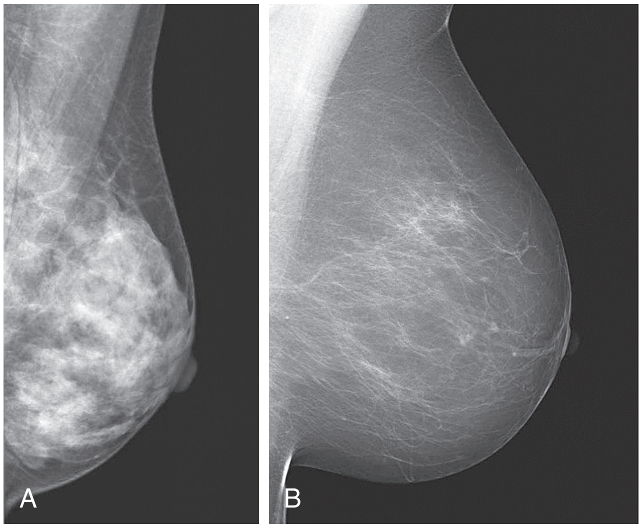

FIGURE 24-38 **Breast Density Varies Among Women.** The sensitivity of mammography for detecting malignancy is significantly reduced if the breast consists of a high proportion of fibroglandular (dense) breast tissue **(A)** compared to a breast that is fatty **(B).** (From O'Malley FP, Pinder SE, Mulligan AM: *Breast pathology,* ed 2, Philadelphia, 2011, Saunders.)

Environmental Factors and Lifestyle

The environmental causes of breast cancer possibly affect the breast the most during critical phases or "windows" of development including early differential stages—that is, undifferentiated cells to alveolar buds and then lobules, puberty, pregnancy and lactation, involution, and menopause. During early phases, mitotic activity and cell division are greater than later in life.

Radiation. Ionizing radiation is a known mutagen and established carcinogen for breast cancer. To date, only accidentally or medically induced radiation has been demonstrated to exert a carcinogenic effect on the breast. The Institute of Medicine (IOM) reports that the two most strongly associated environmental factors are exposure to ionizing radiation and combined postmenopausal HT.[294] There are many sources of ionizing radiation, including x-rays, CT scans, fluoroscopy, and other medical radiologic procedures. CT imaging is frequently used in the absence of evidence[295,296] (see Chapter 13), and although only about 10% of diagnostic radiologic procedures in large U.S. hospitals are CTs, they contribute an estimated 65% of the effective radiation dose to the public from all medical x-ray examinations.[297] The IOM conclusion of a causal relationship between radiation exposure in the same range as CT and cancer is consistent from a large varied literature.[292] The IOM makes it clear that *avoidance* of medical imaging is an important and concrete step that women [girls] can take to reduce their risk of breast cancer.[295] Scientists and clinicians also have expressed concern about the increasing number of CT scans performed, including on children.[295,298]

The prevailing view has been that major predictors of risk from radiation are a young age at exposure and the radiation dose.[299] Yet, recent data in cell models and epidemiologic studies in older aged cells shows long-lasting and incomplete DSB repair.[299a,b,c] These data show increased carcinogenic risks of radiation exposure at older ages (see Chapters 2 and 13). Although protocols are continually updated, radiologic exposure of the upper spine, heart, ribs, lungs, shoulders and esophagus also can expose breast tissue to radiation. Breast tissue may be exposed from abdominal CT scans.[300] X-rays and fluoroscopy of infants may constitute whole-body irradiation. The duration of increased risks from radiation is unknown, but increased risk appears to have lasted at least 35 years in women treated for mastitis, those treated with fluoroscopy, and atomic-bomb survivors.

Cancer induction and exposure to low doses and low energy x-rays are controversial and the topic of much debate and research. Biologic understanding related to low doses of radiation is presented in Chapters 2 and 13. There is continuing debate and discussion of questionable radiation-induced cancers caused by mammographic screening,[302-304] especially among women with a positive family history of breast cancer.[305,306] Mammography is a low dose of low-energy x-rays usually of two views done within an interval of a few minutes. The computed average measure of the radiation absorbed by a fixed mass of biologic tissue (dose equivalent) used to account for the different biologic damage potential is about 2 mSv for low-energy x-rays, although this value has been suggested to be higher.[307,308] The mean glandular dose can increase with breast density,[309] volume of breast tissue, lack of breast compression,[310] breast augmentation prosthesis,[311] calling back individuals for more views, and technical variations in the setup of digital mammograms.[310] Radiosensitivity of individuals can vary and become a modifying factor of the radiation response[312-314] (see also Chapter 13).

Data from epidemiologic studies is challenging and controversial because they may lack sufficient statistical power to determine the health risks from low-dose radiation.[312] It is currently accepted that the benefits of screening mammography outweigh the possible risk of radiation-induced breast cancer in women 50 years and older. Still controversial and debated is screening mammography for women 40 to 49 years old and high-risk women especially those with genetic risk of breast cancer (Table 24-15 and Box 24-14). Women with genetic risk might be more susceptible to radiation-induced breast cancer because suppressor genes are implicated in the response to ionizing radiation.[312] Radiation-induced DNA double-strand breaks (DSBs) are considered the most critical lesions and their misrepair could lead to chromosomal instability.[312,315] Several studies have contributed to understanding the biologic responses of low-dose radiation but have not duplicated the protocols of mammographic screening (mGy doses, low-energy x-rays, and repeated exposures) or with an appropriate cellular model (i.e., nontumoral and untransformed breast epithelial cells).[307,315-324]

Investigators assessed in vitro mammographic radiation-induced DNA damage in mammary epithelial cells from 30 women with low (LR) or high (HR) family risk of breast cancer. From this study low and repeated doses simulating a two-view mammogram (2+2 mGy) created more damage than 2 mGy and, overall, more damage than 4 mGy.[312] The low and repeated dose effect was exacerbated in high-risk women, and these investigators even argue for avoidance of two view mammography. According to the National Cancer Institute, two-view examinations decrease the recall rate compared with single-view examinations.[299]

Continuing investigation is whether DSB repair is equally efficient after low and high doses. Using primary human fibroblasts in culture, investigators obtained the surprising finding that DSBs induced by low radiation doses (a few milligray) are repaired at a slower rate than DSBs produced by higher doses.[299c,325] Other investigators confirmed this finding and showed that pretreating cells with 10 μL of H_2O_2 generate single strand breaks and base damage, and improve the ability of cells to repair the DSBs induced by low radiation doses.[326] Overall, these data suggest that the cellular response to DSBs is very different for low versus high radiation doses. Confirmation with additional studies of DNA damage caused by mammographic exposures needs more subjects and analysis of DNA damage repair at more than 24 hours after mammography exposure.[312]

Women treated with chest radiation for a pediatric or young adult cancer have a substantially increased risk of breast cancer. Investigators from international studies have concluded that diagnostic chest irradiation or radiation therapy for benign or malignant diseases increases the risk of breast cancer for cumulative doses as low as 130 mGy. The breast cancer risk did not decrease when increasing the number of radiologic treatment fractions for delivering the same total dose but risk decreased greatly with increasing age of exposure to ionizing radiation.[327] International agencies are assessing the utility of screening MRI and mammography in these high-risk populations.

TABLE 24-15 BENEFITS AND HARMS OF SCREENING MAMMOGRAPHY: SUMMARY OF THE EVIDENCE FOR THE UNITED STATES

Benefit

Screening mammography in women ages 40 to 70 years decreases breast cancer mortality (see Magnitude of Effects below). The benefit is higher for older women, in part because their breast cancer risk is higher.

Evidence

- Study design: Meta-analysis of individual data from four randomized controlled trials (RCTs) and three additional RCTs.
- Internal validity: Validity of RCTs varies from poor to good; internal validity of meta-analysis is good.
- Overall consistency: Fair.
- Magnitude of effects on health outcomes: Relative breast cancer–specific mortality is decreased by 15% for follow-up analysis and 20% for evaluation analysis. Absolute mortality benefit for women screened annually starting at age 40 is 4 per 10,000 women screened over 10.7 years. The comparable number for women screened annually starting at age 50 years is approximately 50 per 10,000. Overall, the absolute benefit is approximately 1%, but depends on inherent breast cancer risk, which increases with age.

HARM	STUDY DESIGN	INTERNAL VALIDITY	CONSISTENCY	MAGNITUDE OF EFFECTS	EXTERNAL VALIDITY
Treatment of insignificant cancers (overdiagnosis, true positives) can result in breast deformity, lymphedema, thromboembolic events, or chemotherapy-induced toxicities	Descriptive population based, autopsy series, and series of mammary reduction specimens	Good	Good	Approximately 33% of breast cancers detected by screening mammograms represent overdiagnosis	Good
Additional testing (false-positives)	Descriptive population based	Good	Good	Estimated to occur in 50% of women screened annually for 10 years, 25% of whom will have biopsies	Good
False sense of security, delay in cancer diagnosis (false-negatives)	Descriptive population based	Good	Good	6% to 46% of women with invasive cancer will have negative mammograms, especially if young, with dense breasts or with mucinous, lobular, or fast-growing cancers	Good
Radiation-induced mutations can cause breast cancer, especially if exposed before age 30 years; latency is more than 10 years, and the increased risk persists lifelong	Descriptive population based	Good	Good	Between 9.9 and 32 breast cancers per 10,000 women exposed to a cumulative dose of 1 Sv; risk is higher for younger women	Good

Data from: National Cancer Institute: *Summary of evidence*. Available at www.cancer.gov/cancertopics/pdq/screening/breast/healthprofessional/page1update 03/30/2012; Nystrom L et al: *Lancet* 359(9310):909–919, 2002.

Currently an important topic is that radiation and other treatments can transform cancer cells into treatment-resistant breast cancer stem cells, even as the treatment kills half of all cells.[328] In some cases, cancer stem cells are generated by the therapy, and scientists are studying the mechanisms of how this occurs. DNA damage is a key factor for stem cell activation. DNA accumulates errors from environmental factors, including radiation, drugs (e.g., chemotherapy, hormones), chemicals, viruses, bacteria, or DNA replication errors.[329-330]

The risk of secondary lung malignancy (SLM) is an important concern for women treated with whole-breast radiation therapy after breast-conserving surgery for early-stage breast cancer.[331] Investigators studied SLM risk associated with several common methods of delivering whole-breast radiation therapy (RT). Compared with supine whole-breast irradiation (WBI), prone breast irradiation is associated with a significantly lower predicted risk of secondary lung malignancy.[331]

Accelerated partial breast irradiation with brachytherapy following lumpectomy versus traditional WBI has become a standard treatment. Use of brachytherapy can shorten treatment from 6 weeks to 5 days, theoretically with less risk for side effects to the heart and lungs (comparison studies are minimal and a randomized trial is ongoing). Concern is that brachytherapy increases the risk of acute skin and wound complications and may lead to increased rates of mastectomies. Retrospective data using Medicare claims data from older women indicate that brachytherapy is more likely than WBI to lead to certain complications, such as deep tissue and bone complications, and lung injury is higher with WBI; more data are needed on the severity of these complications.[332]

BOX 24-14 SUMMARY OF THE USPSTF RECOMMENDATIONS ON SCREENING FOR BREAST CANCER

- The USPSTF recommends against routine screening mammography in women in their 40s who are not at increased risk for breast cancer. The decision to start mammography before age 50 should be based on a woman's risk for breast cancer and personal preferences about the benefits and harms.
- The USPSTF recommends mammography every 2 years for women ages 50 to 74.
- Current evidence is not sufficient to assess the effectiveness of clinical breast examination in addition to screening mammography.
- The USPSTF recommends against clinicians teaching women breast self-examination.
- Current evidence is not sufficient to assess the additional effectiveness of digital mammography or breast magnetic resonance imaging instead of film mammography for breast cancer screening.

Data from U.S. Preventive Services Task Force (USPSTF): *Ann Intern Med* 716–726, 2009.

BOX 24-15 SUMMARY FOR UNDERSTANDING RADIATION EFFECTS FROM SCREENING MAMMOGRAPHY

The understanding of radiation-induced breast cancer from mammographic screening is not simple. The discussion is complex because of several issues: (1) ongoing debate about the significance of epidemiologic studies lacking sufficient statistical power to determine health risks from low-dose radiation; (2) these epidemiologic studies have determined the estimated mathematical extrapolations of low-dose health effects from high doses; (3) lacking are studies with exact protocols of mammographic procedures (mGy, low-energy x-rays, repeated exposures) or appropriate cell models (nontumoral, untransformed breast epithelial cells); (4) different reported mean glandular doses (MGDs) per screening view with changes in equipment over time and MGD can increase with breast density, volume (breast size), breast augmentation prosthesis, recall of women for additional views, and the variations in setup of digital mammographs; (5) differences in individual susceptibility to radiation (i.e., modifying factors such as genetic risk), and (6) carcinogenic effects at older ages.

Data from Colin C et al: *Int J Radiat Biol* 87(11):1103–1112, 2011; Hernandez L et al: *PLOS* 8(5):e63052, 2013.

The first study of its kind using surveillance, epidemiology, and end results (SEER) data examined trends from 1976 through 2008 of screening mammography on breast cancer incidence.[333] These investigators conclude that despite substantial increases in the number of cases of early-stage breast cancer detected, screening mammography has only marginally reduced the rate at which women present with advanced cancer. This imbalance suggests substantial overdiagnosis involving more than 1 million women in the last 30 years and, according to their estimate, more than 70,000 women in 2008 (31% of all breast cancers diagnosed in women 40 years and older) are overdiagnosed. In addition, these investigators report that because the absolute reduction in deaths (estimated at 20 deaths per 100,000 women) is larger than the number of cases of late-stage cancer (8 cases per 100,000 women), the contribution of early detection to decreasing numbers of death must be small.[333] This small reduction has been limited to regional (mostly node-positive) disease, a stage that is often treated successfully with an expected survival rate of 85% among women 40 years of age and older.[334,335] This study is important because overdiagnosis leads to overtreatment whereby women are treated for abnormalities that would not have caused illness and the harms of the treatment; surgery, radiation therapy, hormonal therapy for 5 years or more, chemotherapy, or a combination of the above can lead to significant future health concerns.

The estimated fatal radiation-induced cancer risk for breast-specific gamma imaging (BSGI), which involves a label-recommended dose of 740 to 1100 MBq (20-30 mCi) of technetium 99m-sestamibi is 20 to 30 times that of digital mammography in women age 40 years, and a single positron emission mammography (PEM) involving a labeled dose of 370 MBq (10 mCi) of fluorine 18 fluorodeoxyglucose is 23 times higher than that of digital mammography in women age 40 years.[336] The new 3D tomosynthesis uses a series of 15 low-dose mammographic images. This technology decreases the problem of overlapping breast tissue that occurs with mammography. The radiation is low dose and higher than regular mammography. No data are available on long-term effects and whether it saves lives.

Since the late 1990s, experimental evidence has shown that ionizing radiation can elicit secondary effects in nonirradiated cells.[337] These secondary or nontargeted effects include radiation-induced bystander effects (RIBEs) that are dependent on intercellular communication between the irradiated cells and the so-called innocent bystander cells. Included as a secondary effect is radiation-induced genomic instability (RIGI) in which the biologic effects include increased frequency of mutations and chromosomal aberrations that occur in descendants of irradiated cells. Several studies are ongoing and a comprehensive understanding of the RIBE response is emerging but is now incomplete. Box 24-15 includes a summary for understanding radiation effects from screening mammography.

Diet. Prospective epidemiologic studies on diet and breast cancer risk fail to show an association that is consistent, strong, and statistically significant except for alcohol intake, being overweight, and weight gain after menopause (see following discussion).[338] Diet has been postulated as important for breast cancer risk because of the international correlations of consumption of specific dietary factors (e.g., fats) and breast cancer incidence and mortality, and because migrant studies show greater incidence of breast cancer among descendants who relocated to another country compared with those in the country of origin. International variations also can occur because of differences in reproductive history, physical activity, obesity, and other factors.

Dietary Fat. Dietary fat and breast cancer risk is the subject of much study, controversy, and debate. Potential biologic mechanisms between fat intake and breast cancer risk include: (1) that fat may stimulate endogenous steroid hormone production (also affect weight gain, age of menarche), (2) fat interferes with immune or inflammatory function, and (3) fat influences gene expression. Evidence from large, prospective cohort studies has been mostly unsupportive, and clinical trials have not supported a strong association with total fat intake.[339] Cohort

studies, however, suggest a modest positive association between fat intake and the risk of breast cancer,[340] but so far more than 70 studies of dietary fat during midlife on risk of breast cancer show the relationship is likely to be small. After 8.1 years of follow-up, the largest randomized controlled dietary trial conducted in the United States showed no significant difference in the number of newly diagnosed breast cancer cases in the women in the treatment group (intervention of a low-fat diet) compared with the control group (usual fat intake).[341] The World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR) report indicated that although the evidence is limited, there was an increase in breast cancer risk among postmenopausal women consuming higher-fat diets.[342] Concern also has been that any association with fat intake may be because of total energy intake. Moreover, there is limited evidence that modest reductions in fat intake (less than 20% of caloric intake) reduce breast cancer risk.

A meta-analysis of 57 international and national studies indicates that saturated fat intake is associated with an increased risk for postmenopausal disease, polyunsaturated fats were associated with increased risk regardless of menopausal status, and monounsaturated fats had no significant correlation with risk.[343]

Breast cancer risk may be determined earlier in life, before the period of investigations, and adult dietary exposures *may* have little influence on carcinogenesis. The hypothesis that exposures that occur between menarche and first pregnancy are especially important in determining subsequent risk of breast cancer is supported by several lines of evidence. Animal studies demonstrate increased susceptibility to mammary carcinogens before first pregnancy compared with administration at a later age,[344,345] and epidemiologic investigations of women who survived the atomic bomb in Hiroshima and Nagasaki show no increase in risk among women older than 35 at the time of the bombing but increased breast cancer risk among women younger than 20 years when exposed.[346] A recent and first prospective study of 39,268 premenopausal women observed a modest direct association between adolescent intake of fat and breast cancer.[347] This association persisted after adjusting for adult fat intake. Additionally, from this same study, milk, dairy, and total carbohydrate intake in adolescence, as well as the quality of carbohydrate as assessed by glycemic load, glycemic index, and dietary fiber, was not associated with breast cancer. Frequent consumption of fat, especially saturated fat, during adolescence was positively related to the incidence of hormone receptor–negative breast tumors.

Red Meat. Another area of study is how consumption of red meat could increase breast cancer risk. The hypotheses range from available iron content, growth-promoting hormones used in the cattle industry, and carcinogenic heterocyclic amines released from cooking the fatty acid content. Case-control and cohort studies have shown a modest association of red meat intake with breast cancer incidence but no association in a pooled analysis of prospective studies.[348] Research has reported an increased risk with red meat consumption.[349-351] However, a 2010 meta-analysis supported the WCRF/AICR report that suggested there was no conclusive evidence that red meat or processed meat acts as an independent risk factor for breast cancer.[342,352]

Fiber. Fiber intake could affect breast cancer risk by several mechanisms, including stimulation of the intestinal microflora and reduction of the enterohepatic estrogen circulation that could reduce overall body estrogen concentrations.[353,354] Dietary fiber has been shown to modify estrogen concentrations.[355] A recent meta-analysis of prospective cohort studies showed that every 10-g/day increment in dietary fiber was associated with a significant reduction in breast cancer risk.[356] A meta-analysis of prospective case-control studies also found an inverse association between dietary fiber intake and breast cancer risk.[357] Similar in structure to estrogens, lignans are biphenolic compounds in plant foods.[358] Primarily found in fiber-rich foods (seeds, grains, vegetables, and fruits), lignans are the major source of phytoestrogens in Western populations.[353,354] Plant lignans are converted in the human gut by intestinal bacteria to the enterolignans, enterolactone, and enterodiol, which are bioactive and are subsequently absorbed.[353] Enterolignans may protect against cancer and several mechanisms have been proposed and include: (1) they have weak estrogenic activity, therefore may bind to estrogen receptors (thus preventing other more powerful estrogens from binding to ERs); (2) inhibit tumor growth; (3) stimulate apoptosis; and (4) stimulate production of the carrier SHBG (which presumably lowers circulating free estrogen).[358] Two meta-analyses found lignans to be associated with a small risk reduction in postmenopausal breast cancer but not premenopausal,[359,360] and from a follow-up study those postmenopausal women with higher enterolignan levels may have better survival.[358]

Soy. Soy products are a hot topic because of their consumption in Asian countries that have low rates of cancer. These isoflavone compounds, including daidzein and genistein, can bind estrogen receptors but are far less potent than estradiol. Soy may act like other antiestrogens, such as tamoxifen, by blocking the action of endogenous estrogens to reduce breast cancer risk. Thus, depending on the estradiol concentration and the timing of administration, soy exhibits weak estrogenic or antiestrogenic activity. Isoflavones act through various mechanisms by which they may be cancer protective including antiproliferative effects, tyrosine kinase inhibition, induction of apoptosis, and inhibition of angiogenesis. They modulate enzyme activities, as well as signal transduction, and have antioxidant properties. In 2011 the North American Menopause Society held a symposium to review the latest evidence-based science on the role of soy and found that soy foods generally appear to be breast protective and recommended moderate lifelong soy consumption.[361] Specific recommendations for breast cancer survivors and soy or isoflavone consumption could not be reached, because animals studies indicate potential for risk and studies in humans imply a null or protective effect.[361,362] A recent large study of both American and Chinese women, however, suggested that moderate intake of soy (≥10 mg isoflavones/day) had a significant reduction in breast cancer recurrence as well as a nonsignificant trend toward reduced all-cause mortality.[363] In addition, soy may optimize extrarenal 1,25(OH)2 cholecalciferol or vitamin D_3 (a prodifferentiating vitamin D metabolite), which could result in growth control and, conceivably, inhibition of tumor progression.[364]

There is limited evidence on the role of dietary patterns and breast cancer risk modification. Some limited evidence supports the role of the Mediterranean diet.

Obesity. Obesity has been associated with a *reduced* risk of *premenopausal* breast cancer. One mechanism suggested is the direct relationship between irregular menstrual cycling, especially obesity and anovulatory cycling, which would result in a decrease in estrogens and progesterone and thus decrease the risk of breast cancer. It is possible that in obese women with hyperinsulinemia the higher insulin levels increase the enzymatic conversion of testosterone to dihydrotestosterone, rather than estradiol, lowering their estrogen levels.[365]

Obesity, however, is related to *increased* risk of breast cancer in *postmenopausal* women. Despite strong links with endogenous estrogen levels, body fat has been consistently but *weakly* related to increased postmenopausal risk.[366] This observation has been surprising because obese postmenopausal women have endogenous estrogen levels (estrone and estradiol) nearly double those of lean women.[366,367] This weak association is possibly related to two factors. First, the premenopausal reduction in breast cancer risk related to being overweight possibly persists, opposing the adverse effect of elevated estrogens after menopause. Thus *weight gain* should be more strongly related to postmenopausal breast cancer risk than attained weight. A meta-analysis of 11 studies suggests that adult weight gain is predictive of a twofold increase in the risk for ER+, as well as ER+/PR+, breast tumors with a greater risk in postmenopausal women.[368]

Premenopausal and postmenopausal weight gain also is associated with higher estradiol and estrone levels and lower SHBG as a transporter protein; low levels cause higher bioavailable estrogen.[369] This increase in estrogens, particularly estradiol, is from aromatization in the adipose tissue. Second, use of exogenous hormones postmenopausally obscures the variation in endogenous estrogens caused by adiposity and elevates breast cancer risk regardless of body weight.[366] Excess body fat and weight gain are stronger risk factors for women who do not use hormone therapy. However, a prospective study found weight gained at multiple time points throughout adulthood of 44 to 63 lbs was associated with a 56% higher risk of breast cancer, and weight gain of 88 to 108 lbs doubled the risk of breast cancer among hormone users.[370] A recent animal study showed obese animals deposited excess calories into the tumors themselves.[371] These tumors from obese animals had an increased expression of progesterone receptors.[371]

Weight loss after menopause reduces circulating estrogens and increases SHBG, making weight loss a potentially important prevention strategy especially for those women not on hormone therapy. Weight loss and postmenopausal cancer risk have been examined in prospective studies. In one of the largest studies, women who lost 22 lbs or more after menopause and maintained this weight loss halved their risk for breast cancer. This relationship was clearer in nonhormone users.[372]

The degree of obesity is an important indicator of risk as reported in the largest study to date, a prospective analysis of about 15,000 women with invasive breast cancer. Overweight (55 to 66 lbs) was not associated with any excess risk compared with normal weight. Similar associations were found for breast cancer death and non–breast cancer death but not recurrence of breast cancer. Women who were underweight and morbidly obese before breast cancer diagnosis were at the greatest risk of all-cause mortality. Morbidly obese women (BMI ≥ 88 lbs) were also at increased risk of death from breast cancer.[373]

Alcohol. Data on alcohol and risk of breast cancer continue to mount. From the analysis of the NHS, even low to moderate alcohol intake may increase breast cancer risk, particularly for postmenopausal women.[374] From this same study risk was increased regardless of source of alcohol, wine, beer, or spirits.[374] These investigators studied patterns of drinking and habits earlier in adulthood, as well as binge drinking and both may further increase risk. From the WHI an observational cohort of 87,724 postmenopausal women and 2944 cases of breast cancer over a 5-year follow-up, one drink daily was associated with an 82% greater risk for hormone receptor–positive lobular breast cancer.[375] A follow-up analysis from other investigators evaluated alcohol intake associated with ER+ disease and a lower risk for triple-negative disease.[376] Recently, a comprehensive study of lifetime alcohol intake and risk of breast cancer involved large numbers of Asian Americans.[377] Regular lifetime alcohol intake is a significant risk factor in U.S.-born Asian Americans but not in non–U.S.-born Asian Americans. Results by Asian ethnicity show that the prevalence of lifetime alcohol intake is significantly higher in Japanese than in Chinese and Filipino women and that lifetime alcohol intake is a significant risk factor in Japanese Americans (U.S. born and non-U.S. born) but not in Chinese- and Filipino-American women.[377]

The exact mechanism of how alcohol increases breast cancer risk is unknown. Suggested mechanisms include: (1) alcohol may hinder the liver's ability to rid the body of cancer-causing agents; (2) alcohol stimulates liver enzyme activity and greater sulfation of estrone, thus increasing the bioavailability of estrone and possibly breast exposure to higher levels of estrone/estradiol; (3) alcohol combined with hormone replacement therapy may synergistically enhance the risk; (4) alcohol can down-regulate the expression of *BRCA1* (i.e., the unmutated tumor-suppressor gene) thus increasing estrogen receptor-α responsiveness; (5) alcohol decreases folate levels causing changes in methyl donors for DNA stability and some studies show that folate intake may decrease this risk; and (6) alcohol decreases melatonin levels at night, which might increase circulating estrogen.

Iodine. Iodine deficiency is hypothesized as contributing to the development of breast pathology and cancer.[378-380] Iodine plays a significant role in breast health.[380-383] Although research is just beginning, some evidence reveals that iodine is an antioxidant and antiproliferative agent contributing to the integrity of normal mammary tissue. Seaweed, which is iodine-rich, is an important dietary item in Asian communities and has been associated with the *low* incidence of benign and breast cancer disease in Japanese women.[384] Other foods with iodine content include iodized salt (1 teaspoon = 400 mcg iodine), bread with iodate dough, haddock, shrimp, egg, cottage cheese, cheddar cheese, and ground beef.

Environmental Chemicals. Evidence for linking chemicals to the cause of breast cancer is difficult. It is challenging because it is a life history of exposure that is important, not just a single chemical but also complex mixtures of chemicals and their interaction with endogenous hormones and with radiation. The highest rates of breast cancer are found in superindustrialized countries—North America and Europe—and the lowest rates in central Africa and Asia. With industrial development, breast cancer rates increase. An estimated 85,000 synthetic chemicals are registered for use today in the United States, another 1000 or more are added each year, and toxicologic screening for these chemicals is minimal—only about 7%.[385] EPA researchers are going to change this serious challenge. They and their partners are teaming up and tapping modern technologies such as supercomputers and even robots to advance the scientific hazard identification and risk assessment. Chemicals persist in the environment, accumulate in adipose tissue, interact with local adipose tissue physiology in an endocrine-paracrine manner, and remain in breast tissue for decades. Some of these chemicals are known human carcinogens and many have been linked to mammary tumors in animals. Women who emigrate to the United States from Asian countries experience an enormous percent increase in risk within one generation. A generation later their daughters' risk approaches that of women born in the United States. This change in risk suggests that in utero exposures affect subsequent disease risk. However, it is difficult to know whether these changes in risk come from nutritional content, pollutants, cosmetics, food additives, or other factors.

Xenoestrogens are synthetic chemicals that mimic the actions of estrogens and are found in many pesticides, fuels, plastics, detergents, and drugs. Because many factors correlated with breast cancer (early menarche, delayed pregnancy and breast-feeding, late menopause, etc.) are associated with lifetime exposure to estrogens, investigators reasoned that environmental chemicals affect estrogen metabolism and contribute to breast cancer. The most significant chemicals may be polychlorinated biphenyls (PCBs), pesticides, BPA (pervasive in polycarbonate plastics), tobacco smoke (active and passive), dioxins (vehicle exhaust, incineration, contaminated food supply), alkylphenols (detergents and cleaning products), metals, phthalates (makes plastics flexible, some cosmetics), parabens (antimicrobials), food additives (recombinant bovine somatotropin [rBST] and zeranol to enhance growth in cattle and sheep), HRT, and others. Bisphenol A treatment of breast epithelial cells cultured from premalignant biopsied tissue elicited a genetic expression profile associated with large, high-histologic-grade breast tumors.[386] Some chemicals are fat soluble and the estrogenic effect would require that they either bind to the nuclear estrogen receptor and then cause cell division or gene transcription or they activate reactive oxygen species through oxidative catabolism of estrogens (see p. 853) (Table 24-16).

TABLE 24-16 SELECTED CHEMICALS AND RISK OF BREAST CANCER

CHEMICAL	COMMENTS
Bisphenol-A (BPA)	Studies have shown altered reproductive systems and breast tissue when exposed to BPA in utero[1] BPA is commonly found in plastics[2]
Polyvinyl chloride (PVC)	Used in food packaging, medical products, appliances, cars, toys, credit cards, rainwear[3] Has been found in the air near waste sites, landfills, and tobacco smoke Has been linked to increased mortality from breast and liver cancer among manufacturing workers[4,5]
Pesticides: aldrin and dieldrin (organochlorines)	Used in crops like corn and cotton from 1950s to 1970s Banned by the EPA in 1975 except for termite control; completely banned in 1987 In vitro assays showed estrogenic activity and dieldrin found in 78% of women diagnosed with breast cancer[6] High incidence of breast cancer in Massachusetts study found associations with higher income and regular use of lawn services, termite treatments, and home pesticides[7]
Household products: methylene chloride	Spray paints and paint removers may contain methylene chloride, documented breast cancer in lab animals[8]
Diethylstilbestrol (DES)	Prescribed for women to avert miscarriages between 1941 and 1971 Exposed daughters known to have higher rates of vaginal cancer, and in the mothers slight increased risk of breast cancer[9,10] Daughters now known to have slight increased risk of breast cancer[11]
Solvents (e.g., benzene, toluene, trichloroethylene, chlorinated organic solvents)	Used in manufacture of computers, also some in cosmetics In 2003 a Taiwanese study documented increased risk of breast cancer among electronic workers exposed to chlorinated organic solvents[12] A Danish study of women 22 to 55 years of age employed in industries (fabricated metal, lumber, furniture, printing, textiles) using solvents doubled the risk of breast cancer[13]
Styrene, carbon tetrachloride, formaldehyde	A 1995 study suggested increased risk with occupational exposure—validation in Finland, Sweden, and Italy[14–17]
Ethylene glycol methyl ether (EGME)	A Duke University study found it acts as hormone sensitizer in vivo and in vitro.[18,19] Compounds are found in semiconductor industry, varnishes, paints, dyes, and fuel additives
Valproic acid (anticonvulsant medication)	Found to be hormone sensitizing and prescribed for migraines and bipolar disorder[18,19]
1,3-butadiene	Air pollutant and synthetic rubber product and some fungicides and tobacco smoke. Causes mammary and ovarian tumors in female mice and rats[20,21]
Aromatic amines (heterocyclic, polycyclic, monocyclic)	Found in plastics, tobacco smoke, grilled meats and fish, combustion of wood chips and rubber. Exposure in adolescence before full-term pregnancy may increase risk[22]

Continued

TABLE 24-16 SELECTED CHEMICALS AND RISK OF BREAST CANCER—cont'd

CHEMICAL	COMMENTS
Dichlorodiphenyltrichloroethane (DDT) and polychlorinated biphenyls (PCBs)	PCB used in manufacture of electrical equipment[23] PCB and DDT are banned in the United States since 1970s but are still found in body fat, as well as breast milk[24] DDT was used as pesticide for insects on farms and swamps PCB deteriorates slowly in soil PCB is difficult to study because it is a diverse class of compounds A 1999 in vitro study showed PCBs proliferate in breast cancer cells[25] Conflicting results; several large studies failed to show relationship with PCBs
Polycystic aromatic hydrocarbons (PAHs, including tobacco)	Found in soot and fumes from fuels Increased DNA damage (DNA adducts) implicated from the Long Island Breast Cancer Study Project[26] Tobacco smoke also contains PAHs Smokers who began smoking as adolescents have an increased risk of breast cancer[27–29] In 2004 the California EPA concluded that environmental tobacco smoke (ETS) increases the risk of breast cancer, and the association appears stronger for premenopausal women[30] Tobacco smoke also contains the carcinogens polonium-210, vinyl chloride, benzene, and 1-3 butadiene[31]
Dioxin	Products containing PVC, PCBs, or other chlorinated compounds release dioxin from incineration Declared a known carcinogen by the EPA in 2000 It may be the most prevalent of all toxic chemicals Occurs in meat, poultry, dairy products, and human breast milk A United Kingdom study linked dioxin to the development of mammary tumors in mice[32] A study in Seveso, Italy, connected dioxin with breast cancer[33]
Ethylene oxide	Used to sterilize surgical instruments and in some cosmetics Linked to breast cancer in women exposed to ethylene oxide in commercial sterilization facilities[34]

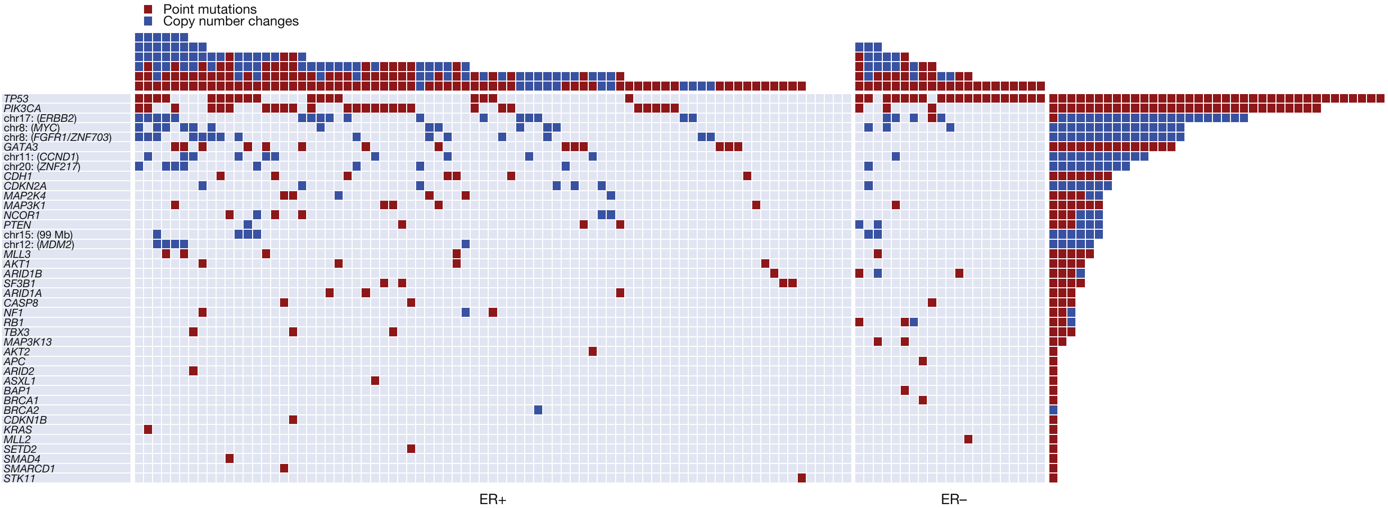

FIGURE 24-39 Driver Mutations and Copy Number Changes in Breast Cancer. The left side identifies each of the 40 cancer genes in which a driver mutation or copy number change has been identified. From investigation of 100 tumors, the number of mutations in each gene is shown (rows) as is the number of driver mutations in each breast cancer (columns). Point mutations are red and copy number changes are blue. (From: Stephens PJ et al: *Nature* 486:400–404, 2012.)

Physical Activity. Physically active individuals have lower rates of many cancers and improved cancer outcomes.[387,388] Activity also may reduce the invasiveness of breast cancer.[389] Consistent evidence from 27 observational studies showed physical activity is associated with all-cause, breast cancer–specific, and colon cancer–specific mortality.[387,390] A large prospective study found walking for 1 hour per day and additional weekly exercise seemed to be protective against breast cancer regardless of menopausal status.[391] Mechanisms for this protective effect are not known but include alterations in endogenous free radical formation and oxidative damage, effects on DNA repair capacity, changes in circulating insulin and insulin-related pathways, inflammation, alteration in carcinogen-metabolizing enzymes, increased intestinal transit times (i.e., reduced exposures to carcinogens), weight loss, changes in endogenous sex hormone, and possibly immunity levels.

Inherited Cancer Syndromes, Genes, Epigenetic Considerations

The causes of breast cancer have been difficult to define because each woman has a different genetic profile called **genetic heterogeneity.**[392] Genetic heterogeneity is common among individuals but also at the level of the tumor itself, involving both genetic and epigenetic processes. These facts are sobering and make the understanding of the genetic driving force behind tumor initiation, progression, and metastasis very complicated. Driver mutations are causally implicated in tumor development. Investigators examined the genomes of 100 tumors for somatic mutations and found they varied markedly between individual tumors.[392] Several new driver mutations were identified, including AKT2, ARIDIB, CASP8, CDKN1B, MAP3K1, MAP3K13, NCOR1, SMARCD1, and TBX3 (Figure 24-39).

A history of breast cancer in first-degree relatives (mother or sister) increases a woman's risk two to three times. Risk increases even more if two first-degree relatives are involved, especially if the disease occurred before menopause and was bilateral. In some families, breast cancer occurs at an earlier age and the frequency of bilateral tumors is greater. A small total proportion of breast cancers (incidence 5% to 10%, although the prevalence is significant) are the result of highly penetrant dominant genes (i.e., hereditary breast cancers). The most important of the dominant genes are the breast cancer susceptibility genes *(BRCA1, BRCA2)*. *BRCA1* is located on chromosome 17 and *BRCA2* is located on chromosome 13. *BRCA1* and *BRCA2* (unmutated; normal) are tumor-suppressor genes. Box 24-16 summarizes key points about *BRCA1* and *BRCA2*.[393]

PATHOGENESIS. Most breast cancers arise from the ductal epithelium (Figure 24-40). Tumors of the infiltrating ductal type do not become large, but they metastasize early. Some types of breast carcinomas are summarized in Table 24-17.This type accounts for the majority of breast cancers. Breast cancer is a heterogeneous—not a single—disease with diverse molecular, biologic, phenotypic, and pathologic, changes.[394] Complex is that breast cancer also is heterogeneous *within* the same tumor (also see above). Despite heroic efforts, this diversity has greatly challenged the understanding of breast cancer evolution and the development of therapeutic strategies. Gene expression profiling studies have identified at least four major subtypes classified as luminal A, luminal B, HER2+, and basal-like.[395] Yet with mounting evidence it appears there are "subtypes within subtypes," and evidence is emerging suggesting that the biology of specific breast cancer subtypes reflects contributions from the tissue microenvironment.[396] In fact, in their updated article "Hallmarks of Cancer," Hanahan and Weinberg state, "In addition to cancer cells, tumors exhibit another dimension of complexity: they contain a repertoire of recruited, ostensibly normal cells that contribute to the acquisition of hallmark traits by creating the 'tumor microenvironment.'"[397, p. 646] Historically, many models of breast carcinogenesis have been suggested

BOX 24-16 KEY POINTS ABOUT *BRCA1* AND *BRCA2*

- A deleterious mutation in *BRCA1* or *BRCA2* increases a woman's risk of developing breast cancer or ovarian cancer, or both.
- Harmful *BRCA1* mutations may increase a woman's risk of developing cervical, uterine, pancreatic, and colon cancer.
- Men with harmful *BRCA1* mutations have an increased risk of breast cancer and possibly of pancreatic, testicular, and early-onset prostate cancer.
- Male breast cancer, however, and pancreatic and prostate cancer appear to be more strongly associated with harmful *BRCA2* mutations
- Harmful mutations in *BRCA1* or *BRCA2* are highest in families with a history of both breast and ovarian cancer, family members with tumors that develop from different sites in the body, or an Ashkenazi (Central European descent) Jewish background. However, not every woman in these families carries a harmful *BRCA1* or *BRCA2* mutation. Additionally, not every woman who has a harmful *BRCA1* or *BRCA2* mutation will develop breast or ovarian cancer, or both.
- A woman with a mutated *BRCA1* or *BRCA2* is about five times more likely to develop breast cancer than a woman without the mutation.
- Women with a harmful *BRCA1* or *BRCA2* have a probability of being diagnosed with ovarian cancer (150 to 400 out of 1000) compared with women without the mutation (14 out of 1000).
- The estimates of cancer risks are based on large families with multiple affected family members and may not accurately reflect other genetic and environmental risk factors.
- Options for those that have a positive test for a harmful *BRCA1* or *BRCA2* mutation include surveillance to find cancers early, prophylactic surgery (i.e., bilateral salpingo-oophorectomy), risk factor avoidance (e.g., avoid hormone replacement therapy [HRT], breast-feed), and chemoprevention.
- *BRCA1* and *BRCA2* function is a common pathway of genome protection. They work at different stages in the DNA damage response (DDR) and in DNA repair.
- *BRCA1* functions in both cell cycle check point activation and DNA repair, whereas *BRCA2* is a mediator of the DNA repair mechanism–homologous recombination.
- Both *BRCA1* and *BRCA2* work together to protect the genome from double-strand DNA damage during DNA replication.
- The prevalence and penetrance of both *BRCA1* and *BRCA2* vary with race; so far evidence indicates highest in whites compared to Asians and blacks.

Data from: National Cancer Institute: *BRCA1 and BRCA2: cancer risk & genetic testing*. Available at www.cancer.gov/cancertopics/factsheet/Risk/BRCA. Accessed February 2013.

including: (1) the multihits sequential acquisition model, (2) sporadic clonal evolution model, (3) telomere crisis, and (4) imprinted stem cell or cancer stem cell model.[398] In an effort to understand breast cancer biology three interrelated themes also have emerged and include: (1) gene addiction, (2) phenotypic plasticity, and (3) cancer stem cells.[399]

Cancer gene addiction includes oncogene addiction, whereby these genes play key roles in human breast cancer, and nononcogene addiction, whereby these genes may not initiate cancer but play major roles in cancer development and progression[399] (see p. 863). Phenotypic plasticity is exemplified by a distinctive phenotype called **epithelial to mesenchymal transition (EMT)** (see Chapter 12).[400] EMT is intimately involved in the generation of tissues and organs during embryogenesis, is essential for driving plasticity during development, and is an unintentional process during cancer progression. The EMT-associated reprogramming is involved not only in migration of cancer cells but also suppression of apoptosis and senescence, recapitulation during wound healing, weakening of cell-cycle progression, and resistance to radiotherapy and chemotherapy.[401] Much research is ongoing to define cancer stem cells in breast carcinogenesis including their origin and renewability properties. Numerous factors govern invasiveness and metastasis and include heterogeneity of cell subsets within the primary tumor, the interaction of tumor cells with the microenvironment, cell signaling factors, and the receptivity of metastatic colonization sites (the soil). EMT generates multiple epithelial cell subsets with different states of stemness relative to more differentiated cells.[402] In an effort to include all of these themes, it is striking that the same pathways and interactions observed in the normal mammary gland during development are exploited by tumors during their progression to metastatic disease (Figure 24-41).

The normal breast and breast tumors *share* molecular, cellular, systemic, and microenvironment components that are necessary for tumor progression.[396] The microenvironment is now recognized as a critical player in tumor progression and therapeutic responses.[403] Components of the microenvironment, including myoepithelial and endothelial cells, macrophages, and many ECM molecules, play a critical role in normal duct morphogenesis, and are increasingly recognized as major regulators of carcinogenesis[397] (see Figure 24-41).

Front and center for breast carcinogenesis is that cancer is a heterogeneous disease based on tumor anatomy, location, grade, lymph node metastasis, expression of growth factor receptors, and—emerging—several biomarkers assessed in the clinic.[396] Some breast tumors may be heterogeneous from their initial preinvasive stages,[398] but tumors are continuously evolving. Emerging is the understanding that the tumor microenvironment plays a major role in driving tumor heterogeneity.[396] Multiple microenvironment-related genes have been identified and include FGF, TGF-B, MMP, and collagen family members. Additionally, genetic signatures of genes involved in wound healing are thought to originate from fibroblasts of the tumor microenvironment. ECM-related gene expression modules are associated with tumor intrinsic subtypes and with clinical outcomes.[396] Gene expression prognostic signatures of motility and proliferation-related genes as well as stromal cells "reactive" phenotype during cancer progression show some commonality with normal branching morphogenesis and involution. Table 24-18 shows a comparison of similarities and differences between normal mammary gland branching and breast cancer invasion.[396]

The majority of studies evaluating gene expression stromal-derived signatures have focused on intratumoral stromal expression rather than the microenvironment surrounding normal breast or extratumoral expression.[404] Intratumoral stromal responses include: (1) elevated expression of immune mediators from stromal tissue,[405] (2) a signature of fibroblast

TABLE 24-17 TYPES OF BREAST CARCINOMAS AND MAJOR DISTINGUISHING FEATURES

HISTOLOGIC TYPE	DISTINGUISHING FEATURES
Carcinoma of Mammary Ducts	
Papillary	Well-delineated cystic masses in multiple areas; hemorrhage often present; majority appear in 40- to 60-year age group; often involves skin
Intraductal (comedo)	Often accompanied with evidence of inflammation; well-circumscribed tumors within the duct; well-differentiated tumor cells; rarely ulcerates the skin
Infiltrating Carcinoma	
Ductal (no specific type [NST])	Fibrous, firm, glistening, gray-tan mass with chalky streaks, mixture of patterns; may cause discharge from the nipple; represents about 79% of all breast cancer
Mucinous	Usually large (>3 cm in diameter), circumscribed, and encapsulated; glistening appearance, varies in color; two types: pure and mixed; pure tumor is surrounded by mucin; infrequent; found in the lateral half of the breast; tends to occur in women after age 70 years
Medullary	Encapsulated and grows to be very large (7-8 cm in diameter); commonly surrounded by lymphocytic inflammatory infiltrate; occurs after age 50 years
Tubular	Well differentiated with orderly tubules in center (stroma) of mass; can be associated with noninfiltrating ductal carcinoma; occurs in women about 50 years of age; nodal metastasis infrequent; occurrence rare
Adenoid cystic	Very rare; well-circumscribed, painless mass arising from the nipple and areola
Metaplastic	Involves cartilage or bone; mixed tumors or osteogenic sarcomas
Squamous cell	Frequent in blacks; originates in ductal epithelium
Carcinoma of Mammary Lobules	
Lobular carcinoma in situ	Found in individuals with fibrocystic disease; localized to upper breast quadrants; risk of 15%-35% becoming invasive; occurs frequently in mid-40s; infiltrating variety occurs in early 50s
Infiltrating lobular	Infiltrates from duct; firm mass with chalky streaks
Paget disease	Eczema of the nipple that extends to the areola; cancer usually found underneath the nipple; poorly circumscribed; large Paget cells arise from the duct and directly invade nipple; history of scaly, red rash spreading from the nipple; lesion palpable beneath the nipple, often bilateral; occurs in middle age
Inflammatory carcinoma	Not a histologic type; fairly diffuse within the breast tissue, diffuse edema of the overlying skin; extremely undifferentiated, very rare, most metastasize to axilla
Sarcoma of the Breast	
Cytosarcoma phyllodes	Usually large (>17 cm in diameter); mostly localized but can rupture through the skin; rarely metastasizes to lymph nodes; history of painless nodule present for years before it forms a large mass; ulceration and bleeding of skin often present; occurs in wide age range (ages 13-77 years)
Fibrosarcoma	Well circumscribed, firm, and usually does not involve the skin or nipple; well differentiated to extremely undifferentiated; arises from connective tissue; extremely rare (e.g., liposarcoma, angiosarcoma)

Data from Beahrs OH, Hutter RV, Kennedy BJ, editors: *Breast manual for staging of cancer,* ed 45, Philadelphia, 1992, Lippincott.

response,[406] (3) fibromatosis and macrophage-associated signature,[407] and (4) stromal responses activated early possibly before invasion.[408] Growing evidence suggests that extratumoral microenvironment—called field effects—also may play a role in tumor progression.[404] Normal homeostatic or developmental pathways and molecular processes, such as wound healing and TGF-β in the presence of initiated tumor cells, become tumor promoting.[404,409] The study of field effects has only just began in human cancer outcomes. Investigators demonstrated that wound responses may be divided into two types: active and inactive. Active cancer-adjacent tissue reveals characteristics of active EMT or cellular dedifferentiation (regression of specialized cellular features or simpler, more embryonic) and was associated with poor survival. Inactive extratumoral tissue has evidence of more differentiated tissue with higher expression of cellular adhesion genes and lower expression levels of EMT-related transcription factors.[404] Complicated and important are future studies to determine intra- and extratumoral changes to understand their dependence and independence on tumor characteristics. It seems clear that cancer heterogeneity and clinical outcome reflect signaling from a heterogeneous microenvironmental recurring theme that hopefully promises greater therapeutic outcomes.

Ductal Carcinoma In Situ

Ductal carcinoma in situ (DCIS) is a complex, heterogeneous group of proliferations limited to breast ducts and lobules without invasion of the basement membrane. About 84% of all in situ disease is DCIS; the remainder is mostly LCIS disease.[410] DCIS occurs predominantly in women but can occur in men. Since 1980, the widespread adoption of screening mammography has led to an epidemic of diagnoses of DCIS.[411] DCIS accounts for about 20% to 27% of newly diagnosed cases of breast cancer in the United States, and about 17% to 34% of mammographically detected cases.[411,412] SEER data from 1983 to 2003 depict a 500% increase in DCIS among women age 50 years and older and a decline of DCIS in 2003.[413] Among

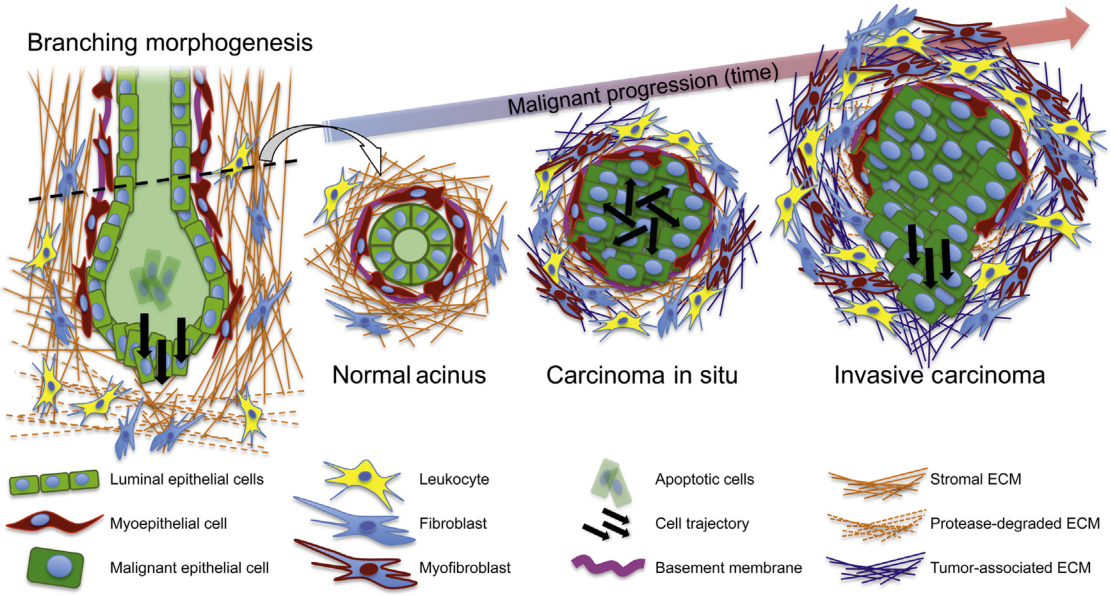

FIGURE 24-41 **A Model of Breast Carcinogenesis: Dynamic Microenvironments Regulate Both Normal Breast Development and Breast Carcinogenesis.** Anatomic changes during mammary gland development, called branching morphogenesis, require extensive dialogue between epithelial and stromal cells and their underlying extracellular matrix (ECM). These events are central and amplified during carcinogenesis and are often required for tumor progression. Loss of the myoepithelial cell layer and basement membrane is key for invasive progression. Potential crosstalk between cell–cell and cell–matrix interactions are abnormally regulated by autocrine and paracrine signaling networks of proteolytic enzymes and chemokines, and cytokines continue to attract leukocytes, modulate tumor remodeling, and increase tumor cell invasion eventually leading to metastasis. Tumors steal or "hack" the normal developmental program to manifest carcinogenesis. (From Boudreau A, van't Veer LJ, Bissell M: *Cell Adh Migr* 6[3]:236–248, 2012.)

TABLE 24-18 **BREAST CANCER INVASION AND NORMAL MAMMARY GLAND BRANCHING SHARE MANY SIMILARITIES**

	BRANCHING MORPHOGENESIS	BREAST TUMOR INVASION
Similarities	Requires heterotypic, paracrine interactions between epithelial cell proliferation and directional migration	
	Stromal cells secrete growth factors guiding epithelial cell proliferation and directional migration	
	Proliferative epithelial cells secrete growth factors to enrich their adjacent stroma	
	Conserved growth factors and receptors used, albeit at different amplitudes of signaling	
Differences	Regulated proliferation and migration	Aberrant mitogenic signaling and network substucture
	Transient stromal-epithelial interactions	Exaggerated stromal-epithelial interactions
	Migration confined by fat pad	Migration infiltrates adjacent tissues and beyond
	Epithelial cell apoptosis yields a lumen	Epithelial cell necrosis yields inflammation
	Deposition of basement membrane	Destruction of basement membrane
	Differentiation into polarized, bilayered ducts	Dedifferentiation; loss of polarity and myoepithelium
	End product is a functional tissue	End product is pathologic tissue

Data from Boudreau A, van't Veer LJ, Bissell M: *Cell Adh Migr* 6(3):236–248, 2012.

women younger than 50 years, there has been a 290% increase in DCIS since 1983 and the incidence is still increasing.[411] The American Cancer Society estimates about 64,640 new cases of carcinoma in situ in 2013.[414] The type of DCIS across all age groups not associated with subsequent DCIS or invasive cancer (i.e., noncomedo type) has mostly increased, and subsequent DCIS or invasive cancer has been constant or decreased. Importantly and despite 20 years of detecting DCIS by mammography, a decline in invasive cancer in the United States was not observed until the large decline in postmenopausal hormone therapy. Population data report screening rates of DCIS to be similar among white, black, and Asian/Pacific Islanders.[415] The majority of DCIS presents as linear or multiple clusters of calcifications on a mammogram.

Although risk factors for DCIS and invasive breast cancer are similar and therefore suggest a common etiology for both diseases, some characteristics are more strongly associated with invasive cancer. The risk factors that increase the risk of both DCIS and invasive cancers include family history of a first-degree relative, nulliparity or late age of first birth, history of biopsy, late age at menopause, long-term use of postmenopausal HRT, and increased BMI in postmenopausal

women not taking hormone therapy.[415] A strong risk factor for invasive breast cancer and for DCIS is high mammographic breast density.[415,416] Conflicting studies for DCIS have been on smoking, lactation, early menarche, increased alcohol consumption, and oral contraceptive use. The prevalence of mutation carriers *BRCA1* and *BRCA2* is similar among women diagnosed with DCIS to that of women with invasive breast cancer.[415]

Recently it was shown that about 5900 genes are expressed in the epithelium during the transition from normal to DCIS and that only three epithelial genes had differential expression from DCIS to invasive carcinoma, suggesting the importance of the stroma in cancer progression.[396] Allinen and coworkers[417] performed the first systematic profiling of the various stromal cell types. They demonstrated gene expression alterations in all cell types within the tumor microenvironment accompanying progression from normal breast tissue to DCIS to invasive ductal carcinoma (IDC) provided evidence that these cell types all participate in tumorigenesis.[396]

Changes in the tumor microenvironment are observed early at the DCIS stage or even earlier.[396] With the secretion of chemokines causing accumulation of leukocytes and many other cells, stromal and epithelial cells participate in reciprocal and paracrine acting signaling loops (Figure 24-42). These communicating signaling links appear to stabilize the increased localization of macrophages, myofibroblasts, and fibroblasts at the DCIS stage, which ultimately remodel the ECM and promote tumor proliferation.[396] Depending on location, genetics, and other changes, the altered microenvironment may stiffen, increase blood vessel density, increase breast density, and result in calcifications. Although DCIS may remain stable and never progress (or may regress), for invasive DCIS the cells within the DCIS *breach* the myoepithelial layer and the basement membrane defining the moment when an invasive carcinoma is formed.[396] Importantly, the layer of myoepithelial cells is thought to be natural "tumor suppressors" and critical to maintaining tissue polarity (cell directional orientation) (see Figure 1-11), a role that is lost in invasive breast carcinomas. Investigators and clinicians are intensely studying this key step, or breach, in terms of cellular alterations because of tumor biology or iatrogenic stimuli, or both.

The natural history of DCIS is actually elusive and reflects the diversity of the condition. Preinvasive lesions do not invariably progress to invasive malignancy. DCIS is detected more often in younger women than in older women.

Although there is no universally accepted histopathologic classification, historically most pathologists divided DCIS into five subtypes (papillary, micropapillary, cribriform, solid, and comedo) and often compare the first four types, noncomedo, with comedo. In a single biopsy, however, several types may be mixed and some noncomedo types may express characteristics of the comedo type. Although the term *comedo type* is widely used it does not specify a grade or an architecture, so newer categories most often use nuclear grade (high, intermediate, or low) and record the architectural pattern separately.[418] When it comes to the architecture of DCIS, however, the literature is full of contradictory information.

Lobular Carcinoma In Situ

Lobular carcinoma in situ (LCIS) originates from the terminal duct–lobular unit (see Figure 24-40, *B*). Unlike DCIS, LCIS has a uniform appearance in which the cells occur in noncohesive (discohesive) clusters, primarily in lobules. Today, however, there is limited knowledge of the biology of LCIS.[419] Atypical lobular hyperplasia (ALH) and LCIS represent a spectrum of breast disease called **lobular neoplasia (LN).** Research suggests that some lobular and ductal carcinomas are closely related.[420] LCIS is not associated with calcifications or a stromal involvement that would form a density (lump). Thus it is usually an incidental finding from biopsy for something else. LCIS is fairly uncommon (up to 3.8% of all specimens).[421] LCIS is bilateral in 20% to 40% of women, and the majority (80% to 90%) occur before menopause. Although the cells of LCIS and invasive lobular carcinoma are identical,[177] whether LCIS is a true neoplasm or a marker of breast cancer risk remains controversial. Evidence to support LCIS as a precursor lesion of invasive carcinoma comes from molecular genetic data highlighting chromosomal alterations and that LOH on chromosome 16q is present in an invasive carcinoma.[47,422] Invasive carcinoma develops in 25% to 35% of women with LCIS, and the contralateral (opposite) breast also is at risk.[423] Chemoprevention is recommended for atypia types, including LCIS, to reduce breast cancer risk.[424]

Inflammatory Stroma in Breast Cancer

Dominating the cancer field is the idea that epithelial function depends on the *entire* tissue, including the stroma or microenvironment. The specific location where a tumor develops in the breast can have a major influence on its breast cancer outcome.[425] Variations in tumor development depend on the architecture and the microenvironment of the tumor in vivo and plays an important role in phenotypic outcome of genetic mutations.[426] Importantly, people can harbor potentially malignant tumors that remain dormant for many years.[425] The microenvironment surrounding a tumor may normally suppress tumor development by providing tumor-suppressive signals, and the loss of tissue homeostasis causes the development of an aberrant microenvironment and over time becomes a potent tumor promoter.[396,409,427-429] The stromal response (the "soil") is often associated with invasive breast cancer. Emerging are two views regarding the tissue stromal response to breast carcinogenesis—is the stromal response unique to the tumor or is the stromal response a host response, an individual's innate healing response to disrupted tissue? Embedded in these views is the stromal response, sometimes called an aberrant "wound" with an **inflammatory stromal (reactive stroma) component**[430] (see Chapter 12). This "wound response" is exemplified by expression of a set of genes associated with healing. Evidence of the link between wound healing and carcinogenesis is based on the fact that these two distinct pathologies share a common "footprint" or "signature," a common molecular gene expression signature.[201] Gene expression signatures derived from tumor stroma have been linked to clinical outcomes.[403] The genetic expression profile from a wound-healing model of fibroblasts actually predicted metastasis and death in several epithelial cancers. The "activated fibroblast gene signature" also

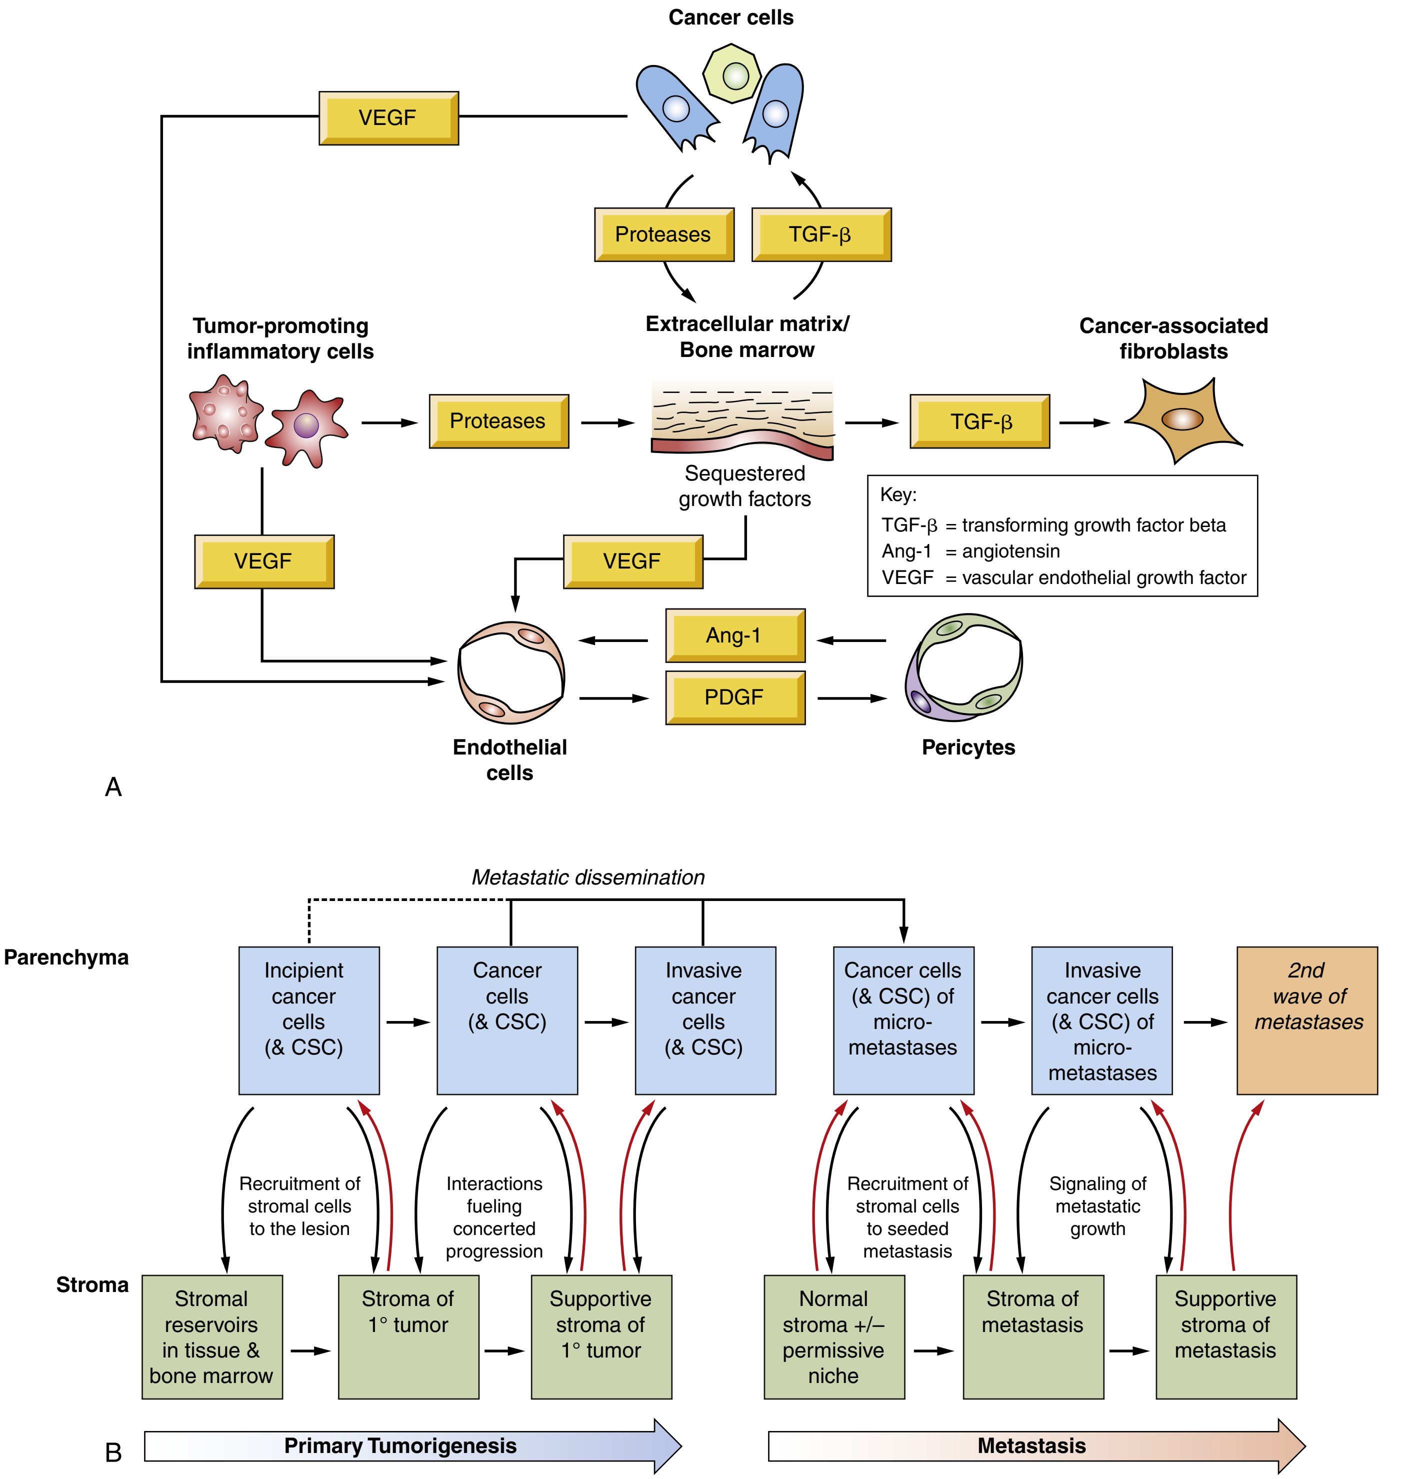

FIGURE 24-42 Signaling Interactions in the Tumor Microenvironment During Malignant Progression. **A,** Numerous cell types constitute the tumor microenvironment and are orchestrated and maintained by reciprocal interactions. **B,** The reciprocal interactions between the breast main tissue or parenchyma and the surrounding stroma are important for cancer progression and growth. Certain organ sites of "fertile soil" or "metastasis niches" facilitate metastatic seeding and colonization. Cancer stem cells are involved in some or all stages of tumor development and progression. (Adapted from Hanahan D, Weinberg R: *Cell* 144:646–674, 2011.) *CSC,* Cancer stem cells.

was shown to be an independent marker for local recurrence of breast cancer.[430,431]

Early alterations in the stroma that occur with wound healing and inflammation include activation of (1) mesenchymal cells (embryonic) fibroblasts; (2) endothelial cells; and (3) immune cells, including macrophages. Evidence of this type of activation is noted adjacent to tumors and is pathologically known as *desmoplastic stroma*.

To help answer the question as to whether the stromal response is unique to the tumor (tumor-provoked) or a host reaction (patient-dependent) to tissue alteration, investigators studied the variability in stromal responses in clinically distinct tumors from the same patient (paired primary tumors). They did studies of the stromal response to biopsy site changes and carcinoma to identify the differences and similarities.[279] These studies indicate that the **desmoid-type fibromatosis (DTF) fibroblast response** (clonal fibroblastic proliferations arise in deep soft tissue characterized by infiltrative growth and local recurrence) is present in individuals with paired breast primary tumors. Stroma taken from normal breast and biopsy site changes showed that the response to biopsy site changes is similar to the response to carcinoma and concluded that the DTF fibroblast response is a generalized response to tissue disruption and injury that appears to be specific to individual patients.[279] From the larger study cohort, the macrophage-associated pattern of gene overexpression called the **CSF1 response** showed no significant similarity or concordance in separate tumors within a given patient. The DTF fibroblast signature showed more concordance across normal, cancer, and biopsy site samples from within a patient than across a random group of patients' normal, cancer, and biopsy site samples but the CSF1 macrophage response did not. In summary from these studies is that the DTF fibroblast response is host-specific and the CSF1 response may be tumor-provoked.[279] Studies of this nature are challenging and are continuing to better understand the characteristics of the stromal response in breast carcinogenesis. Emerging evidence suggests that the development of this wound-reactive pattern and change in tumor tissue architecture creates an EMT (see p. 864 and Chapter 12).[400]

Invasive Breast Carcinoma

Invasive breast carcinoma is a malignant invasive epithelial lesion derived from the terminal duct lobular unit (Figure 24-40, *B*, p. 865). It can arise from anywhere in the breast parenchyma or accessory breast tissue, but it appears to be more common in the upper outer quadrant. The exact molecular events leading to invasion are complex and not completely understood. Because myoepithelial cells form a semi-continuous protective sheet separating the human breast epithelium and the surrounding stroma, it has been a major focus of understanding invasive carcinogenesis (Figure 24-43).

Two theories are proposed for the mechanism of tumor epithelial cells' progression from the in situ to invasive carcinogenesis stages.[432] The first theory of invasion is the result of proteolytic enzymes and their degradation capacities by myoepithelial cells and surrounding tumor cells. The second theory is that tumor invasion is a multistep process, involving dynamic interactions between damaged myoepithelial cells, and the immunoreactive cells initiate the release of basement membrane–degrading enzymes causing tumor progression.[432] Several lines of evidence suggest that myoepithelial cells block proliferation of breast carcinoma cells by inducing growth arrest and apoptosis. They also secrete many effector and inhibitor molecules that interfere or suppress the invasive behavior of tumor cells and block angiogenesis and basement membrane degradation.[433] Patterns of local dissemination are strongly constrained by the local ECM microenvironment and critically, if the basement membrane remains intact, cancer cells remain indolent. Studies have shown that even microscopic breaks in the myoepithelium are correlated with a poor prognosis.[434,435] The critical difference in clinical prognosis between in situ and invasive or metastatic cancer results importantly and predominantly from the presence or absence of the surrounding basement membrane (BM).[436] The BM physically segregates all normal or preinvasive tumor epithelia from lymphatic ducts and blood vessels and from vascular structures within the stroma.[436] The BM continuous sheet, commonly called the **tumor capsule,** consists of mainly type IV collagen, laminins, and other molecules[436] In human breast, prostate, and major salivary glands, the capsule is further reinforced by the single layer of myoepithelial cells in the breast and salivary glands and "basal cells" in the prostate.[436] The basal or myoepithelial cell layer lies between the epithelial cells and the BM. In the gastrointestinal tract, the normal mucosa and in situ cancer are further separated from the submucosa by the muscularis mucosa, a dense band composed of two layers of smooth muscle cells.[437] Because of these structural relationships, the disruption of the tumor capsule and its associated physical barriers is an absolute prerequisite for tumor cell invasion or metastasis.[436] Importantly, myoepithelial cells modulate the expression of matrix metalloproteinases (MMPs) in the tumor, as well as in the surrounding cells, and assist in the prevention of tumor invasion, which is possibly mediated by these proteolytic enzymes.[438]

A long-standing theory is that progression from in situ to invasive or metastatic cancer is caused by proteolytic enzymes produced by tumor cells that increase linearly with tumor progression, reaching their highest level at the in situ cancer stage. It has been hypothesized that these proteolytic enzymes cause degradation or disruption of the tumor capsule and allow the in situ cancer cells to migrate into the adjacent stroma or to disseminate to distant organs. This theoretic model of tumor invasion and metastasis is consistent with results obtained from tissue culture and animal model studies; however, it is debated because it appears inconsistent with a number of other well-established observations.[436] Therefore, other models exist for understanding tumor invasion and metastases and prominently include the role of the ECM, immune cells, and stem cells (Box 24-17). The intrinsic impact of focal myoepithelial cell degeneration, aberrant lymphocyte infiltration, and capsule disruptions is likely to be associated with tumor progression and invasion. Advanced breast cancer is associated with complete loss of the myoepithelial cell layer and basement membrane, invasion of epithelial cells, and angiogenesis (Figure 24-44).

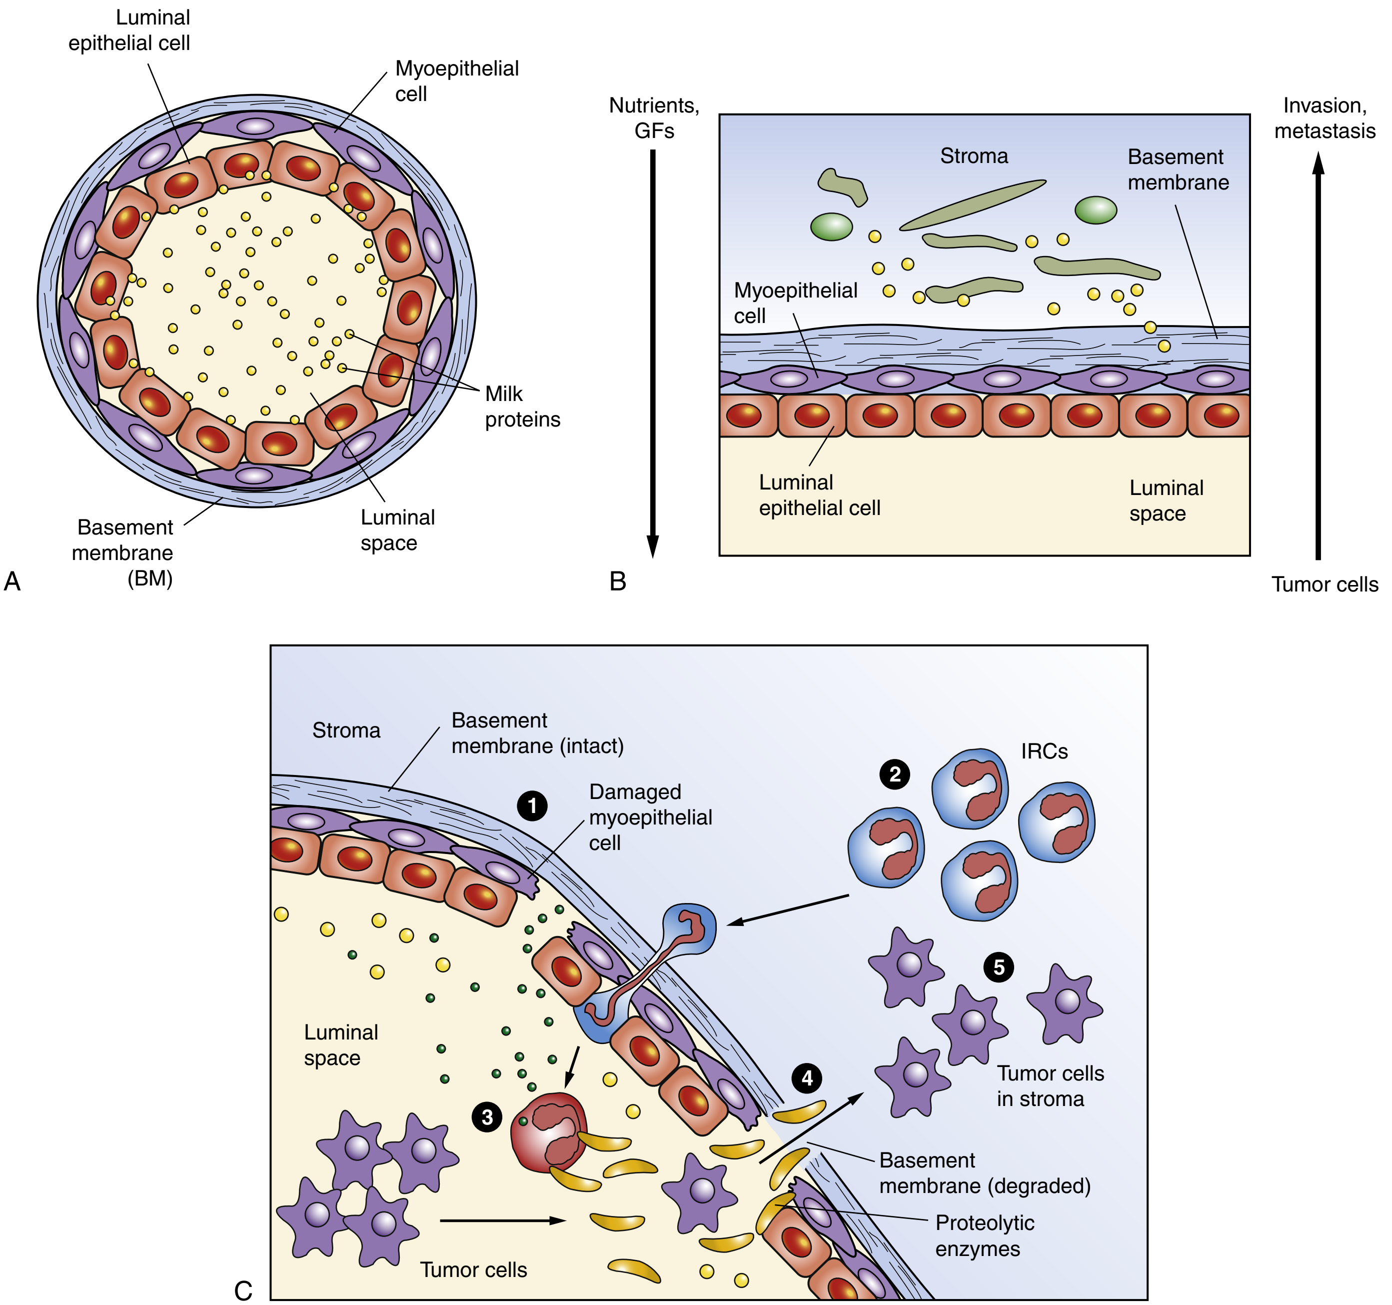

FIGURE 24-43 The Role of Myoepithelial Cells in Invasive Breast Cancer. **A,** Cross section of a normal mammary gland. **B,** Schematic of the anatomic relationship between mammary gland duct cells, basement membrane (BM), and stroma. **C,** With degradation of the normal "tumor suppressing" basement membrane tumor cells invade the stroma; **(1)** myoepithelial cells are damaged by various factors and release their inner contents (for example, diffusible molecules and chemoattractants); **(2)** immunoreactive cells (IRCs) are drawn to the luminal space by these chemoattractants; **(3)** IRCs become activated after contact with chemoattractants and secrete various proteolytic enzymes; **(4)** these enzymes then degrade the basement membrane resulting in gaps; and **(5)** tumor cells enter the stromal region through these gaps. (Data and adapted figures from Pandey PR, Saidou J, Watabe K: *Front Biosci* 15:226–236, 2011.) *GF,* Growth factor.

BOX 24-17 EXISTING THEORIES OF TUMOR INVASION AND METASTASES

Proteolytic Enzyme Theory

Proteolytic enzymes cause degradation or disruption of the tumor capsule and allow the in situ cancer cells to migrate into the adjacent stroma or to disseminate to distant organs.

Infiltrating Immune Cells Reduce Tumor Cell Progression and Invasion

Infiltration of immune cells into tumor tissues and direct physical contact between tumor cells and infiltrated immune cells are associated with physical destructions of the tumor cells, reduction of the tumor burden, and improved clinical prognosis.

Infiltrating Immune Cells Promote Tumor Cell Progression and Invasion

Hypotheses

Macrophage and Tumor Invasion

Macrophages are recruited to the invasive tumor front by expression of tumor-derived chemotactic factors and in response to the disruption of the basement membrane. At this invasive site macrophages increase tumor cell migration and invasion through their secretion of chemotactic and chemokinetic factors including epidermal growth factor (EGF). Macrophages promote angiogenesis by the synthesis of angiogenic factors including vascular endothelial growth factor (VEGF), and they remodel the extracellular matrix and in particular, regulate collagen fibrillogenesis.

Interleukin (IL)-4–Expressing CD4+ T Lymphocytes Promote Tumor Invasion

IL-4-expressing CD4+ T lymphocytes indirectly promote invasion and subsequent metastasis of breast cancer by directly regulating the phenotype and effector function of tumor-associated macrophages that in turn enhance metastasis through activation of epidermal growth factor receptor signaling in breast cancer epithelial cells. The same concept and similar pathways have been extended to lymphocytes and their subtypes.

Cancer Cell–Leukocyte Fusion

Macrophages ingest tumor cells leading to the fusion of genetic materials from the two cell types, resulting in the creation of a hybrid phenotype. This phenotype is associated with chemotactic migration in vitro toward fibronectin and shows high frequencies of metastasis when implanted in mice.

Regulatory T Cells (Treg) Induced Immunosuppression

Recruitment of Treg cells to the tumor supports disease progression through a dual mechanism: (1) the decrease of antitumor immunity, and (2) through the establishment of a proangiogenic reprogramming of the tumor microenvironment.

Monocyte-Mediated Protection Against Natural Killer (NK) Cell Lysis of Cancer Stem Cells

Alterations in NK cell effector function could ultimately aid in driving differentiation of a population of surviving healthy as well as transformed stem cells. Because the majority of NK cells have lost cytotoxic activity in those with cancer, they may eventually *contribute* rather than *halt* the progression of cancer by allowing the growth and expansion of the pool of cancer stem cells.

This hypothesis provides a general mechanism how immune cells may behave in inflammatory microenvironment for the ultimate goal of tissue regeneration and the resolution of inflammation.

Aberrant Lymphocyte Infiltration–Induced Focal Capsule Disruptions

Focal basal or myoepithelial cell degeneration, aberrant lymphocyte infiltration, and capsule disruptions may be correlated events that contribute to tumor progression and invasion. Research findings suggest that tumor invasion or metastasis is triggered by focal capsule degeneration–induced lymphocyte infiltration that causes physical disruptions within the capsule, which selectively favors proliferation and dissemination of overlying tumor stem cells.

Lymphocyte-Mediated Cell Dissemination and Metastasis

An extension of the above hypothesis is that aberrant tumor-infiltrating lymphocytes can trigger tumor metastasis through three correlated pathways: (1) the physical movement of infiltrated lymphocytes into the budding tumor cell nest can disrupt intercellular junctions and surface adhesion molecules, causing dissociation of some cells from the tumor core; (2) lymphocytes can conjoin with dissociated tumor cells through cell membrane fusion to form tumor-lymphocyte chimeras (TLCs; fusion); and (3) the ability to migrate and to cross intercellular barriers enables lymphocytes to physically drag tumor cells to remote sites and to intravasate into blood vessels or lymph ducts.

Data from Man YG et al: *J Cancer* 4:4(1):84–95, 2013.

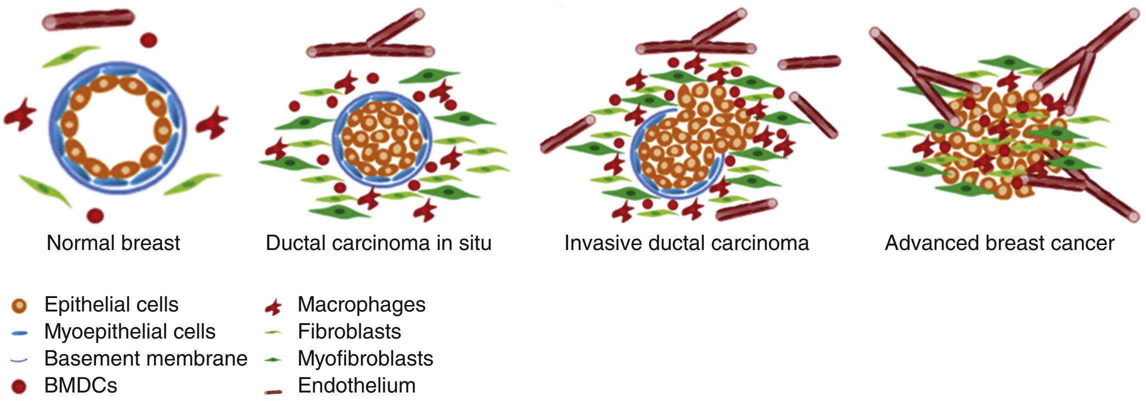

FIGURE 24-44 **Breast Cancer Progression with Stromal Cells.** The normal breast duct is composed of a layer of epithelial cells and a layer of myoepithelial cells, which is separated from the stroma by a basement membrane (BM). Examples of stromal cells include fibroblasts, bone marrow–derived cells (BMDCs), endothelial cells (important for angiogenesis), and other cells. Ductal carcinoma in situ (DCIS) is associated with luminal epithelial cell proliferation, and recruitment and expansion of stromal cells. In invasive ductal carcinoma, the myoepithelial cell layer is degraded with the underlying basement membrane and cancerous cells invade the surrounding microenvironment. Advanced breast cancer is associated with complete loss of myoepithelial cell layer and basement membrane, invasion of epithelial cells, proliferation of stromal cells, and angiogenesis. (From Khamis ZI, Sahab ZJ, Sang QX: *Int J Breast Cancer* 2012:574025, 2012.)

FIGURE 24-45 Retraction of Nipple Caused by Carcinoma. (From del Regato JA, Spjut HJ, Cox JD: *Ackerman and del Regato's cancer: diagnosis, treatment, and prognosis,* ed 6, St Louis, 1985, Mosby.)

CLINICAL MANIFESTATIONS. The first sign of breast cancer is usually a painless lump. Lumps caused by breast tumors do not have any classic characteristics. Other presenting signs include palpable nodes in the axilla, retraction of tissue (dimpling) (Figure 24-45), or bone pain caused by metastasis to the vertebrae. Table 24-19 summarizes the clinical manifestations of breast cancers. Manifestations vary according to the type of tumor and stage of disease.

EVALUATION AND TREATMENT. Clinical breast examination, mammography, ultrasound, thermography, MRI, biopsy or minimally invasive biopsy, hormone receptor assays, and gene expression profiling are used in evaluating breast alterations and cancer.

Treatment is based on the extent or stage of the cancer. The extent of the tumor at the primary site, the presence and extent of lymph node metastasis, and the presence of distant metastases are all evaluated to determine the stage of disease. Treatment includes surgery, radiation, chemotherapy, hormone therapy, and biologic therapy.

TABLE 24-19 CLINICAL MANIFESTATIONS OF BREAST CANCER

CLINICAL MANIFESTATION	PATHOPHYSIOLOGY
Chest pain	Metastasis to the lung
Dilated blood vessels	Obstruction of venous return by a fast-growing tumor; obstruction dilates superficial veins
Dimpling of the skin	Can occur with invasion of the dermal lymphatics because of retraction of Cooper ligament or involvement of the pectoralis fascia
Edema	Local inflammation or lymphatic obstruction
Edema of the arm	Obstruction of lymphatic drainage in the axilla
Hemorrhage	Erosion of blood vessels
Local pain	Local obstruction caused by the tumor
Nipple/areolar eczema	Paget disease
Nipple discharge in a nonlactating woman	Spontaneous and intermittent discharge caused by tumor obstruction
Nipple retraction	Shortening of the mammary ducts
Pitting of the skin (similar to the surface of an orange [peau d'orange])	Obstruction of the subcutaneous lymphatics, resulting in the accumulation of fluid
Reddened skin, local tenderness, and warmth	Inflammation
Skin retraction	Involvement of the suspensory ligaments
Ulceration	Tumor necrosis

SUMMARY REVIEW

Alterations of Sexual Maturation

1. Sexual maturation, or puberty, should begin in girls between ages 8 and 13 years. Delayed puberty is the onset of sexual maturation after these ages; precocious puberty is onset before these ages. The average age of puberty has been occurring earlier than in previous generations.
2. Alterations of sexual maturation can be idiopathic or caused by a disease or congenital anomaly. In most cases of delayed puberty, the hypothalamic pituitary gonadal (HPG) axis is intact but the surge of activity that stimulates puberty is delayed. Precocious puberty, more common in girls, also can be caused by mistiming of the stimulatory surge in a child whose HPG system is otherwise normal. Obesity is associated with younger pubertal age.
3. Precocious puberty can be complete (sex appropriate), mixed (not sex appropriate), or partial (development of one secondary sex characteristic only). Causes of delayed or incomplete puberty can be divided into categories based on gonadotropic secretion: hypergonadotropism (increased levels of FSH and LH), and hypogonadotropism (decreased LH and FSH levels).

Disorders of the Female Reproductive System

1. The female reproductive system can be altered by hormonal imbalances, infectious microorganisms, inflammation, structural abnormalities, and benign or malignant proliferative conditions.

SUMMARY REVIEW—cont'd

2. Menstrual disorders usually involve some disruption of the HPG axis and subsequent alteration of hormone production, reception by target organs, or feedback mechanisms.
3. Primary dysmenorrhea is painful menstruation not associated with pelvic disease. It often results from excessive synthesis of prostaglandins (or sensitivity to prostaglandins), which cause the myometrium to contract and constrict blood vessels, resulting in ischemic pain.
4. Primary amenorrhea is the continued absence of menarche and menstrual function by 14 years of age without the development of secondary sex characteristics or by age 16 years if these changes have occurred.
5. Secondary amenorrhea is the absence of menstruation for a time equivalent to more than three cycles or 6 months in women who have previously menstruated. Secondary amenorrhea is usually associated with anovulation.
6. Amenorrhea is divided into compartments that reflect the underlying disorder: compartment I, disorders of the outflow tract or uterine target organ; compartment II, disorders of the ovary; compartment III, disorders of the anterior pituitary; and compartment IV, disorders of the CNS or hypothalamic factors.
7. Dysfunctional uterine bleeding (DUB) is heavy or irregular bleeding caused by a disturbance of the menstrual cycle.
8. Polycystic ovary syndrome (PCOS) is a difficult syndrome to diagnose because several factors are involved. It is a syndrome in which at least two of the following are present: oligo-ovulation or anovulation, elevated levels of androgens, or clinical signs of hyperandrogenism and polycystic ovaries. Prolonged anovulation leads to infertility, menstrual bleeding disorders, hirsutism, acne, endometrial hyperplasia, cardiovascular disease, and diabetes mellitus in women with hyperinsulinemia.
9. PMS is the cyclic recurrence of physical, psychologic, or behavioral changes distressing enough to disrupt normal activities or interpersonal relationships. More than 200 emotional, physical, and behavioral symptoms have been attributed to PMS. Emotional symptoms, particularly depression, anger, irritability, and fatigue, are reported as the most distressing; physical symptoms tend to be less problematic. Treatment is symptomatic and includes self-help techniques, lifestyle changes, counseling, and selective serotonin reuptake inhibitors (SSRIs).
10. Infection and inflammation of the female genitalia can result from microorganisms from the environment or overproliferation of microorganisms that normally populate the genital tract.
11. Pelvic inflammatory disease (PID) is an acute ascending polymicrobial infection of the upper genital tract and is sexually transmitted.
12. Vaginitis, or vaginal infection, is usually caused by sexually transmitted pathogens or *C. albicans*, which causes candidiasis. Development is related to the overall health of a woman and local defense mechanisms, particularly vaginal pH. Variables such as antibiotics, douching, soaps, feminine hygiene sprays, and pregnancy alter vaginal pH or the bactericidal nature of secretions and predispose a woman to infection.
13. Cervicitis, which is inflammation of the cervix, can be acute (mucopurulent cervicitis) or chronic.
14. Vulvovestibulitis is an inflammation of the skin of the vulva. It can be caused by chemical and mechanical irritants, allergens, skin disorders, nerve problems, or vaginal infections, such as candidiasis.
15. Bartholinitis, also called Bartholin cyst, is an inflammation of the ducts that lead from the *Bartholin glands* to the surface of the vulva. Inflammation blocks the glands, preventing the outflow of glandular secretions, and is caused by trauma or infection.
16. Pelvic organ prolapse—uterine prolapse, cystocele, rectocele, and urethrocele—is caused by loss of support provided by the pelvic muscles and fascia. Age and pelvic trauma are associated. Women with a familial or genetic predisposition have a higher risk.
17. Benign growths and proliferative conditions of the female reproductive tract tend to affect the ovaries (benign ovarian cysts) or uterine tissues (endometrial polyps, leiomyomas, and endometriosis).
18. Benign ovarian cysts develop from mature ovarian follicles that do not release their ova (follicular cysts) or from a corpus luteum that persists abnormally instead of degenerating (corpus luteum cyst). Cysts usually regress spontaneously.
19. Endometrial polyps are overgrowths of endometrial tissue and often cause abnormal bleeding.
20. Leiomyomas, also called *uterine fibroids,* are tumors arising from the muscle layer of the uterus, the myometrium. Incidence increases in women between ages 30 and 50; most myomas remain small and asymptomatic. Adenomyosis is the presence of endometrial glands and stroma within the uterine myometrium.
21. Endometriosis is the presence of functional endometrial tissue (i.e., tissue that responds to hormonal stimulation) at sites outside the uterus. Endometriosis causes an inflammatory reaction at the site of implantation and is a cause of infertility.
22. Most cancers of the female genitalia involve the uterus (particularly the cervix) and the ovaries. Cancer of the vagina is rare.
23. Infection with high-risk HPV, a sexually transmitted infection, is a necessary precursor to developing CIN and cervical cancer. Smoking, immunosuppression, and poor nutrition are cofactors. HPV vaccination can substantially reduce the risk of cervical cancer.
24. Cervical cancer arises from the cervical epithelium. The progressively serious neoplastic alterations are: (1) cervical intraepithelial neoplasia (cervical dysplasia), (2) cervical carcinoma in situ, and (3) invasive cervical carcinoma.
25. Risk factors for vaginal cancer are in utero diethylstilbestrol (DES) exposure and prior or concurrent cervical cancer.

SUMMARY REVIEW—cont'd

Like cervical cancers, vaginal cancers arise from the epithelium and are identified as intraepithelial neoplasia (dysplasia), carcinoma in situ, or invasive carcinoma. Most are secondary in nature.

26. The major risk for vulvar cancer is a history of HPV infection or squamous dysplasia of the vagina or cervix. Symptoms include chronic vulvar irritation, pruritus, bloody discharge, and a hard, ulcerated area of the vulva or large cauliflower-like lesions. Peak incidence is in postmenopausal women, but younger women can be affected.
27. Endometrial cancer is the most common cancer of the pelvic region. Risk factors for endometrial cancer include unopposed estrogen exposure, obesity, infertility, failure to ovulate, early menarche or late menopause, and tamoxifen. Oral contraceptive use protects against endometrial and ovarian cancers. Peak incidence occurs at 58 to 60 years of age, approximately 10 years later than peak incidence of precursor lesions.
28. Risk factors for ovarian cancer include an increased number of total lifetime ovulations including early menarche, late menopause, nulliparity, use of fertility drugs. *BRCA1, BRCA2,* and HNPCC gene abnormalities also are linked with ovarian cancer. Ovarian cancer causes more deaths than any other genital cancer in women.
29. Awareness of sexual dysfunction is relatively new. Chronic illness, medications, infection, sexual trauma, and a variety of psychosocial concerns have been implicated as causes.
30. Infertility, or the inability to conceive after 1 year of unprotected intercourse, affects approximately 15% of all couples. Women's fertility decreases with age, and older women may opt for intervention sooner than younger women. Fertility can be impaired by factors in the male, female, or both partners. Treatment depends on the cause of the infertility; ovulation disorders and tubal blockages are the most common pathologies.

Disorders of the Female Breast

1. Most disorders of the breast are disorders of the mammary gland, that is, the female breast.
2. Galactorrhea, or inappropriate lactation, is the persistent secretion of a milky substance by one or both breasts in nonpregnant, nonlactating women. It can occur in men. Its most common cause is nonpuerperal hyperprolactinemia, a rise in serum prolactin levels that is not associated with pregnancy and childbirth. Hyperprolactinemia can be caused by medications, pituitary tumors, hypothyroidism, chronic stress, or persistent and repeated suckling.
3. Numerous benign conditions occur in ducts and lobules in the breast. Benign breast disease is a spectrum of noncancerous changes in the breast. Benign lesions are broadly classified as (1) nonproliferating breast lesions, (2) proliferative breast disease, and (3) atypical (atypia) hyperplasia.
4. The term *nonproliferative lesions* is used to discriminate such lesions from the "proliferative" changes associated with increased risk of breast cancer.
5. Fibrocystic changes or physiologic nodularity and cysts are not clinically definitive because they include a heterogeneous group of disorders and refer to nonproliferative lesions. Symptoms affect women ages 30 to 50 and include cyclic bilateral breast tenderness and transient breast lumps.
6. Proliferative breast lesions without atypia are characterized by proliferation of ductal epithelium and/or stroma. Criteria for the diagnosis of intraductal proliferative lesions have been the subject of much research and controversy and include the following structurally diverse lesions: (1) usual ductal hyperplasia, (2) intraductal papillomas, (3) sclerosing adenosis, and (4) simple fibroadenoma.
7. Proliferative breast lesions with atypia include ADH and ALH. ADH is an increased number of cells mostly within the lumen of the terminal ducts. It includes a continuum of changes—cell structure and placement—ranging from an increase in cellularity to features of DCIS. The cells in ALH do not distend more than 50% of the acini within a lobule.
8. Breast cancer is the most common form of cancer in American women and second only to lung cancer as the most frequent cause of cancer death. Most breast cancer occurs in women older than 50 years. The major risk factors for breast cancer are classified as reproductive, such as nulliparity; familial, such as inherited gene syndromes; and environmental and lifestyle, such as hormonal factors and radiation exposure. Important factors not easily classified are involution of the mammary gland and breast density.
9. Most breast cancers arise from the ductal epithelium and then may metastasize to the lymphatics, opposite breast, abdominal cavity, lungs, bones, kidneys, liver, adrenal glands, ovaries, and pituitary glands.
10. Breast cancer is a heterogeneous disease with diverse molecular, biologic, phenotypic, and pathologic changes. Breast cancer also is heterogeneous *within* the same tumor. With mounting evidence it appears there are "subtypes within subtypes" and that the biology of specific breast cancer subtypes reflect contributions from the tissue microenvironment.
11. Several models of pathogenesis exist for breast cancer. Evidence suggests multiple genetic and epigenetic pathways of complex crosstalking networks that progress toward malignancy. Components of the microenvironment, including myoepithelial and endothelial cells, macrophages, and many ECM molecules, play a critical role in normal duct morphogenesis and increasingly recognized as major regulators of carcinogenesis.
12. DCIS refers to a complex heterogeneous group of lesions limited to ducts and lobules without invasion to the basement membrane. Preinvasive lesions do not invariably progress to invasive malignancy. LCIS originates from the duct-lobular unit, and the biology of LCIS is limited.
13. Dominating the cancer field is the idea that epithelial function depends on the *entire* tissue including the stroma or microenvironment. Breast cancer and other types of cancer are getting known as tissue-based diseases with a possible

SUMMARY REVIEW—cont'd

abnormal aberrant wound healing and inflammatory stromal (reactive stroma) component. Early alterations in the stroma that occur with wound healing and inflammation include activation of (1) mesenchymal cells (embryonic) fibroblasts; (2) endothelial cells; and (3) immune cells, including macrophages

14. Epithelial-mesenchymal transition (EMT) is the distinctive phenotype created from the change in tumor tissue architecture (remodeled tissue).
15. The exact molecular events leading to invasion are complex and not completely understood. Because myoepithelial cells form a semi-continuous protective sheet separating the human breast epithelium and the surrounding stroma, it has been a major focus of understanding invasive carcinogenesis. The critical difference in clinical prognosis between in situ and invasive or metastatic cancer results importantly and predominantly from the presence or absence of the surrounding basement membrane (BM).
16. The first clinical manifestation of breast cancer is usually a small, painless lump in the breast. Other manifestations include palpable lymph nodes in the axilla, dimpling of the skin, nipple and skin retraction, nipple discharge, ulcerations, reddened skin, and bone pain associated with bony metastases.
17. Treatment is based on the extent or stage of the cancer and includes surgery, radiation, chemotherapy, hormone therapy, and biologic therapy.

CHAPTER OUTLINE

Alterations of the reproductive system span a wide range of concerns, from delayed sexual development and suboptimal sexual performance to structural and functional abnormalities. Many common male reproductive disorders carry potentially serious physiologic or psychologic consequences. Sexual or reproductive dysfunction, such as impotence or infertility, can dramatically affect self-concept, relationships, and overall quality of life. Conversely, organic and psychosocial problems, such as alcoholism, depression, situational stressors, chronic illness, and medications, can affect sexual performance and fertility and may be risk factors for the development of some types of reproductive tract cancers. Prostate cancer is the second leading cause of cancer death in men and is the most frequently diagnosed cancer in men aside from skin cancer. Incidence rates for prostate cancer changed substantially between the mid-1980s and mid-1990s and have since fluctuated widely from year to year, in large part reflecting changes in prostate cancer screening with the prostate specific antigen (PSA) blood test. Since 2004, incidence rates have act actually decreased by 2.7% per year among men 65 years of age and older and have remained stable among men younger than 65 years.[1] Diagnosis and treatment of male reproductive system disorders are, like female reproductive system disorders, complicated because of the stigma and symbolism associated with the reproductive organs and the emotion-laden beliefs and behaviors related to reproductive health. Treatment and diagnosis for related problems may be delayed because of embarrassment, guilt, fear, or denial.

ALTERATIONS OF SEXUAL MATURATION

The process of sexual maturation, or puberty, is marked by the development of secondary sexual characteristics, rapid growth, and, ultimately, the ability to reproduce. A variety of congenital and endocrine disorders can disrupt the timing of puberty, or sexual maturation. These disorders may cause puberty to occur too late (delayed puberty) or too early (precocious puberty). Both types involve a disrupted onset of sex hormone production by the gonads, although there is little change in the age of puberty for boys.

Delayed Puberty

About 3% of children in North America experience delayed development of secondary sex characteristics.[2] Normally, boys tend to mature later than girls, around 14 to 14.5 years of age. In boys the first sign is enlargement of the testes and thinning of the scrotal skin. Puberty is considered delayed if there are no clinical signs of puberty by age 14 in boys (2 standard deviations [SDs] above the mean age of pubertal onset). Boys especially tend to be embarrassed by sexual immaturity;[3] therefore, early diagnosis and treatment are recommended, as well as reassurance for boys as well as girls.

In 95% of cases delayed puberty is a physiologic delay, that is, hormonal levels are normal and the hypothalamic-pituitary-gonadal (HPG) axis is intact, but maturation is happening slowly.[4] This constitutional delay tends to be familial and is much more common in boys than in girls. Physiologic delay is difficult to distinguish from isolated gonadotropin deficiency and is usually diagnosed retrospectively once pubertal progression is complete.

Delayed puberty also may be related to consequences of any chronic condition that delays bone aging (i.e., lung disease, renal failure, cystic fibrosis) (Box 25-1).[2] Many clinicians recommend intervention (i.e., exogenous sex steroid administration) in physiologic cases of delayed puberty to reduce the psychologic effects (e.g., self-esteem issues, embarrassment) often associated with delayed puberty.[4]

The other 5% of cases are caused by a disruption of the HPG axis of various etiologies (see Box 25-1).[5] Human gonadal function is partially controlled by luteinizing hormone (LH) and follicle-stimulating hormone (FSH), the release of which is regulated by the pulsatile secretion of hypothalamic gonadotropin-releasing hormone (GnRH).[4,5] Most recently, the G-protein–coupled receptor 54 (GPR54) has been identified as the gatekeeper gene for activation of the GnRH axis based on loss of function studies in mice and humans. GPR54 is required for the normal function of this axis, and data suggest that the ligand kisspeptin-1 may act as a neurohormonal regulator of the GnRH axis.[6] The mechanisms of childhood inhibition of GnRH release and activation are poorly understood but appear to involve feedback inhibition by sex steroids and presumably other central nervous system (CNS) pathways.[7] Given the myriad etiologies contributing to the occurrence of delayed puberty, a thorough evaluation should be conducted that includes physical examination and medical and family history. Such evaluation should specifically target known contributors to delayed puberty.[4] Laboratory workup generally consists of x-ray studies for bone age, measurement of thyroid function, serum levels of prolactin and adrenal and gonadal steroids, radioimmunoassay of plasma gonadotropins, and screening for systemic disorders. Adolescents with high gonadotropin levels require a karyotype, to rule out genetic causes, and those with low levels need skull imaging (lateral skull film, computed tomography [CT], or magnetic resonance imaging [MRI]) to rule out pituitary or other CNS infiltrate or tumor.[2] Although several genes involved in the HPG maturation cascade have been characterized from familial or sporadic cases of primitive isolated hypogonadotropic hypogonadism, many genes regulating puberty onset remain undetermined. Treatment of delayed puberty depends on the cause; the goal of treatment is the development of secondary sex characteristics and fertility, when possible. Insufficient sex hormone secretion can be corrected by hormone replacement therapy, such as testosterone for boys.[8] Idiopathic hypogonadotropic hypogonadism is treated with synthetic GnRH or sex hormone administration, or both, and may be lifelong.[2,4,8]

BOX 25-1 CAUSES OF DELAYED OR ABSENT PUBERTY

Chronic or Systemic Conditions

- Chronic renal disease
- Cystic fibrosis
- Diabetes mellitus
- Excessive exercise
- Hematologic diseases
- Hypothyroidism
- Irritable bowel diseases
- Poor nutrition (eating disorders, GI diseases, poverty)
- Gonadal dysgenesis
  - Turner syndrome (genetic karyotype 45, XO)
- Bilateral gonadal failure
  - Autoimmune
  - Congenital anorchia
  - Postsurgical, postirradiation, postchemotherapy
  - Traumatic or infectious

Hypogonadotropic Hypogonadism (Deficient FSH/LH)

- Central nervous system defects (GnRH deficiency)
  - Craniopharyngioma
  - GPR54 mutations
  - Hemochromatosis
  - Hypopituitarism
  - Kallmann syndrome, Bardet-Biedl syndrome, Prader-Willi syndrome
  - Marijuana use
  - Pituitary adenoma/tumor
  - Prolactinomas

Disordered Puberty

Data from Burchett MLR, Hanna CE, Steiner RD: Endocrine and metabolic diseases. In Burns CE, Brady MA, Dunn AM, editors: *Pediatric primary care*, ed 4, St Louis 2009, Saunders; Jospe N: Disorders of pubertal development. In Osborn LM et al, editors: *Pediatrics*, Philadelphia, 2005, Mosby; Karagiannis A, Harsoulis F: *Eur J Endocrinol* 152(4):501–513, 2005.
FSH, Follicle-stimulating hormone; *GI,* gastrointestinal; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone.

Precocious Puberty

Precocious puberty is a rare event in boys, affecting less than 1 in 50,000. Precocious puberty in boys has been redefined as sexual maturation before age 9.[9] One study has noted observed mean ages of beginning male genital and pubic hair growth and early testicular volumes tending toward younger ages than earlier studies have suggested, although this seems to be dependent on race and ethnicity.[10] For instance, black boys are showing significantly earlier mean ages for stages 2 to 4 genital

BOX 25-2 PRIMARY FORMS OF PRECOCIOUS PUBERTY

Complete Precocious Puberty

Premature development of appropriate characteristics for the child's sex
Hypothalamic-pituitary-ovarian axis working normally but prematurely
In about 10% of cases, lethal central nervous system tumor may be the cause

Partial Precocious Puberty

Partial development of appropriate secondary sex characteristics
Premature thelarche (breast budding) seen in girls between 6 months and 2 years of age
Does not progress to complete puberty (ovulation and menstruation)
Premature adrenarche (growth of axillary and pubic hair) tends to occur between 5 and 8 years of age
Can progress to complete precocious puberty; may be caused by estrogen-secreting neoplasms or may be a variant of normal pubertal development

Mixed Precocious Puberty

Causes the child to develop some secondary sex characteristics of the opposite sex
Common causes: adrenal hyperplasia or androgen-secreting tumors

Data from Burchett MLR et al: Endocrine and metabolic diseases. In Burns CE et al, editors: *Pediatric primary care*, St Louis, 2009, Saunders; Jospe N: Disorders of pubertal development. In Osborn LM et al, editors: *Pediatrics,* Philadelphia, 2005, Mosby.

BOX 25-3 CAUSES OF PRECOCIOUS PUBERTY

Central (Gonadotropin-Releasing Hormone [GnRH] Dependent)

Idiopathic
Central nervous system (CNS) disorders
- Congenital anomalies (hydrocephalus)
- Hypothalamic hamartoma
- Postinflammatory/infectious condition
- Trauma
- Tumors (hypothalamic, pineal, other)

Hypothyroidism (severe)

Peripheral Puberty (GnRH Independent)

Adrenal hyperplasia or tumor
Environmental endocrine disruptors
Exogenous sex steroid exposure
Exogenous anabolic steroids
Familial Leydig cell hyperplasia
Gonadal tumors or cysts
Human chorionic gonadotropin (hCG)–secreting tumors (hepatoblastomas, intracranial lesions)
McCune-Albright syndrome
Testotoxicosis

From Bhagavath B, Layman LC: *Semin Reprod Med* 25(4):272–286, 2007; Burchett MLR et al: Endocrine and metabolic diseases. In Burns CE et al, editors: *Pediatric primary care*, St Louis, 2009, Saunders; Caserta DL et al: *Hum Reprod Update* 14(1):59–72, 2008; Cesario SK, Hughes LA: *J Obstet Gynecol Neonatal Nurs* 36(3):263–274, 2007; Jospe N: Disorders of pubertal development. In Osborn LM et al, editors: *Pediatrics,* Philadelphia, 2005, Mosby.

development and stages 2 to 4 pubic hair than white and Hispanic boys. All cases of precocious puberty require thorough evaluation.

Precocious puberty may be partial, complete, or mixed (heterosexual) types (Box 25-2) and can be further categorized into central (GnRH-dependent) and peripheral (GnRH-independent) (Box 25-3). **Central precocious puberty** is GnRH-dependent and occurs when the HPG axis is working normally but prematurely. Besides the premature development of secondary sex characteristics, precocity causes premature closure of the epiphysis of long bones, which results in shorter stature. Central precocious puberty results from failure of central inhibition of the GnRH pulse generator (the gonadostat). The diagnosis of central precocious puberty is one of exclusion. Because a CNS lesion may be missed, children with presumed central precocious puberty require long-term surveillance. Peripheral puberty is GnRH-independent and develops when sex hormones are produced by some mechanism other than stimulation by the gonadotropins. Sex steroid–producing tumors (i.e., gonadal tumors), testotoxicosis, and exposure to exogenous sex steroids (i.e., hormonal contraceptives and environmental endocrine disruptors) are some of the causes (see Box 25-3).

Complete precocious puberty refers to the onset and progression of all pubertal features. **Partial precocious puberty** is the partial development of appropriate secondary sex characteristics alone or in combination. Premature pubarche tends to occur between ages 5 and 8 years. Premature pubarche is usually the consequence of an early increase in the adrenal androgens that leads to early growth of pubic hair and possibly a transient acceleration in growth and bone maturation that has no significant effect on timing of puberty or final height.

The diagnosis and cause of premature development are often obvious. A thorough history and physical examination are done to determine the velocity of the process and to rule out life-threatening CNS or adrenal neoplasms. Family occurrence helps exclude tumors. Children with precocious puberty also have a tendency toward obesity.[7,11]

Treatment for all forms of precocious puberty includes identifying and removing the underlying cause (see Boxes 25-2 and 25-3) or administering appropriate hormones. In many cases precocious puberty can be reversed. Management goals include diagnosing and treating intracranial disease; arresting maturation until early teen years; maximizing eventual adult height; reducing emotional problems; and providing contraception, if necessary. The most common form, central precocious puberty, is usually treated with potent GnRH agonist analogs, which induce reversible, selective suppression of the HPG axis. Treatment does not seem to affect body composition or increase obesity in children with central precocious puberty. Because many of these children are obese and childhood obesity is predictive of morbidity in adolescence and adulthood, it is important for clinicians to include assessment and management of obesity as part of the treatment for central precocious puberty.

Mixed precocious puberty (e.g., feminization of a boy) causes the child to develop some secondary sex characteristics of the opposite sex. This condition is usually evident at birth and is rare in older children (Box 25-4).

BOX 25-4 CAUSES OF MIXED PRECOCIOUS PUBERTY

Female (Virilization)

Congenital adrenal hyperplasia
Androgen-secreting tumors
- Adrenal
- Ovarian
- Teratoma
- Exogenous androgens

Male (Feminization)

Estrogen-producing tumors
- Adrenal
- Teratoma
- Hepatoma
- Testicular

Exogenous estrogens
Increased peripheral conversion of androgens to estrogens

From Jospe N: Disorders of pubertal development. In Osborn LM et al, editors: *Pediatrics,* Philadelphia, 2005, Mosby.

DISORDERS OF THE MALE REPRODUCTIVE SYSTEM

Disorders of the Urethra

Urethritis and urethral strictures are common disorders of the male urethra. Urethral carcinoma occurs in men older than 60 years, but it is an extremely rare form of cancer.

Urethritis

Urethritis is an inflammatory process of the urethra without concurrent bladder infection that is usually, but not always, caused by a sexually transmitted microorganism. Biologic agents associated with infectious urethritis in males include *Neisseria gonorrhoeae* and *Chlamydia trachomatis, Ueaplasma urealyticum,* and other, less common, mycobacteria; parasites (e.g., *Trichomonas vaginalis*); and viruses (herpes simplex virus [HSV]).[12,13] Infectious urethritis caused by *N. gonorrhoeae* often is called *gonococcal urethritis (GU);* infection caused by other microorganisms is called *nongonococcal urethritis (NGU).*[14] (Sexually transmitted urethritis is described in Chapter 26.) Nonsexual origins of urethritis include inflammation or infection as a result of urologic procedures, insertion of foreign bodies into the urethra, anatomic abnormalities, or trauma.

Noninfectious urethritis is rare and is associated with the ingestion of wood alcohol, ethyl alcohol, or turpentine. It is seen also with Reiter syndrome, which involves a number of mucocutaneous lesions.

Symptoms of urethritis include urethral tingling, itching, or burning sensation on urination (dysuria), frequency, and urgency. The individual may note a purulent or clear mucus-like discharge from the urethra. Nucleic acid detection amplification tests allow easy detection of *N. gonorrhoeae* and *C. trachomatis* in first-void urine.[14] Treatment consists of appropriate antibiotic therapy for infectious urethritis and avoidance of future chemical or mechanical irritation.

Urethral Stricture

A **urethral stricture** is a fibrotic narrowing of the urethra caused by scarring. The scars may be congenital but are more likely to result from trauma or untreated or severe urethral infections, most often from long-term use of indwelling urinary catheters. It can present at any age and has a wide range of etiologic factors, including infection, trauma, and instrumentation. Large catheters and instruments cause internal trauma and ischemia, whereas external trauma, such as pelvic fracture, can partially or completely sever the urethra and cause severe and complex strictures.[15] In addition, a report has concluded that stricture may occur decades after initial hypospadias surgery.[16] Urethral carcinoma is a less common cause of urethral stricture. Prostatitis and infection secondary to urinary stasis are common complications. Severe and prolonged obstruction can result in hydronephrosis and renal failure. In addition, chronic, severe strictures may lead to urethral fistulas and periurethral abscesses.[15,17]

The clinical manifestations of urethral stricture are caused by bladder outlet obstruction. The primary symptom is diminished force and caliber of the urinary stream; other symptoms include urinary frequency and hesitancy, mild dysuria, double urine stream or spraying, and postvoiding dribbling. Symptoms of acute urinary retention may occur in the presence of infection or urinary obstruction. Induration at the stricture site may be palpable. Tender, enlarged masses along the urethra usually indicate periurethral abscesses. Urethral stricture often manifests itself as lower urinary tract symptoms or urinary tract infections with significant impairment in the quality of life.

Urethral stricture is diagnosed on the basis of history, physical examination, urinary flow rates, voiding cystourethrogram, and urethroscopy; biopsy confirms carcinoma. Treatment is usually surgical and may involve urethral dilation, urethrotomy, or a variety of open surgical techniques. The choice of surgical intervention depends on the age of the individual and the severity of the problem. Strictures may recur up to 1 year after treatment. Follow-up is necessary during this time; urinary flow measurements and urethrogram help determine extent of residual obstruction.

Disorders of the Penis

Phimosis and Paraphimosis

Phimosis and paraphimosis are disorders in which the foreskin (prepuce) is "too tight" to be moved easily over the glans penis. **Phimosis** is a condition in which the foreskin cannot be retracted back over the glans, whereas **paraphimosis** is the opposite: the foreskin is retracted and cannot be moved forward (reduced) to cover the glans (Figure 25-1). Both conditions can cause penile pathologic conditions.

The inability to retract the foreskin is normal in infancy and is caused by congenital adhesions. During the first 3 years of life these adhesions separate naturally with penile erections and are not an indication for circumcision. Although most cases occur in uncircumcised males, stenosis and resultant phimosis can occur in males with excessive skin remaining after circumcision.[17] Phimosis can occur at any age and is caused most commonly by poor hygiene and chronic infection. Chronic

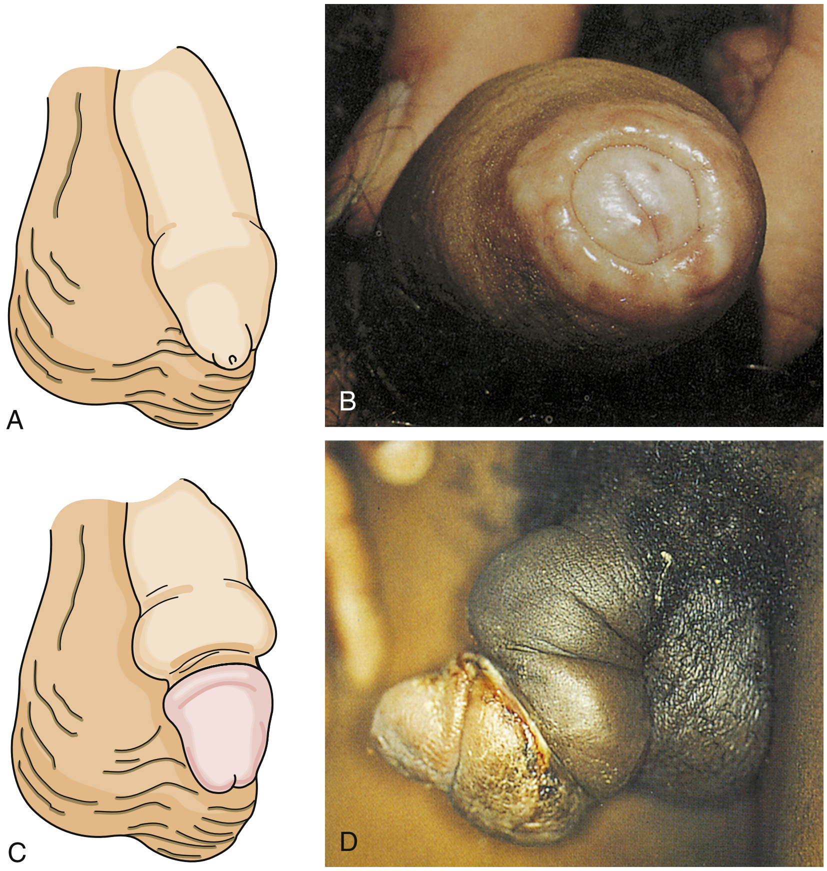

FIGURE 25-1 **Phimosis and Paraphimosis. A,** Phimosis: the foreskin has a narrow opening that is not large enough to permit retraction over the glans. **B,** Lesions on the prepuce secondary to infection cause swelling, and retraction of foreskin may be impossible. **C,** Paraphimosis: the foreskin is retracted over the glans but cannot be reduced to its normal position. Here it has formed a constricting band around the penis. **D,** Ulcer on the retracted prepuce with edema. (**A, C** from Monahan FD, et al: *Phipps' medical-surgical nursing,* ed 8, St Louis, 2007, Mosby; **B** from Taylor PK: *Diagnostic picture tests in sexually transmitted diseases,* London, 1995, Mosby-Wolfe; **D** from Morse SA, Holmes KK, Ballard RC: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2011, Saunders.)

balanoposthitis (inflammation of the glans and prepuce) predisposes older diabetic men to phimosis. It rarely occurs with normal foreskin.

Edema, erythema, and tenderness of the prepuce and purulent discharge are usually the reasons for seeking treatment; inability to retract the foreskin is a less common complaint. Circumcision, if needed, is performed after infection has been eradicated. Complications of phimosis include inflammation of the glans (balanitis) or prepuce (posthitis) and paraphimosis. There is a higher incidence of penile carcinoma in uncircumcised males, which is associated with morbidity and mortality, but chronic infection, most likely with HPV, is usually the underlying factor in such cases. Approximately 40% of invasive penile carcinomas are attributable to HPV.[17,18]

Paraphimosis, in which the foreskin is retracted, can constrict the penis, causing edema of the glans. If edema is such that the foreskin cannot be reduced manually, surgery must be performed to prevent necrosis of the glans caused by constricted blood vessels. Severe paraphimosis is a surgical emergency and phimosis may require immediate release if there is urinary obstruction.

Peyronie Disease

Peyronie disease (bent nail syndrome) is a fibrotic condition of the tunica albuginea of the penis resulting in varying degrees of curvature and sexual dysfunction[19] (Figure 25-2). Peyronie disease develops slowly and is characterized by tough, fibrous thickening of the fascia in the erectile tissue of the corpora cavernosa. A dense fibrous plaque is usually palpable on the dorsum of the penile shaft. The problem usually affects middle-age men and is associated with painful erection, painful intercourse (for both partners), and poor erection distal to the involved area. In some cases, impotence or unsatisfactory penetration occurs. There is no pain when the penis is flaccid.

Although the exact cause is unknown, a local vasculitis-like inflammatory reaction occurs and decreased tissue oxygenation results in fibrosis and calcification. Peyronie disease is associated with Dupuytren contracture (a flexion deformity of the fingers or toes caused by shortening or fibrosis of the palmar or plantar fascia), diabetes, tendency to develop keloids, and in rare cases, use of beta-blocker medications.

There is no definitive treatment for Peyronie disease. Spontaneous remissions occur in as many as 50% of cases. Treatment

FIGURE 25-2 Peyronie Disease. (From Taylor PK: *Diagnostic picture tests in sexually transmitted diseases,* London, 1995, Mosby-Wolfe.)

FIGURE 25-3 Priapism. (From Lloyd-Davies RW, Gow JG, Davies DR: *Color atlas of urology,* ed 2, London, 1994, Mosby-Wolfe.)

with pharmacologic therapies include colchicine, aminobenzoate potassium (Potaba), L-carnitine, and liposomal superoxide dismutase. Men suffering with Peyronie disease who have significant penile deformity precluding successful coitus can be appraised for surgical correction. Surgery is considered the gold standard and includes plication, incision and grafting, or penile-prosthesis-related procedures.[17,19]

Priapism

Priapism is an uncommon condition of prolonged penile erection. It is usually painful and is not associated with sexual arousal (Figure 25-3). Priapism is idiopathic in 60% of cases; the remaining 40% of cases are associated with spinal cord trauma, sickle cell disease, leukemia, pelvic tumors or infections, or penile trauma. Priapism also has been associated with cocaine use.[20,21] Intracavernous injection therapy for impotence seems to be the most common cause. Prolonged sexual stimulation often is associated with initial development of the idiopathic type.[17] The two corpora cavernosa within the erect penis are filled with blood and are tender to palpation; neither the corpus spongiosum nor the glans is engorged. The vascular congestion is thought to be associated with venous obstruction. If the erection remains over a period of days, edema and fibrosis develop, leading to erectile dysfunction (impotence).

Priapism is a urologic emergency. Treatment within hours is effective and prevents impotence. Conservative approaches include iced saline enemas, ketamine administration, and spinal anesthesia. Needle aspiration of blood from the corpus through the dorsal glans is often effective and is followed by catheterization and pressure dressings to maintain decompression. More aggressive surgical treatments include the creation of vascular shunts to maintain blood flow. Erectile dysfunction results in up to 50% of prolonged cases.

Balanitis

Balanitis is an inflammation of the glans penis (Figure 25-4) and usually occurs in conjunction with posthitis, an inflammation of the prepuce. It is associated with poor hygiene and

FIGURE 25-4 Balanitis. Itchy, red rash on glans of penis secondary to *Candida albicans.* (From Taylor PK: *Diagnostic picture tests in sexually transmitted diseases,* London, 1995, Mosby-Wolfe.)

phimosis. The accumulation under the foreskin of glandular secretions (smegma), sloughed epithelial cells, and *Mycobacterium smegmatis* can irritate the glans directly or lead to infection. Skin disorders (e.g., psoriasis, lichen planus, eczema) and candidiasis must be differentiated from inflammation resulting from poor hygienic practices. Balanitis is seen most commonly in men with poorly controlled diabetes mellitus and candidiasis. Antimicrobials are used to treat infection. Circumcision can prevent recurrences and can be considered after the inflammation has subsided.

Penile Cancer

In the United States, carcinoma of the penis is rare and affects about 1 in 100,000 men. Approximately 1570 cases and 310 deaths were estimated in the year 2012.[1] Although rare in North America and Europe, where it accounts for about 0.2% of cancers and 0.1% of cancer deaths in men, penile cancer may account for up to 10% of cancers in African and South American men.

In the United States, about four out of five cases of the disease are diagnosed in men older than age 55 years.[22] Major risk factors include infection with HPV (mainly serotypes 16 and

FIGURE 25-5 Squamous Cell Carcinoma Involving the Glans Penis. (From Callen JP et al: *Color atlas of dermatology,* Philadelphia, 1993, Saunders.)

18), smoking, and psoriasis treated with a combination involving the drug psoralen and ultraviolet (UV) light. Men circumcised at birth have less than half the chance of getting penile cancer than those who were not. Penile cancer is more common in men with phimosis and those with acquired immunodeficiency syndrome (AIDS).[22] About two thirds of men with penile cancer are diagnosed at more than 65 years of age.[1]

Before the development of penile cancer, signs of premalignant cancer or epidermal cancer in situ are present.[23] These include thick white plaque (leukoplakia) that typically involves the meatus; red, inflamed areas of Paget disease; red, velvety, ulcerative lesions of erythroplasia of Queyrat that usually involve the glans; large, invasive, scaly growths of Buschke-Löwenstein tumor; red plaque with encrustations of Bowen disease; and in situ carcinoma that generally affects the penile shaft. Men with leukoplakia or erythroplasia of Queyrat may have concurrent invasive penile carcinoma.[22,24] Pain and bleeding are late signs of penile cancer. Condylomata (genital warts) caused by HPV may be involved in the development of precancerous lesions (see Chapter 26 for a discussion of HPV). At times the penis might be the site of metastatic spread of solid tumors from the bladder, prostate, rectum, or kidney. Early squamous cell carcinoma and premalignant epidermal lesions are easily treated but are often ignored. Delays in seeking treatment are attributed to denial, embarrassment, failure to detect lesions under a phimotic foreskin, fear, guilt, and ignorance.

Penile cancer is mostly squamous cell carcinoma, which usually begins as a small, fat, ulcerative or papillary lesion on the glans or foreskin that grows to involve the entire penile shaft (Figure 25-5). Extensive lesions are associated with metastases and a poor prognosis.[23] These lesions are not as painful as the amount of tissue involvement would seem to indicate. The regional femoral and iliac nodes are common metastatic sites. Rarely the urethra and bladder are involved. Weight loss, fatigue, and malaise accompany chronic suppurative lesions. Untreated, progressive disease causes death within 2 years.

The specific diagnosis is made by biopsy after examination to document the location, size, and fixation of the lesion. After a positive biopsy the extent of cancer spread is determined by imaging tests such as ultrasound, CT, or MRI. Fine-needle aspiration of lymph tissue confirms absence or presence of regional adenopathy.[22] About 30% of penile cancers spread to lymph nodes before diagnosis. Distant metastases occur in less than 10% of cases and may involve lung, liver, bone, or brain.[24] The following stages are used for penile cancer: stage 0 (carcinoma in situ), stage I, stage II, stage III, and stage IV.[25]

Penile carcinoma is primarily managed with surgery. Newer, innovative surgical techniques can preserve as much penile tissue as possible without compromising cancer control. For invasive penile carcinoma, complete excision leaving adequate tumor-free margins is the goal. A simple circumcision may be sufficient for localized lesions of the prepuce. If the primary site is the glans and distal shaft, removal of the penis may be necessary. Although conventional radical surgery continues to be an effective approach, the emasculating nature of the treatment has serious psychologic and sexual consequences. Recent studies have challenged the conventional belief that a 2-cm margin was required for adequate cancer control.[23] Newer innovative surgical techniques can preserve as much penile tissue and functional integrity as possible without compromising cancer control. Inguinal lymph nodes also are removed if metastasis to these structures is known or suspected. Palliative treatment with radiation or chemotherapy may be used when the disease is inoperable and bulky inguinal metastases have occurred. Options for individuals with carcinoma in situ include local excision, radiation, laser surgery, cryosurgery, chemosurgery, or chemotherapy with topical (5%) 5-fluorouracil (5-FU). Differentiation, tumor stage, and age influence prognosis.[23,26] The 5-year survival rate for stage I disease is greater than 80%; average 5-year survival rate for all stages is 50%.[1,22]

Disorders of the Scrotum, Testis, and Epididymis

Disorders of the Scrotum

Men may seek treatment for painful or painless scrotal masses. Masses may be serious (cancer or torsion) or benign (hydrocele or cyst) and may require immediate surgical intervention or allow for careful observation.[27] Varicocele, hydrocele, and spermatocele are common intrascrotal disorders.[28-30] A **varicocele** is an abnormal dilation of a vein within the spermatic cord and is classically described as a "bag of worms" (Figure 25-6). Most (95%) occur on the left side and may be painful or tender. Varicocele occurs in 10% of males and is seen most often after puberty. Sudden development of a varicocele in an older man is a late sign of renal tumor.[31] Unilateral right-sided varicoceles are rare and result from compression or obstruction of the inferior vena cava by a tumor or thrombus. Color Doppler ultrasonography is used to confirm the diagnosis.[27]

The cause of varicocele is incompetent or congenitally absent valves in the spermatic veins. The valves that normally prevent backflow are absent or do not close adequately, permitting blood to pool in the veins rather than flow into the venous system. Varicocele decreases blood flow through the testis. This interferes with spermatogenesis and is a cause of infertility.[28,32] If infertility is a problem, treatment consists of ligation of the spermatic vein or occlusion of the vein by percutaneous methods, such as balloon catheter and sclerosing fluids.[32] If varicocele is mild and fertility is not an issue, a scrotal support

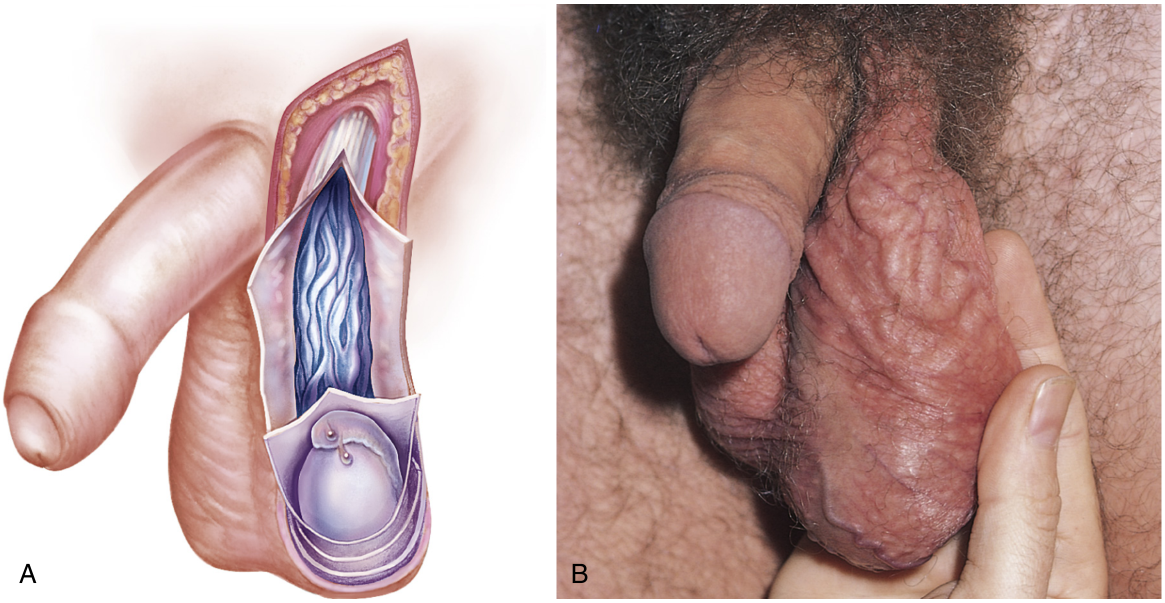

FIGURE 25-6 Varicocele. **A,** Dilation of veins within the spermatic cord. **B,** Varicocele on physical examination. (**A** from Seidel H et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby. **B** from Swartz MH: *Textbook of physical diagnosis,* ed 6, Philadelphia, 2010, Saunders.)

usually is sufficient to relieve symptoms of scrotal heaviness or "dragging."

A **hydrocele** is a collection of fluid within the tunica vaginalis[28,33] (Figure 25-7). It is the most common cause of scrotal swelling. Hydroceles occur in 6% of male newborns and are congenital malformations (patent processus vaginalis) that often resolve spontaneously in the first year of life. Surgical ligation is recommended if hydrocele persists after age 1 year.[30] Hydroceles in adults may be caused by an imbalance between the secreting and absorptive capacities of scrotal tissues. Hydroceles range in size from slightly larger than the testes to the size of a grapefruit or larger and may be flaccid or tense. Compression of testicular blood supply may lead to atrophy.

The exact mechanism of idiopathic hydrocele is unknown. Secondary hydrocele may result from trauma or infection of the testis or epididymis or from a testicular tumor. Rapid accumulation of fluid occurs after local injury, radiotherapy, or infection (epididymitis or orchitis), or it may accompany testicular neoplasm. Chronic hydroceles are more common and occur in men older than 40 because of an imbalance between fluid secretion and reabsorption in the tunica vaginalis. A painless, extratesticular mass that easily transilluminates is found on physical examination. Ultrasonography of a large hydrocele, which may conceal a testicular tumor, is recommended. Treatment is usually not required unless a large, bulky hydrocele causes considerable physical discomfort or undesirable cosmetic appearance.[28] Treatment for uncomplicated hydrocele is aspiration of the fluid and injection of a sclerosing agent into the scrotal sac.[33-35] The goal of treatment is to remove the hydrocele and prevent recurrence by sclerosing or excising the tunica vaginalis.

Spermatoceles (epididymal cysts) are benign cystic collections of fluid of the epididymis located between the head of the epididymis and the testis. Efferent ducts of the epididymis have potential for cystic dilation to form a spermatocele [33,35] (Figure 25-8). Spermatoceles are filled with milky fluid that contains sperm. Spermatocele is differentiated from a hydrocele in that aspiration of the hydrocele recovers a clear, yellow fluid, and unlike a hydrocele, a spermatocele does not cover the entire anterior surface of the testis.

Spermatoceles manifest as discrete, firm, freely mobile masses distinct from the testis that may be transilluminated. Epididymal cysts do not require treatment.[33] A spermatic cord tumor may feel like a tense spermatocele but does not contain fluid and will not transilluminate.[27] Spermatoceles that cause pain or discomfort are excised. Usually, however, spermatoceles are asymptomatic or produce mild discomfort that is relieved by scrotal support.[35] Neither hydroceles nor spermatoceles are associated with infertility.

Cryptorchidism and Ectopy

Cryptorchidism is a condition of testicular maldescent, whereas an **ectopic testis** has strayed from the normal pathway of descent. Ectopy may be caused by an abnormal connection at the distal end of the gubernaculum testis that leads the gonad to an abnormal position, usually at the superficial inguinal site. In cryptorchidism the descent of one or both testes is arrested, with unilateral arrest occurring more often than bilateral arrest.[35] The testes may remain in the abdomen, or testicular descent may be arrested in the inguinal canal or the puboscrotal junction. Cryptorchidism is a common congenital anomaly, with an incidence of approximately 3% in full-term infants. However, this rate increases significantly with low birth weight infants; for instance, the rate of cryptorchidism at 3 months has been found to be 7.7% for infants with birth weights less than 2000 g, 2.5% for birth weights of 2000 to 2500 g, and 1.41% for birth weights of 2500 g or more.[35,36] The incidence of cryptorchidism in adults is 0.7% to 0.8%.[32] Cryptorchidism is commonly associated with vasal or epididymal abnormalities. These

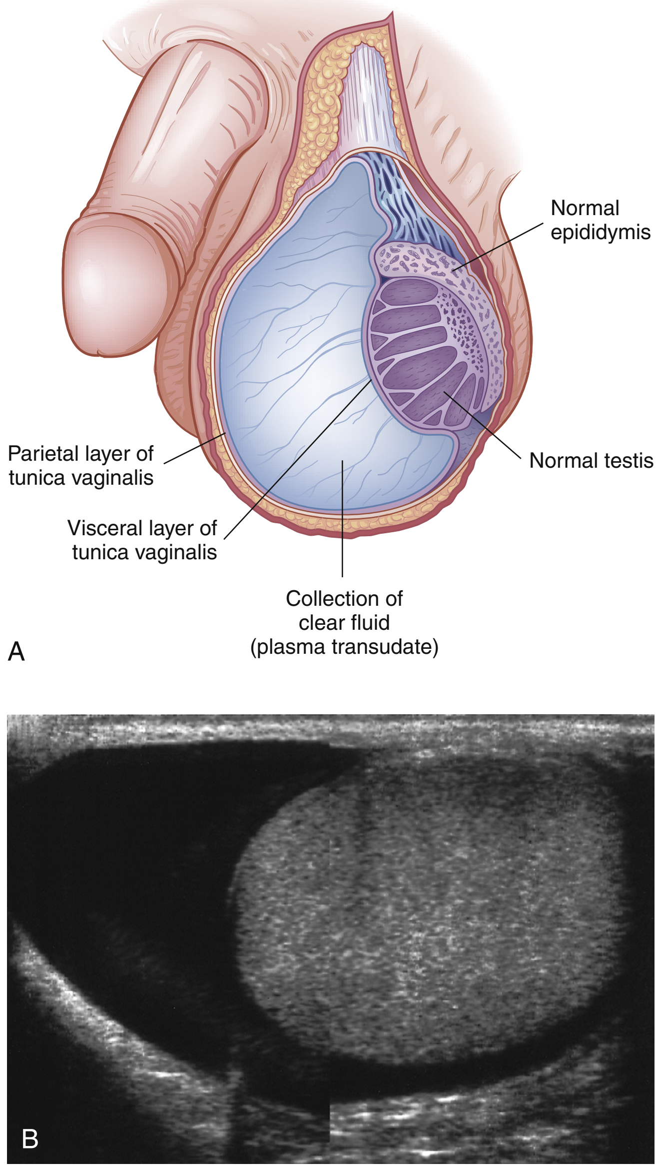

FIGURE 25-7 **Depiction of a Hydrocele. A,** Accumulation of clear fluid between the visceral (inner) and parietal (outer) layers of the tunica vaginalis. **B,** The appearance of a hydrocele on ultrasound examination. (**B** from Adam A, et al: *Grainger & Allison's diagnostic radiology,* ed 6, London, 2008, Churchill Livingstone.)

congenital anomalies affect about one third to two thirds of newborns with cryptorchidism. Other structural anomalies include posterior urethral valves (less than 5%), upper tract abnormalities (less than 5%), and hypospadias. The presence of hypospadias as well as cryptorchidism raises the suspicion of mixed gonadal dysgenesis (intersex infant). It has been hypothesized that cryptorchidism may result from an absence or abnormality of the gubernaculum, a cordlike structure that extends from the lower pole of the testis to the scrotum; a congenital gonadal or dysgenetic defect that makes the testes insensitive to gonadotropins (a likely explanation for unilateral cryptorchidism); or lack of maternal gonadotropins (a likely explanation for bilateral cryptorchidism of prematurity).[32] Mechanical possibilities include a short spermatic cord, fibrous bands or adhesions in

FIGURE 25-8 **Spermatocele.** Retention cyst of the head of the epididymis or of an aberrant tubule or tubules of the rete testis. The spermatocele lies outside the tunica vaginalis; therefore, on palpation it can be readily distinguished and separated from the testis. (From Lloyd-Davies RW, Gow JG, Davies DR: *Color atlas of urology,* ed 2, London, 1994, Mosby-Wolfe.)

the normal path of the testes, or a narrowed inguinal canal. Chromosomal studies do not support a genetic component. Physiologic cryptorchidism, also called *retractile* or *migratory testis,* is an involuntary retraction of the testes out of the scrotum that occurs with excitement, physical activity, or exposure to cold and is caused by the small mass of prepubertal testis and the strength of the cremaster muscle. This is a common phenomenon that is self-limiting (descent occurs at puberty).

Physical examination discloses the absence of one or both testes in the scrotum and an atrophic scrotum on the affected side. If the undescended testis is in a vulnerable position, for example, over the pubic bone, an individual may complain of severe pain secondary to trauma. The adult male with bilateral cryptorchidism may be infertile. Ultrasonography, CT, or MRI can be used to locate an intra-abdominal or nonpalpable testis.

Testicular cancer is also a well-established complication of cryptorchidism. In men with a history of unilateral cryptorchidism, neoplasms also develop more commonly in the contralateral testis. This finding suggests cryptorchidism affects the testes and is a process more significant than simply the position of the testis in childhood.[35] The risk of testicular cancer is 35 to 50 times greater for men with cryptorchidism or a history of cryptorchidism than for the general male population. Because definite histologic change (decreased Leydig cells, loss of germ cells, and peritubular fibrosis) occurs in the cryptorchid testis by 1 year of age, surgical correction is recommended earlier.[37] Treatment often begins with administration of GnRH or human chorionic gonadotropin (hCG), hormones that may initiate descent, making surgery unnecessary. GnRH is given as a nasal spray in Europe and may enhance germ-cell counts even when the testis does not descend.[37] If hormonal therapy is not successful, the testis is located and moved surgically (orchiopexy) in young children or removed (orchiectomy) in adults and children older than 10 years.[37] The testis that is properly placed in the scrotum provides adequate hormonal function and gives the scrotum a normal appearance. A successful operation does not ensure fertility if the testis is congenitally defective. Approximately 20% of males with unilateral undescended testis remain infertile even

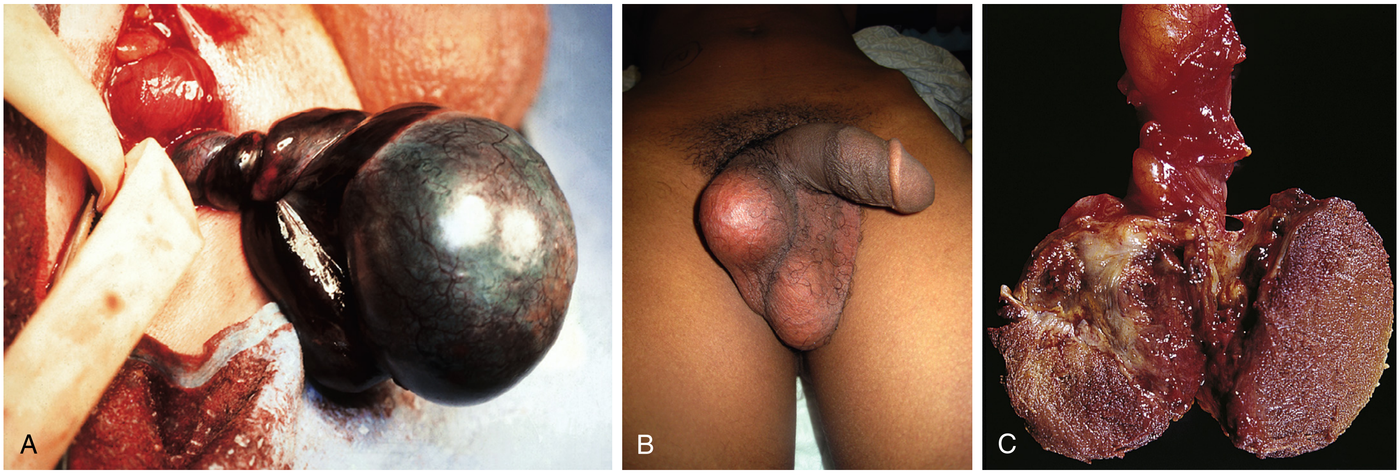

FIGURE 25-9 Torsion of the Testes. **A,** Left testicular torsion in an adolescent with acute scrotum; the testis is necrotic. **B,** Late phase torsion in an adolescent with severe testicular pain 1 month previously. Note the absence of inflammation and high position of testis in scrotum. **C,** The testes appear dark red and partially necrotic owing to hemorrhagic infarction. (**A** and **B** from Kliegman RM et al: *Nelson's textbook of pediatrics,* ed 19, Philadelphia, 2011, Saunders. **C** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

TABLE 25-1 **DIAGNOSIS OF SELECTED CONDITIONS RESPONSIBLE FOR THE ACUTE SCROTUM**

CONDITION	ONSET OF SYMPTOMS	AGE	TENDERNESS	URINALYSIS	CREMASTERIC REFLEX	TREATMENT
Testicular torsion	Acute	Early puberty	Diffuse	Negative	Negative	Surgical exploration
Appendiceal torsion	Subacute	Prepubertal	Localized to upper pole	Negative	Positive	Bed rest and scrotal elevation
Epididymis	Insidious	Adolescence	Epididymal	Positive or negative	Positive	Antibiotics

though orchiopexy is performed by age 1 year; most individuals with treated or untreated bilateral testicular maldescent have poor fertility. In addition, placement of the cryptorchid testis into the scrotal sac does not decrease the potential for malignancy; it does facilitate examination and tumor detection.

Torsion of the Testis

Torsion of the testis is rotation of a testis, which twists blood vessels in the spermatic cord. It causes an acute scrotum, which is testicular pain and swelling (Figure 25-9). Differentiation between testicular torsion and two other common causes of an acute scrotum is based on physical examination and history[35] (Table 25-1). This event is most common among neonates and pubertal adolescents, but it can occur in males at any age.[30] Onset may be spontaneous or follow physical exertion or trauma. Torsion twists the arteries and veins in the spermatic cord, reducing or stopping circulation to the testis. Vascular engorgement and ischemia develop, causing scrotal swelling and pain. These manifestations are not relieved by scrotal elevation (Prehn sign), rest, or scrotal support. On physical examination, men have a tender high-riding testis, a thickened spermatic cord, and an absent cremasteric reflex. Unlike epididymitis, the epididymis cannot be differentiated from the testis.[35] Diagnostic testing includes urinalysis (to rule out infection) and color Doppler ultrasonography.[32] Torsion of the testis is a surgical emergency. If the torsion cannot be reduced manually, surgery must be performed within 6 hours after the onset of symptoms to preserve normal testicular function. Surgery includes untwisting the spermatic cord and anchoring both testes in correct position within the scrotum to prevent recurrences. With successful manual detorsion, surgical fixation should be done within a few days.

Orchitis

Orchitis is an acute infection of the testes (Figure 25-10) and is uncommon except as a complication of systemic infection or as an extension of an associated epididymitis[38] (see p. 897). Infectious microorganisms may reach the testes through the blood or the lymphatics or, most commonly, by ascent through the urethra, vas deferens, and epididymis. Most cases of orchitis are actually cases of epididymo-orchitis. Occasionally, in middle-age men, a nonspecific, apparently noninfectious, inflammatory process (called *granulomatous orchitis*) occurs. It seems to be an autoimmune disease that triggers a granulomatous response to spermatozoa.

Mumps is the most common infectious cause of orchitis and usually affects postpubertal males. The onset is sudden, occurring 3 to 4 days after the onset of parotitis. Signs and symptoms include high fever, reaching 40° C (104° F), marked prostration, bilateral or unilateral erythema, edema and tenderness of the

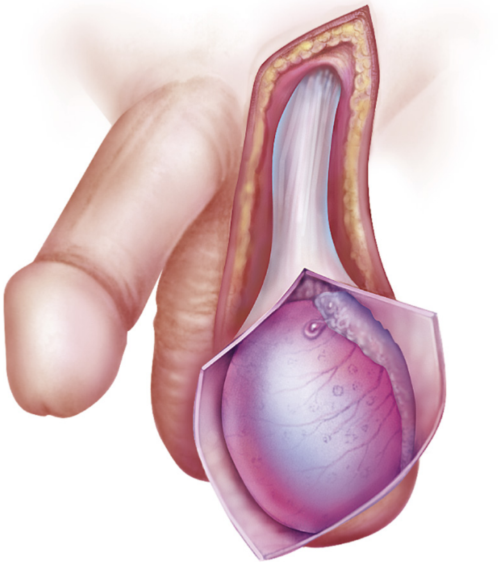

FIGURE 25-10 **Orchitis.** Inflammation of the testicle with enlargement or swelling. (From Seidel H et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

FIGURE 25-11 **Testicular Tumor.** (From Wolfe J: *400 Self assessment picture tests in clinical medicine,* London, 1984, Mosby.)

scrotum, and leukocytosis. An acute hydrocele may develop. Urinary signs and symptoms, which accompany epididymitis, are absent. Atrophy with irreversible damage to spermatogenesis may result in 30% of affected testes. Bilateral orchitis does not affect androgenic function but may cause permanent sterility.

Treatment is supportive and includes bed rest, scrotal support, elevation of the scrotum, hot or cold compresses, and analgesic agents for relief of pain. If an acute hydrocele develops, it is aspirated. Testicular abscess usually requires orchiectomy (removal of the testis). Appropriate antimicrobial drugs should be used for bacterial orchitis, and corticosteroids are indicated in proved cases of nonspecific granulomatous orchitis.

Cancer of the Testis

Testicular cancer is a highly treatable, usually curable, cancer that most often develops in young and middle-aged men. For men with seminoma (all stages combined), the cure rate exceeds 90%. For those with low-stage seminoma or nonseminoma, the cure rate approaches 100%.[39] Overall, testicular cancers are rare, yet they are the most common form of cancer in young men between ages 15 and 35. Approximately 8590 cases and 360 deaths were estimated for 2012.[1] In the United States, the lifetime probability of developing testicular cancer is 0.2% for white men, an incidence that is four times higher than for blacks. Testicular tumors are slightly more common on the right side than on the left, a pattern that parallels the occurrence of cryptorchidism; about 1% to 2% of primary testicular cancers are bilateral (Figure 25-11), and 50% of these tumors arise from treated or untreated cryptorchid testes.

PATHOGENESIS. Ninety percent of testicular cancers are germ-cell tumors arising from the male gametes. Germ-cell tumors constitute 90% of testicular cancers and can be broadly classified into two types: seminomas and nonseminomas. Seminomas are the most common, are the least aggressive, and make up about 30% to 35% of testicular cancers. Nonseminomas include embryonal carcinomas, teratomas, and choriocarcinomas, the most aggressive but rare (less than 1%) form of testicular cancer. Testicular cancers can include a mix of types.[40] In addition, testicular tumors can arise from specialized cells of the gonadal stroma. These tumors, which are named for their cellular origins, are Leydig cell, Sertoli cell, granulosa cell, and theca cell tumors and constitute less than 10% of all testicular cancers.[41]

The cause of testicular neoplasms is unknown. A genetic predisposition is suggested by the fact that the incidence is higher among brothers, identical twins, and other close male relatives. Genetic predisposition is supported further by statistics showing that the disease is relatively rare among black Africans, black Americans, Asians, and native New Zealanders. Familial testicular germ cell tumors may be associated with transgenerational inheritance of epigenetic events.[42] Risk factors include history of cryptorchidism, abnormal testicular development, human immunodeficiency virus (HIV) and AIDS, Klinefelter syndrome, and history of testicular cancer.[40]

CLINICAL MANIFESTATIONS. Painless testicular enlargement commonly is the first sign of testicular cancer. Enlargement is usually gradual and may be accompanied by a sensation of testicular heaviness or dull ache in the lower abdomen.[40] Occasionally, acute pain occurs because of rapid growth, resulting in hemorrhage and necrosis. Ten percent of affected men have epididymitis, 10% have hydroceles,[35] and 5% have gynecomastia or hydrocele. Incidence of gynecomastia increases considerably (30% to 45%) in men with Sertoli or Leydig tumors. Approximately 10% of individuals already have symptoms related to metastases at the time of initial diagnosis, which correlates with the typical delay of 3 to 6 months from initial recognition to definitive treatment. Lumbar pain may be present

TABLE 25-2 **TESTICULAR TUMORS OF GERM CELL ORIGIN**

CELL TYPES	OCCURRENCE	METASTATIC PATTERN	PROGNOSIS/REMISSION RATE
A. Seminoma (germinoma)	30%-35% of all testicular tumors	Rarely to retroperitoneal lymph nodes	Excellent; tumor usually remains localized and is responsive to radiation; cure rate stages I and II >95%; stages III and IV >80%
B. Nonseminomatous tumors	60% of all testicular tumors		
1. Single cell			
a. Embryonal carcinoma	20%-25% of all testicular tumors; most common testicular tumor in infants and children	Earlier to regional lymphatics, also lung, liver, bone	Good; complete remission rate stages I and II >95%; stages III and IV >70%-80%
b. Teratoma	5%-10% of all testicular tumors (occurs in children and adults)	Through lymphatics and bloodstream; affects same organ systems as embryonal type	Fair
c. Choriocarcinoma	<1% of all testicular tumors	Earliest and widest, initially through bloodstream	Poor; early metastasis
2. Mixed tumors	30%-40% of all testicular tumors		
a. Teratocarcinoma	20%-25% of all testicular tumors	Mixed pattern; depends on cell types	Variable; prognosis becomes that of the most malignant element
b. Other i. Teratocarcinoma with seminoma ii. Embryonal cancer with seminoma iii. Teratoma with seminoma iv. Any combination with choriocarcinoma	10%-15% of all testicular tumors	Mixed pattern; depends on cell types	Variable; prognosis becomes that of the most malignant element
3. Non–germ cell tumors (Leydig cell, Sertoli cell, granulosa cell, and thecal cell tumors)	<10%		

Data from American Cancer Society. In *Cancer response system document #10029,* New York, 1995, The Society; Cancer Net: *Cancer facts: questions and answers about testicular cancer,* National Cancer Institute, 2000. Available at www.cancernet.nci.nih.gov.

and usually is caused by retroperitoneal node metastasis. Signs of metastasis to the lungs include cough, dyspnea, and bloody sputum (hemoptysis). Supraclavicular node involvement may cause difficulty swallowing (dysphagia) and neck swelling. Alterations in vision or mental status, papilledema, and seizures may be experienced with metastasis to the CNS. Approximately 10% of affected individuals are asymptomatic; the tumor may be detected by the man's sexual partner or incidentally following trauma.

EVALUATION AND TREATMENT. An incorrect diagnosis at the initial examination occurs in as many as 25% of men with testicular cancer. Epididymitis and epididymo-orchitis are the most common misdiagnoses; others include hydrocele and spermatocele. Evaluation begins with careful physical examination, including palpation of the scrotal contents with the individual in the erect and supine positions. The abdomen and lymph nodes are palpated to rule out metastases. Signs of testicular cancer include abnormal consistency, induration, nodularity, or irregularity of the testis. A firm, nontender testicular mass or diffuse enlargement is found in the majority of cases. Primary testicular cancer can be assessed rapidly and accurately by scrotal ultrasonography. Tumor markers are higher than normal in the presence of a tumor and may help detect a tumor that is too small to be palpated during physical examination or seen on imaging.[35] Tumor type is identified after inguinal biopsy or orchiectomy. Scrotal incisions may cause dissemination of the tumor and increase the risk of local recurrence and therefore are avoided. Chest x-ray, lymphangiogram, intravenous pyelogram (IVP), abdominal ultrasound, and CT are used in clinical staging of disease. Treatment is based on type of tumor, stage of disease, general health, and age. Besides surgery, treatment involves radiation and chemotherapy singly or in combination. A number of factors influence the prognosis (Table 25-2). They include histology of the tumor, stage of the disease, and selection of appropriate treatment. Serum markers, such as alpha fetoprotein (AFP), β-hCG, and lactate dehydrogenase, are useful for detecting metastases and assessing responses to therapy. With appropriate treatment survival rates from testicular cancer are excellent, although some have persistent paresthesias, Raynaud phenomenon, or infertility. According to the National Cancer Institute, the overall 5-year survival rate from testicular cancer was 95.3% between 1999 and 2005. If the cancer was confined to the testis at the time of diagnosis, the survival rate was 99.2% and dropped only slightly to 95.9% with regional extension. For those with distant metastases, the survival rate was 71%.[35,40] Orchiectomy does not affect sexual function, but infertility can result from chemotherapy or surgical removal of affected abdominal lymph nodes if nerves

FIGURE 25-12 Epididymitis Secondary to Gonorrhea or Nongonococcal Urethritis. This infection spread to the testes, and rupture through the scrotal wall is threatened. (From Taylor PK: *Diagnostic picture tests in sexually transmitted diseases,* London, 1995, Mosby-Wolfe.)

necessary for ejaculation are severed. After orchiectomy, testicular silicone implants may be used to restore "normal" scrotal appearance.

Epididymitis

Epididymitis, or inflammation of the epididymis, generally occurs in sexually active young males (younger than 35 years) and is rare before puberty (Figure 25-12). In young men the usual cause is a sexually transmitted microorganism, such as *N. gonorrhoeae* or *C. trachomatis*. Men who practice unprotected anal intercourse may acquire sexually transmitted epididymitis because of *Escherichia coli, Haemophilus influenzae,* tuberculosis (especially in regions where incidence of pulmonary tuberculosis is high), *Cryptococcus,* or *Brucella.*[35] In men older than 35 years, enterobacteriaceae (intestinal bacteria) and *Pseudomonas aeruginosa* associated with urinary tract infections and prostatitis also may cause epididymitis. Besides an infectious etiology, epididymitis may result from a chemical inflammation caused by the reflux of sterile urine into the ejaculatory ducts.[43] It is associated with urethral strictures, congenital posterior valves, and excessive physical straining in which increased abdominal pressure is transmitted to the bladder. Chemical epididymitis is usually self-limiting and does not require evaluation or intervention unless it persists.

PATHOGENESIS. The pathogenic microorganism usually reaches the epididymis by ascending the vasa deferentia from an already infected urethra or bladder. The presence of bacteria initiates the inflammatory response, causing symptoms of bacterial epididymitis. Epididymitis caused by heavy lifting or straining results from reflux of urine from the bladder into the vas deferens and epididymis. Urine is extremely irritating to the epididymis and initiates an inflammatory response called *chemical epididymitis.*

CLINICAL MANIFESTATIONS. Pain is the main symptom of epididymitis. Scrotal or inguinal pain is caused by inflammation of the epididymis and surrounding tissues. The pain is usually acute and severe. Flank pain may occur if, as the urethra passes over the spermatic cord, edematous swelling of the cord obstructs the urethra. The individual may have pyuria and bacteriuria and a history of urinary symptoms, including urethral discharge. The scrotum on the involved side is red and edematous as a result of inflammatory changes. The tail of the epididymis near the lower pole of the testes usually swells first; then swelling ascends to the head of the epididymis. The spermatic cord also may be swollen and tender.

Complications of epididymitis include abscess formation, infarction of the testis, recurrent infection, and infertility. Infarction probably is caused by thrombosis (obstruction by blood clots) of the prostatic vessels secondary to severe inflammation. Recurrent epididymitis may result from inadequate initial treatment or failure to identify or treat predisposing factors. Chronic epididymitis can cause scarring of the epididymal endothelium. Once scarring has occurred, treatment with antibiotics is ineffective because adequate antibiotic levels cannot be achieved within the epididymis.[43]

EVALUATION AND TREATMENT. A history of recent urinary tract infection or urethral discharge suggests the diagnosis of epididymitis. The relief of pain when the inflamed testis and epididymis are elevated (Prehn sign) is also diagnostic. Definitive diagnosis is based on culture or Gram stain of a urethral swab. Epididymal aspiration may be necessary to obtain a specimen, especially if the individual has been taking antibiotics and has sterile urine.

Treatment includes antibiotic therapy for the infection itself (see Chapter 26). Analgesics, ice, and scrotal elevation can provide symptomatic relief. If the individual does not steadily improve, he should be reevaluated for possible complications, such as abscess formation, sepsis, or continued infection.[35] Bed rest and scrotal elevation are recommended until the scrotum is no longer tender. Scrotal elevation facilitates maximal lymphatic and venous drainage. Abscess formation is rare with antibiotic therapy. If an abscess occurs and persists, it is drained surgically and an orchiectomy may be indicated. Complete resolution of swelling and pain may take several weeks to months. The individual's sexual partner should be treated with antibiotics if the causative microorganism is a sexually transmitted pathogen.

Disorders of the Prostate Gland

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH), also called **benign prostatic hypertrophy,** is the enlargement of the prostate gland (Figure 25-13). Because the major prostatic changes are caused by hyperplasia, not hypertrophy, benign prostatic hyperplasia is the preferred term. This condition becomes problematic as prostatic tissue compresses the urethra, where it passes through the prostate, resulting in frequency of lower urinary tract symptoms. The prevalence among U.S. men 60 years and older is about 50% and among men 70 years or older 90%.[44] BPH is common and involves a complex pathophysiology with several endocrine and local factors and remodeled microenvironment. Its relationship to aging is well documented. At birth the prostate is pea sized, and growth of the gland is gradual until puberty.

	Prostate zone		
	Peripheral	Transition	Central
Focal atrophy	High prevalence	Medium-high prevalence	Low prevalence
Acute inflammation	Low prevalence	None	None
Chronic inflammation	Medium-high prevalence	Medium-high prevalence	Low prevalence
Benign prostatic hyperplasia	None	High prevalence	None
High-grade PIN	Medium-high prevalence	Low prevalence	Low prevalence
Carcinoma	Medium-high prevalence	Low prevalence	None

FIGURE 25-13 **Prostate Zones, Benign Prostatic Hyperplasia (BPH), and Prostate Cancer Locations.** BPH occurs in the peripheral zone of the prostate gland that can enlarge (not shown). BPH nodules and atrophy are associated with inflammation in the transition zone. Most cancer lesions occur in the peripheral zone. Carcinoma can involve the central zone but rarely occurs in isolation, suggesting that prostatic intraepithelial neoplasia (PIN) lesions do not easily progress to carcinoma in this region. (Adapted from De Marzo AM et al: *Nat Rev Cancer* 7:256–269, 2007.)

A period of rapid development continues until the third decade of life, when the prostate reaches adult size. Around 40 to 45 years of age, benign hyperplasia begins and continues slowly until death. Although dihydrotestosterone (DHT) is necessary for normal prostatic development, its role in BPH remains unclear. Among all androgen-metabolizing enzymes within the human prostate, 5α-reductase is the most powerful. This reductase corresponds to an age-dependent DHT level. Therefore, although 5α-reductase and DHT decrease with age in the epithelium, they remain relatively constant in the stroma of the prostate gland.

PATHOGENESIS. Current causative theories of BPH focus on levels and ratios of endocrine factors such as androgens, estrogens, gonadotropins, and prolactin and changes in the balance between autocrine/paracrine growth-stimulatory and growth-inhibitory factors. These factors include insulin-like growth factors (IGFs), epidermal growth factor, nerve growth factor, fibroblast factors, IGF binding proteins, and transforming growth factor-beta (TGF-β).[45]

Aging and circulating androgens are associated with BPH and enlargement. These factors are predisposed as disrupting the *balance* of growth factor signaling pathways and stromal/epithelial interactions creating a growth-promoting and tissue remodeling microenvironment. However, BPH is a multifactorial disease, and not all men respond well to available treatments, suggesting factors other than androgens are involved. Testosterone, the primary circulating androgen in men, also can be metabolized through CYP19/aromatase into the potent estrogen, estradiol-17β. The prostate is an estrogen target tissue and estrogens directly and indirectly affect growth and differentiation of prostate. The precise role of endogenous and exogenous estrogens in directly affecting prostate growth and differentiation in the context of BPH is an understudied area. Estrogens and selective estrogen receptor modulators have been shown to promote or inhibit prostate proliferation, signifying potential roles in BPH.[46] Taken together these interactions lead to an increase in prostate volume. The remodeled stroma promotes local inflammation with altered cytokine, reactive oxygen/nitrogen species, and chemoattractants.[47] The resultant increased oxygen demands of proliferating cells causes a local hypoxia that induces angiogenesis and changes to fibroblasts. Functional and phenotypic changes (transdifferentiation) of fibroblasts to the myofibroblasts is a hallmark of the remodeled microenviroment.[48]

BPH begins in the periurethral glands, which are the inner glands or layers of the prostate. The prostate enlarges as nodules form and grow (nodular hyperplasia) and glandular cells enlarge (hypertrophy). The development of BPH occurs over a prolonged period, and changes within the urinary tract are slow and insidious.

CLINICAL MANIFESTATIONS. As nodular hyperplasia and cellular hypertrophy progress, tissues that surround the prostatic urethra usually compress it but not always cause **bladder outflow obstruction.** These symptoms are sometimes called the spectrum of lower urinary tract symptoms (LUTS). Symptoms include the urge to urinate often, some delay in starting urination, and decreased force of the urinary stream. As the obstruction progresses, often over several years, the bladder cannot empty all the urine and the increasing volume leads to long-term urine retention. The volume of urine retained may be great enough to produce uncontrolled "overflow incontinence" with any increase in intra-abdominal pressure. At this stage the force of the urinary stream is significantly reduced, and much more time is required to initiate and complete voiding. Hematuria, bladder or kidney infection, bladder calculi, acute urinary retention hydroureter, hydronephrosis, and renal insufficiency are common complications.[49]

Some men initially have signs of uremia and renal failure. On digital rectal examination the hyperplastic prostate is a soft or firm enlargement with smooth mucosal surface and no discernible distinction between lobes; asymmetry is common. The palpated prostate does not always reflect the degree of BPH because a substantial portion of the enlargement is intravesicular.[50] Thirty percent of men with mild to moderate symptoms improve with watchful waiting.

EVALUATION AND TREATMENT. Diagnosis is made from a medical history, physical exam, and laboratory tests including urinalysis. Careful review of symptoms is necessary. Digital rectal examination (DRE) and PSA are conducted to determine hyperplasia. PSA alone, however, cannot determine whether symptoms are caused by BPH because PSA is elevated in both BPH and prostate cancer. Annual DREs are used to screen men older than 40 years of age for BPH, sooner in high-risk men.[51] If marked enlargement, moderate to severe symptoms, or complications are present, transrectal ultrasound (TRUS) is used to determine bladder and prostate volume and residual urine. Urinalysis, serum creatinine and blood urea nitrogen, uroflowmetry, postvoid residual (PVR) urine, pressure-flow study, cystometry, and cystourethroscopy are used to determine kidney and bladder function.[49] BPH has been treated successfully with drugs. α_1-Adrenergic blockers (prazosin and tamsulosin) are used to relax the smooth muscle of the bladder and prostate. Antiandrogen agents, such as finasteride (Proscar), selectively block androgens at the prostate cellular level and cause the prostate gland to shrink.[51] By shrinking the prostate, these drugs have been shown to improve BPH-related symptoms and reduce the risk of future urinary retention and BPH-related surgery. α_1-Adrenergic blockers do not affect PSA and have no effect on prostate cancer risk. However, antiandrogen agents lower PSA by 50% after 6 months of therapy.[51]

Newer minimally invasive procedures include interstitial laser therapy, transurethral radiofrequency procedure (TUNA), cooled Thermo Therapy and prostate artery embolization. When necessary, the hyperplastic tissue may be removed surgically to prevent the serious consequences of urethral obstruction. A permanent indwelling catheter is inserted if the individual cannot tolerate surgery.

BOX 25-5 NATIONAL INSTITUTES OF HEALTH CLASSIFICATION OF THE PROSTATITIS SYNDROMES

This system, developed for clinical research purposes, can be simplified for use in primary care practice.

Category I, or acute bacterial prostatitis (ABP), is an acute infection of the prostate and is manifested by systemic signs of infection and a positive urine culture.

Category II, or chronic bacterial prostatitis (CBP), is a chronic bacterial infection, in which bacteria are recovered in significant numbers from a purulent prostatic fluid. These bacteria are thought to be the most common cause of recurrent urinary tract infection in men.

Category III, or chronic pelvic pain syndrome (CPPS), is diagnosed when no pathogenic bacteria can be localized to the prostate (culture of expressed prostatic fluid or postprostatic massage urine specimen) and is further divided into IIIa and IIIb. Category IIIa refers to inflammatory CPPS in which a significant number of white blood cells (WBCs) are localized to the prostate, whereas, category IIIb is noninflammatory.

Category IV refers to asymptomatic inflammatory prostatitis, in which bacteria or WBCs are localized to the prostate, but individuals are asymptomatic.

Prostatitis

Prostatitis is an inflammation of the prostate. Some degree of prostatic inflammation is present in 4% to 36% of the male population, increasing to 50% in older men. Inflammation is usually limited to a few of the gland's excretory ducts.

Prostatitis syndromes have been classified by the National Institutes of Health as: (1) acute bacterial prostatitis (ABP), (2) chronic bacterial prostatitis (CBP), (3) chronic pelvic pain syndrome (CPPS), and (4) asymptomatic inflammatory prostatitis (Box 25-5). ABP and CBP are caused mostly by gram-negative enterobacteriaceae and enterococci species, which originate in the gastrointestinal flora. The most common microorganism is *E. coli*, which is identified in the majority of infections.[52] *Klebsiella* species, *P. aeruginosa*, and *Serratia* species are common gram-negative cultured microorganisms. Nonbacterial prostatitis (CP/CPPS) syndromes are caused by a cascade of inflammatory, immunologic, neuroendocrine, and neuropathic mechanisms in which the initiating cause is unknown.

Bacterial Prostatitis. **Acute bacterial prostatitis (ABP, category I)** is an ascending infection of the urinary tract that tends to occur in men between the ages of 30 and 50 years but also is associated with BPH in older men. Infection stimulates an inflammatory response in which the prostate becomes enlarged, tender, firm, or boggy. The onset of prostatitis may be acute and unrelated to previous illnesses or it may follow catheterization or cystoscopy.

Clinical manifestations of acute bacterial prostatitis are those of urinary tract infection or pyelonephritis. Sudden onset of malaise, low back and perineal pain, high fever (up to 40° C [104° F]) and chills is common, as are dysuria, inability to empty

the bladder, nocturia, and urinary retention. The individual also may have symptoms of lower urinary tract obstruction, such as slow, small, "narrowed" urinary stream, which may be a medical emergency. Acute inflammatory prostatic edema can compress the urethra, causing urinary obstruction. Systemic signs of infection include sudden onset of a high fever, fatigue, arthralgia, and myalgia. Prostatic pain may occur, especially when the individual is in an upright position, because the pelvic floor muscles tighten with standing and the prostate gland is compressed. Some individuals experience low back pain, painful ejaculation, and rectal or perineal pain. Palpation discloses an enlarged, extremely tender and swollen prostate that is firm, indurated, and warm to the touch.

Because ABP is usually associated with a bladder infection caused by the same microorganism, urine cultures disclose its identity. Prostatic massage may express enough secretions from the urethra for direct bacterial examination, but massage may be painful and increases the risk that the infection will ascend to adjacent structures or enter the bloodstream and cause septicemia.

To resolve the infection and control its spread, individuals may require antibiotics. In severe cases, the individual is hospitalized and treated with intravenous antibiotics, followed by oral antibiotics. Analgesics, antipyretics, bed rest, and adequate hydration also are therapeutic. Complications include urinary retention that resolves with antibiotic therapy; prostatic abscess that may rupture into the urethra, rectum, or perineum; epididymitis; bacteremia; and septic shock. Urinary retention requiring drainage is best managed with a suprapubic catheter. Foley catheterization is contraindicated during acute infection.

Chronic bacterial prostatitis (CBP, category II) is characterized by recurrent urinary tract symptoms and persistence of pathogenic bacteria (usually gram negative) in urine or prostatic fluid. This form of prostatitis is the most common recurrent urinary tract infection in men. Symptoms may be similar to those of an acute bladder infection, such as frequency, urgency, dysuria, perineal discomfort, low back pain, myalgia, arthralgia, and sexual dysfunction. The prostate may only be slightly enlarged or boggy but it may be fibrotic because repeated infections can cause it to be firm and irregular in shape.

When the initial urine sample is bacteria-free, prostatic massage is used to express secretions. Subsequently, the first 10 ml of voided urine is collected and examined microscopically. Prostatic secretions showing more than 10 white blood cells (WBCs) per high-power field and macrophages containing fat are indicative of bacterial infection; diagnosis is confirmed by culture. A pelvic x-ray or TRUS may show prostatic calculi.

Treatment of chronic bacterial prostatitis is difficult because it is often caused by prostatic calculi. Calculi are silent and are found in up to 50% of men with prostatitis, and infected calculi can serve as a source of bacterial persistence and relapsing urinary tract infection.[53] Calculi harbor pathogens within the stone, and consequently pathogens cannot be eradicated from the urinary tract. Permanent cure is achieved by surgical intervention.

Chronic Prostatitis/Chronic Pelvic Pain Syndrome. **Chronic prostatitis/chronic pelvic pain syndrome (CPPS, category III)** is diagnosed when no pathogenic bacteria can be localized to the prostate and is further divided into categories IIIa and IIIb (see Box 25-5). Category IIIa refers to inflammatory chronic pelvic pain syndrome where WBCs are elevated and localized to the prostate. Symptoms tend to be milder but are persistent and annoying. Presumably, noninfectious prostatitis or pain is caused by reflux of sterile urine into the ejaculatory ducts because of high-pressure voiding.[53] Reflux may be triggered by spasms of the external or internal sphincters. Category IIIb is noninflammatory; in **category IV,** individuals are asymptomatic but have an increase in bacteria and WBCs localized to the prostate. Microorganisms suspected of causing CP/CPPS include *E. coli*, *Enterobacter*, *P. aeruginosa*, and *Helicobacter pylori*, a new suspect.[54]

Men with **nonbacterial prostatitis** may complain of pain or a dull ache that is continuous or spasmodic in the suprapubic, infrapubic, scrotal, penile, or inguinal area. Other symptoms are pain on ejaculation and urinary symptoms, such as frequency of urination. The prostate gland generally feels normal on palpation.

Nonbacterial prostatitis is a diagnosis by exclusion. Digital examination of the prostate, bacterial cultures of the urogenital tract, microscopic examination of expressed prostatic fluid, urethroscopy, and urodynamic studies are used to verify the diagnosis of nonbacterial prostatitis.

There is no generally accepted treatment for nonbacterial prostatitis. Hot sitz baths, bed rest, alpha-blockers, anticholinergics, and anti-inflammatory drugs can relieve symptoms.

Cancer of the Prostate

Prostate cancer is the most commonly diagnosed nonskin cancer in men in the United States, with a lifetime risk for diagnosis currently estimated at 15.9%.[55] The incidence varies greatly worldwide (Figure 25-14), but it is still considered to be the second most frequently diagnosed cancer and the sixth leading cause of death worldwide. Importantly, incidence rates vary by more than 25-fold worldwide, and the highest rates recorded mostly in developed countries include Oceania, Europe, and North America, largely because of the wide use or overuse of PSA testing.[56] Screening with PSA can amplify the incidence of prostate cancer by allowing detection of prostate lesions that although meeting the pathologic criteria for malignancy, may have low potential (e.g., latent, indolent, preclinical) for growth and metastasis. In countries with higher use of PSA testing, such as United States, Canada, Australia, and the Nordic countries, trends in incidence rates follow similar patterns.[56]

Different from Western countries, incidence and mortality rates are rising in several Asian (including Japan) and central and Eastern European countries.[56] Death rates have been decreasing in several countries including Australia, Canada, the United Kingdom, the United States, Italy, and Norway, in part from improved treatment. Males of African descent in the Caribbean have the highest mortality rates from prostate cancer in the world.[56] Most cases of prostate cancer have a good prognosis even without treatment but some cases are aggressive; the lifetime risk for dying of prostate cancer is 2.8%. Prostate cancer is rare before age 50 years and very few men die from it

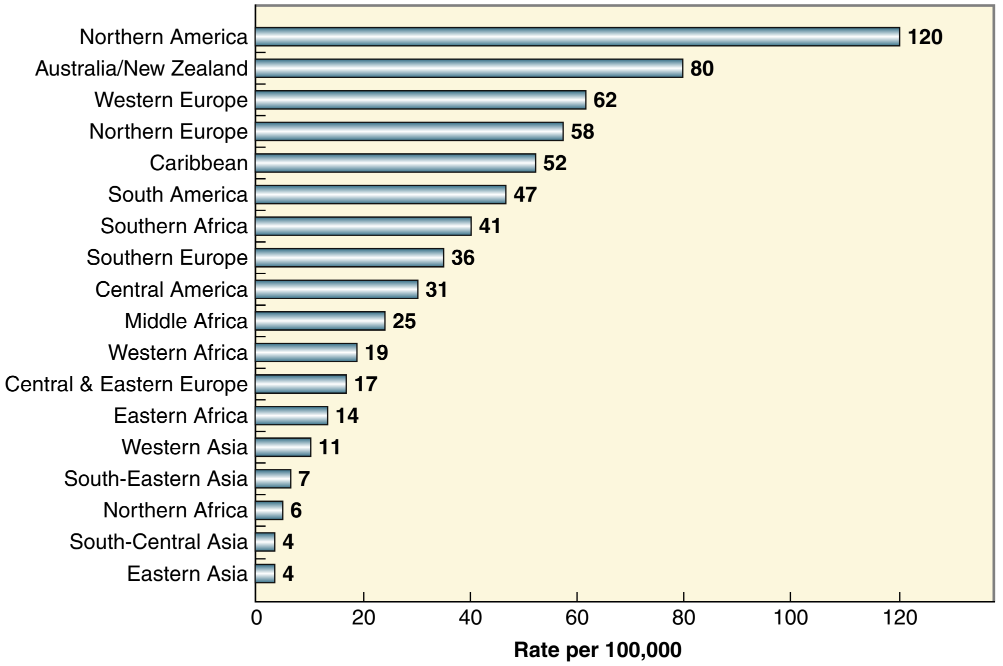

FIGURE 25-14 Selected World Population Age-Standardized (to the World Population) Incidence Rates of Prostate Cancer. (Modified from Jemal A et al: *Biomark Prev* 19:1893, 2010.)

before 60 years of age. Indeed, more than 75% of all prostate cancer is diagnosed in men older than 65.[55] With aging, most of the androgen-metabolizing enzymes undergo significant alteration and older age, race (black), and family history remain the well-established risk factors.[56]

Dietary Factors. Although evidence exists for a dietary role in prostate cancer, the epidemiologic evidence is inconsistent. The problem has been confounded by lack of biomarkers for certain nutrients, difficulties in measuring and quantifying diet, and a limitation of clinical trials to study diet over time. Important are the effects of diet on signaling pathways, hormones, oxidative stress, and reactive oxygen species (ROS). The nutrients in the epidemiology of prostate cancer that have received the most attention include carotenoids, fat, vitamin E, vitamin D/calcium, and selenium. Less studied are isoflavones, curcumin, lycopene, zinc, green tea, omega 3 polyunsaturated fats, and sulforaphane (see Nutrition & Disease: Summary of Diet for Prostate Cancer). Associations between obesity and prostate cancer are not clear, with some research inconsistencies, but obesity seems to be negatively associated with more indolent prostate cancer and positively associated with more aggressive disease and a worse outcome.[57] In process is a randomized clinical trial of diet and early-stage prostate cancer, Men's Eating and Living Study (MEAL). The hypothesis for MEAL is that a change in diet of higher intake of animal products to vegetables and fruits will slow the progression of the indolent to the aggressive form of prostate cancer.[57] As adipose tissue is increasingly being regarded as hormonally active tissue, high body fat and obesity need in-depth exploration to understand the associated risk of prostate problems. Adipose tissue is now known to affect circulating levels of several bioactive messengers and therefore could affect the risk of developing prostate problems in addition to several other well-recognized health problems.[58] High-energy intake (consumption of excess calories) indicates that this may indeed increase insulin levels and IGF-1, a powerful carcinogenic agent[59] (see Pathogenesis, p. 904). More robust, high-quality research trials are needed to guide understanding of the complex relationship between diet and prostate cancer.

Hormones. Prostate cancer develops in an androgen-dependent epithelium and is usually androgen sensitive. Androgens are synthesized not only in the testis, accounting for 50% to 60% of the total testosterone in the prostate, but also in the prostate gland itself. In a process called **intraprostatic conversion,** the hormone dehydroepiandrosterone (DHEA) produced by the adrenal glands[60,61] is converted to testosterone and then into DHT in the prostate (Figure 25-15). Additionally, prostate cancer cells have been reported to make androgens from cholesterol (i.e., de novo).[62] However, these overall relative contributions from intratumoral sources remain to be determined. Population studies have not, however, provided clear and convincing patterns involving associations between circulating hormone concentrations (e.g., not tissue concentrations) and prostate cancer risk.[63,64] Thus there is universal agreement that androgens are important for prostatic growth, development, and maintenance of tissue balance but their role in cancer is controversial.[65] Evidence for involvement of 5α-reductase activity, which is critical in androgen activity in the prostate, is contradictory and inconsistent[63,64] (see Figure 25-15). A prevention study has provided some of the strongest hormonal data with the drug finasteride, which inhibits 5α-reductase. The 7-year intervention study reduced prostate cancer risk in healthy men by about 25%.[66] Important, however, was that more high-grade tumors were found in those men who developed prostate cancer while on the drug. In men younger than 50 years, circulating levels of androgens

Summary of Diet for Prostate Cancer

- Epidemiologic studies have found total fat intake, animal and saturated fat, red meat, and dairy products are associated with an increase in prostate cancer risk.
- Obesity is linked to advanced and aggressive prostate cancer.
- High body mass index (BMI) is associated with more aggressive disease and a worse outcome.
- Calorie-dense or excessive carbohydrate intake and obesity, independent of dietary fat intake, may increase the risk of developing prostate cancer.
- Dietary fat may increase androgens, increase oxidative stress, and increases reactive oxygen species (ROS).
- Monounsaturated fats may decrease the risk of prostate cancer.
- High levels of linoleic acid (e.g., found in corn oil; safflower) tend to act as a proinflammatory eicosanoid, which is implicated in promotion of cell proliferation and angiogenesis as well as inhibition of apoptosis.
- The Western diet has increased omega-6/omega-3 ratios and therefore is proinflammatory.
- Cooking meat at high temperatures produces heterocyclic amines and aromatic hydrocarbons that are carcinogenic.
- Carcinogenic nitrosamines are formed after consumption of processed meat that contains nitrites and from heme iron present in large quantities of red meat.
- Vitamin E has been long considered a candidate for prostate cancer prevention from in vitro and in vivo animal studies. Vitamin E belongs to the family of tocopherols and tocotrienols that exist as α, β, γ, and δ isoforms. Among these, δ-tocopherol is the major dietary isoform, whereas supplements contain α-tocopherol. Vitamin E is a fat-soluble vitamin obtained from vegetable oils, nuts, and egg yolk. It is a potent intracellular antioxidant known to inhibit peroxidation and DNA damage. The Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC) study showed supplementation with vitamin E could reduce the incidence of prostate cancer among men who smoked. In vitro studies demonstrate that γ- and δ-tocopherol induces cell cycle arrest in human prostate cancer cells (i.e., induces apoptosis) and inhibits the androgen receptor. Mouse studies show vitamin E can inhibit the growth-promoting effects of a high-fat diet; however, vitamin E in combination with selenium does not reduce the incidence of prostate cancer in lady mice models. In the prospective large clinical trial SELECT, the study found no apparent benefit of administering vitamin E.
- Selenium is a trace mineral and exists in food as selenomethionine and selenocysteine. It is essential for the functioning of many antioxidant enzymes and proteins in the body. Humans receive selenium in their diet through plant (dependent on soil concentrations) and animal products. Several large prospective studies reported 50% to 65% reductions in prostate cancer risk with high levels versus low levels of selenium as measured in toenails and plasma. The Nutritional Prevention of Cancer (NPC) trial reported a 50% reduction in risk of developing prostate cancer. No potential benefit was found in the SELECT trial, whereas a small insignificant increase was noted for type 2 diabetes. From these two trials two different forms of selenium were used—the NPC trial used selenized yeast and the SELECT trial used selenomethionine. A meta-analysis of 12 studies with 13,254 subjects and 5007 cases of prostate cancer showed that the risk of prostate cancer decreased with increasing plasma/serum selenium up to 170 ng/ml. Selenium has several modes of action depending on its form. Selenomethionine inhibits cell proliferation and induces cell cycle arrest of human prostate cells (i.e., apoptosis) and inhibits angiogenesis mediated in part by the androgen receptor. This also is true of methylselenic acid. Sodium selenite's anticancer effects are mediated through cellular antioxidants, leading to increased apoptosis and sensitizing cells to radiation-induced killing. Selenium and its derivatives can activate both intrinsic and extrinsic pathways of apoptosis. Selenium intervention may depend on individual genotype.
- Vitamin D may play an important role in prostate cancer prevention.
- Zinc may be important for prostate cancer; however, data are lacking.
- Soy contains isoflavones purported to have anticancer properties including inhibition of cell proliferation and angiogenesis and reduction in prostate specific antigen (PSA) and androgen receptor levels.
- Tomatoes or tomato products ingested daily seem to reduce prostate cancer risk. In vitro studies show lycopene inhibits DNA strand breaks. Unresolved is whether lycopene itself or a metabolic product is responsible for its biologic effect. In clinical studies tomato paste, which is high in lycopene, reduced plasma PSA levels in those men with benign prostatic hyperplasia. Lycopene administration is associated with cell cycle arrest (apoptosis) and growth factor signaling. In 2007 the U.S. Food and Drug Administration (FDA) evaluated 13 available studies and found the relationship between lycopene and reduced risk of prostate cancer inadequate. A Cochrane review found that given only three randomized controlled trials were included in the analysis and a high risk of bias in two, there is insufficient evidence to support or refute lycopene for the prevention of prostate cancer.
- Vegetables including broccoli, cabbage, cauliflower, Brussels sprouts, Chinese cabbage, and turnips (all crucifers) may be protective (several epidemiologic studies) against prostate cancer. In particular, a diet high in broccoli reduced cancer risk. By contrast, four studies revealed no cancer preventive effects. Cruciforms have anticancer properties mediated by the phytochemicals phenethyl isothiocyanate, sulforaphane, and indole-3-carbinol. Sulforaphane is a naturally occurring isothiocyanate that was first isolated in broccoli. It protects against carcinogen-induced cancer in many rodents. Mice given 240 mg of broccoli sprouts per day showed a significant reduction in growth of prostate cancer cells. Sulforaphane treatment lowered androgen receptor protein and gene expression.
- Green tea contains polyphenols, including epigallocatechin gallate (EGCG). Green tea consumption has been associated with a reduced incidence of several cancers including prostate cancer. Green tea consumed within a balanced controlled diet in humans improved overall antioxidant potential. The anticancer effect potential of green tea from in vitro and experimental studies shows these compounds bind directly to carcinogens and induce phase II enzymes that inhibit heterocyclic amines. EGCG administration decreased NF-$\kappa\beta$ activity. Green tea was shown to inhibit IGF-1 and increase IGFBP3, leading to inhibition of prostate cancer development and progression. Yet, in two small randomized studies in individuals with high-grade prostatic neoplasia, it showed no effects. In a population prospective large study ($n = 27{,}293$) green tea did not protect against prostate cancer and black tea showed a positive association with prostate cancer.
- Curcumin has anticarcinogenic potential with well-characterized anti-inflammatory, antiangiogenic, and antioxidant properties. Recent studies report curcumin modulates the Wingless signaling pathway (Wnt) that supports its antiproliferative potential.
- Overall, multiple signaling pathways are involved in prostate cancer development and progression, many of which are affected by dietary and lifestyle factors.

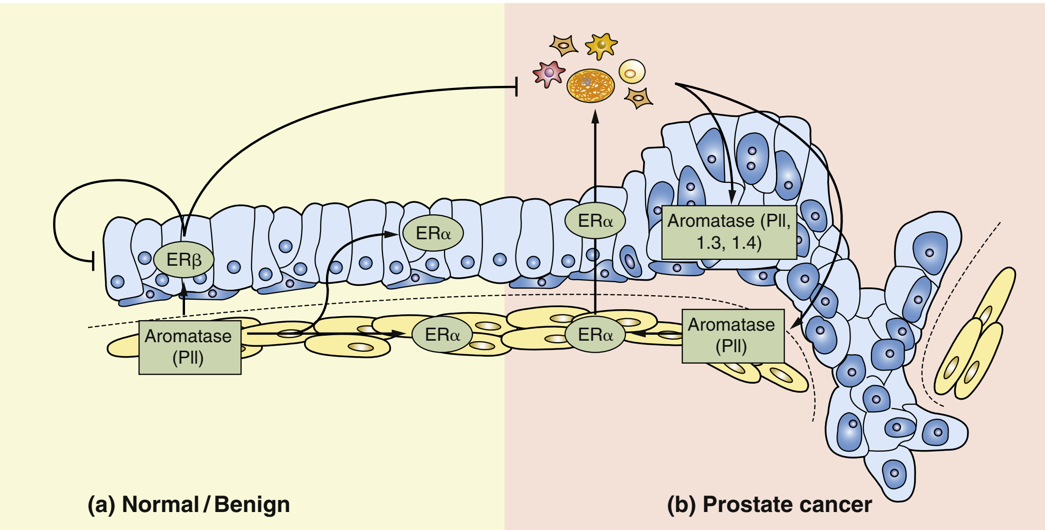
A



B

FIGURE 25-15 Sources of Androgens and Aromatase and Estrogen Signaling in the Prostate. **A,** Body sources of androgens in the prostate gland. Hypothalamic GnRH causes the release of LH from the anterior pituitary gland. LH stimulates the testes to produce testosterone, which then accumulates in the blood. Pituitary ACTH release stimulates the adrenal glands, which secrete the androgen precursor DHEA into the blood. DHEA is converted into testosterone and then into DHT in the prostate. **B,** Aromatase and estrogen signaling in the prostate. In normal and benign tissue, aromatase is expressed within the stroma and regulated by promoter PII. Estrogen then exerts its effects in an autocrine fashion through the stromal ER-α receptor and also in a paracrine fashion through both ER-α and ER-β receptors. With prostate cancer, aromatase is now expressed within the tumor cells and in stromal cells, and regulated by aromatase promoters 1.3, 1.4, and PII. Thus estrogen exerts its effects in an autocrine way through stromal and epithelial ER-α and ER-β. Consequently, the increased levels of estrogen and abnormal ER-α signaling promote inflammation, which increases aromatase expression and the development of a positive feedback cycle. Inflammation drives aromatase expression, thus increasing estrogen, which in turn promotes further inflammation. *ACTH,* Adrenocorticotropic hormone; *DHEA,* dehydroepiandrosterone; *DHT,* dihydrotestosterone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone. (**A** adapted from Labrie F: *Nat Rev Urol* 8:73-80, 2011; **B** from Ellem SJ, Risbridger GP: *J Steroid Biochem Mol Biol* 118[4-5]:246–251, 2010.)

and estrogens appear to be higher in men of African descent than in European-American men.

Despite the well-documented importance of androgens, their pathophysiologic process in prostate diseases is incomplete.[65] Androgens also are metabolized to estrogens (see Figures 25-17 and 24-35) through the action of the enzyme aromatase, and a growing body of evidence implicates estrogens in the etiology of prostate disease (see Pathogenesis section). Importantly, the aberrant expression of aromatase has been implicated in other tissues, such as the breast and endometrium.[65]

Only a few associations with prostate cancer risk have been observed consistently (in at least three studies), and their associations are weak: (1) slightly higher circulating testosterone and estrogen levels and lower DHEA (sulfate) levels in high-risk black men as compared with lower-risk European-American men; and (2) a cytosine-adenine-guanine (CAG) repeat-length polymorphism in the androgen-receptor gene associated with increased risk and increased receptor activity (androgen receptor). Moreover, in a more recent collaborative analysis of existing worldwide epidemiologic data (18 prospective studies), the Endogenous Hormones and Prostate Cancer Collaborative Group found no associations between the risk of prostate cancer and serum concentrations of testosterone, calculated free testosterone, dihydrotestosterone, dehydroepiandrosterone sulfate, androstenedione, androstanediol glucuronide, estradiol, or calculated free estradiol.[67]

As the results of the above-mentioned Endogenous Hormones and Prostate Cancer Collaborative Group suggest, investigations directed at understanding the hormonal basis of prostate carcinogenesis have numerous problems. The complexities of interacting hormones and separating out the effects of a single hormone are profound. In addition, only single *blood* samples are generally available, *tissue* hormone samples important for paracrine signaling are not consistently measured, and within-subject variations over time and differences in circadian rhythms cannot be adequately measured. The results of several animal studies do support elevation of bioavailable and bioactive androgens in the circulation and in target tissue as an important risk factor. Animal studies also indicate that increased biologic activity of the androgen receptor may be associated with prostate cancer. See the Pathogenesis section for a more thorough discussion of the role of hormones in the pathogenesis of prostate cancer.

Vasectomy. Vasectomy has been identified as a possible risk factor for prostate cancer in case-controlled and cohort studies.[68-70] Three mechanisms by which vasectomy could increase risk are (1) elevation of circulating androgens; (2) immunologic mechanisms involving antisperm antibodies; and (3) reduction of seminal fluid levels of 5α-dihydrotestosterone, the active metabolite of testosterone in the prostate, in vasectomized men. These results suggest an elevation of circulating free testosterone following vasectomy. However, with these combined mechanisms it is unlikely that vasectomy plays a causal role.[71]

Chronic Inflammation. Data from the Medical Therapy of Prostatic Symptoms (MTOPS) study suggest the risk of BPH progression and acute urinary retention is greater in men with prostatic inflammation.[72,73] In certain mouse models prostatic hyperplasia is associated with inflammation.[74] The results of a 5-year longitudinal study of the influence of chronic inflammation and prostate cancer have been reported.[75] The study included 144 men, 33 of whom presented with chronic inflammation in their initial biopsy. Biopsies revealed prostatic hyperplasia and proliferative inflammatory atrophy in those with chronic inflammation. Upon repeat biopsy, 29 new cancers were diagnosed, representing a new cancer incidence of 20%.[75] In contrast, of the 33 men initially showing no inflammation, 2 (6%) were found to have adenocarcinoma. Certain metabolic comorbidities, including obesity, diabetes, sleep apnea, and erectile dysfunction may be linked to both BPH and inflammation.[76] The causes of chronic inflammation are unknown (possible causes are shown in Figure 25-16). Thus chronic inflammation may be an important risk factor for prostatic adenocarcinoma.

Genetic and Epigenetic Factors. Other possible causes are genetic predisposition (familial and hereditary forms). Genetic studies suggest that strong familial predisposition may be responsible for 5% to 10% of prostate cancers.[1] Compared with men with no family history, those with one first-degree relative with prostate cancer have twice the risk and those with two first-degree relatives have five times the risk.[77] Germline mutations in the breast cancer predisposition gene 2 *(BRCA2)* are the genetic events known to date that confer the highest risk of prostate cancer (8.6-fold in men ≤65 years). Although the role of *BRCA2* and *BRCA1* in prostate tumorigenesis remains unrevealed, deleterious mutations in both genes have been associated with more aggressive disease and poor clinical outcomes.[78] Men with *BRCA2* germline mutations have a 20-fold increase in risk for prostate cancer. Using previously estimated population carrier frequencies, investigators have recently found that deleterious *BRCA1* mutations confer a relative risk of prostate cancer of approximately 3.75-fold, translating to an 8.6% cumulative risk by age 65.[79] A common type of somatic mutation that gives rise to chromosomal rearrangements is the *ETS* gene. The most common epigenetic alteration in prostate cancer is hypermethylation of the glutathione S-transferase *(GST-P1)* gene. This gene is located on chromosome 11 and is part of the pathway that helps protect against carcinogen damage. More than 30 independent peer reviewed studies have reported a consistently high sensitivity and specificity of *GST-P1* hypermethylation in prostatectomy or biopsy tissue.[80] A number of other epigenetic modifications found on tumor suppressor genes include *PTEN, RB, p16/INK4a, MLH1, MSH21,* and *APC*.[81,82] There is no clear evidence of a causal link between BPH and prostate cancer even though they may often occur together. Variations in several other genes related to inflammatory pathways might affect the probability of developing prostate cancer.[83]

PATHOGENESIS. More than 95% of prostatic neoplasms are adenocarcinomas[84] and most occur in the periphery of the prostate. Prostatic adenocarcinoma is a heterogeneous group of tumors with a diverse spectrum of molecular and pathologic characteristics and therefore clinical behaviors and challenges.[85]

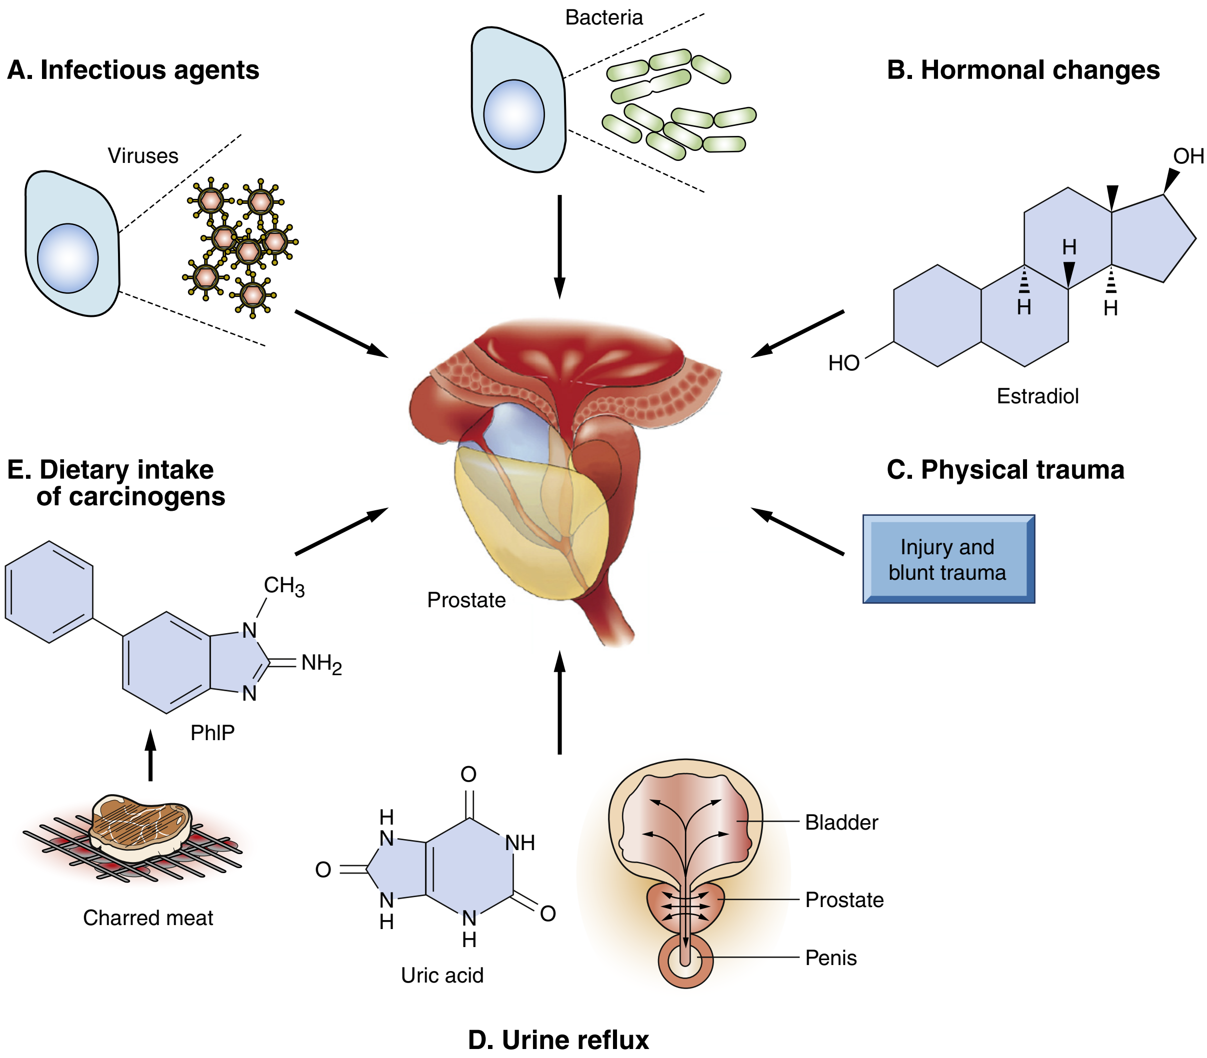


FIGURE 25-16 **Possible Causes of Prostate Inflammation. A,** Infection, including viruses, bacteria, fungi, and parasites. **B,** Hormones, for example, estrogen at key times during development. **C,** Physical trauma, any type of blunt physical injury. **D,** Urine reflex. **E,** Certain dietary factors (see text).

The biologic aggressiveness of the neoplasm appears to be related to the degree of differentiation rather than the size of the tumor (Box 25-6).

Hormonal. Just as the testicles are the male equivalent of the female ovaries, the prostate is the male equivalent of the female uterus; in both situations they originate from the same embryonic cells. This may be important in understanding the role of the associated hormones testosterone (T), DHT, and estrogens in prostate carcinogenesis. Testicular testosterone synthesis and serum testosterone levels fall as men age, remaining unchanged or increasing with age; however, the levels of estradiol do not decline.[86,87] The relationship between hormones and the pathophysiology of prostate carcinogenesis is incomplete and controversial. The main issues and controversies include: (1) sources of androgen production outside of the testes, or extratesticular sources (e.g., from adrenal DHEA and from prostate cholesterol [de novo], itself); (2) the role of prostatic androgen receptor (AR); (3) the role of estrogens, aromatase enzyme, and the

BOX 25-6 DETERMINING THE GRADE OF PROSTATE CANCER WITH THE GLEASON SCORE

Grade 1: The cancer cells closely resemble normal cells. They are small, uniformly shaped, evenly spaced, and well differentiated (i.e., they remain separate from one another).

Grade 2: The cancer cells are still well differentiated, but they are arranged more loosely and are irregular in shape and size. Some of the cancer cells have invaded the neighboring prostate tissue.

Grade 3: This is the most common grade. The cells are less well differentiated (some have fused into clumps) and are more variable in shape.

Grade 4: The cells are poorly differentiated and highly irregular in shape. Invasion of the neighboring prostate tissue has progressed further.

Grade 5: The cells are undifferentiated. They have merged into large masses that no longer resemble normal prostate cells. Invasion of the surrounding tissue is extensive.

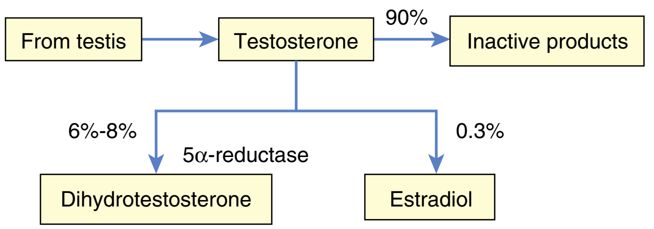

FIGURE 25-17 Testosterone and Conversion to Dihydrotestosterone (DHT).

estrogen receptors (ERs) ER-α and ER-β; and (4) the role of the surrounding microenvironment or stroma.

Testicular testosterone provides the main source of androgens in the prostate (see Figure 25-15) and is the major circulating androgen, whereas DHT predominates in prostate tissue and binds to the AR with greater affinity than does T.[88] The adrenal cortex contributes the far less potent DHEA that promotes synthesis of androgens in the prostate. In the target tissues and, to a lesser extent, in the testes themselves, testosterone is converted to DHT by the enzyme 5α-reductase (Figure 25-17). Thus DHT is the most potent intraprostatic androgen. About half of circulating testosterone is bound to sex hormone–binding globulin (SHBG), about half binds to albumin, and about 1% to 2% exists in a free state. Free testosterone, including testosterone disassociated from albumin and possibly SHBG, enters the prostate cell, where it is converted to DHT.[88] DHT is a paracrine hormone because it affects the local environment or stroma. Several intraprostatic enzymes encoded by genes, *HSD3A* and *HDS3B*, are activated by DHT and are important components of intraprostatic androgen regulation. The conjugated byproduct, 3α-androstenediol glucuronide (AAG), a terminal metabolite of DHT, can be measured in the circulation and used as an indicator of DHT levels.

Accumulating evidence shows that estrogens participate in the pathogenesis and development of BPH and prostate cancer by activating estrogen receptor-α. In contrast, estrogen receptor-β is involved in the differentiation and maturation of prostatic epithelial cells, and thus possesses antitumor effects in prostate cancer.[89] The effect of estrogen is determined by the two receptors ER-α and ER-β. ER-α leads to abnormal proliferation, inflammation, and the development of premalignant lesions. In contrast, ER-β leads to antiproliferative, anti-inflammatory, and potentially anticarcinogenic effects that act in concert or balance the actions of ER-α and androgens.[87] Increased expression of ER-α has been found to be associated with prostate cancer progression, metastasis, and the so-called castration-resistant (medical treatment that suppresses androgens) phenotype.[90] A specific oncogene is regulated by ERs, and those hormones that stimulate the ER-α receptor–like (i.e., agonists) endogenous estrogens can stimulate oncogene expression.[91]

Normally a small amount of estrogen is produced per day—estrone and estradiol—by the aromatization of androstenedione and testosterone, respectively. This reaction is catalyzed by the enzyme system aromatase. A small quantity of estradiol is released by the testes (see Figure 25-17); the rest of the estrogens in males are produced by adipose tissue, liver, skin, brain, and other nonendocrine tissue. Thus testosterone is a precursor of the two hormones, DHT and estradiol.

Studies show aromatase is expressed in stromal tissue in the benign human prostate gland.[92] Thus it appears that both normal prostate and benign prostate have the capacity to locally metabolize androgens to estrogens through aromatase. Investigators have demonstrated altered aromatase expression in prostate cancer[87,92] (see Figure 25-15, *B*).

Chronic exposure to arsenic, as well as estrogen, is a known risk factor for prostate cancer. Though the evidence suggests that exposure to arsenic or estrogens can disrupt normal DNA methylation patterns and histone modifications, the mechanisms by which these chemicals induce epigenetic changes are not fully understood. Moreover, the epigenetic effects of coexposure to these two chemicals are little known. Investigators have revealed that exposure to arsenic, estrogen, and their combination alters the expression of epigenetic regulatory genes and changes global DNA methylation and histone modification patterns.[93]

Most of the androgen-metabolizing enzymes undergo a significant age-dependent alteration. In epithelium, both the 5α-reductase activity and the DHT level decrease with age, whereas in stroma (prostate), not only the 5α-reductase activity but also the stromal DHT level is rather constant over the lifetime. In contrast to the relatively unaltered DHT level over time, the estrogen concentration follows an age-dependent increase. Thus the age-dependent decrease of the DHT accumulation in epithelium and the concomitant increase of the estrogen accumulation in stroma lead to a tremendous increase with age of the estrogen/androgen ratio in the human prostate. In animal studies chronic exposure to testosterone plus estradiol is strongly carcinogenic, whereas testosterone alone is weakly carcinogenic.[64] In mice studies elevated testosterone level in the absence of estrogen leads to the development of hypertrophy and hyperplasia but not malignancy. High estrogen and low testosterone levels have been shown to lead to inflammation with aging and the emergence of precancerous lesions.[87] The mechanism is not clearly understood and may involve estrogen-generated oxidative stress and DNA toxicity, and it requires androgen-mediated and estrogen receptor–mediated processes, such as changes in sex steroid metabolism and receptor status.[64] In addition, there are changes in the balance between autocrine/paracrine growth-stimulatory and growth-inhibitory factors, such as the IGFs.[94] When exogenous estradiol is added to testosterone treatment of rats, prostate cancer incidence is markedly increased, and even a short course of estrogen treatment results in a high incidence of prostate cancer.[64]

Androgen Receptor Signaling. The androgenic hormone responses in the normal prostate and prostate cancer are mediated by AR signaling. Exactly how AR drives the growth of prostate cancer cells is not fully known. Several mechanisms have been suggested,[95] and specific pathways of signaling are important because they can provide novel therapeutic targets. A study using animal models found that loss of androgen receptor function prevented prostatic carcinogenesis, malignant transformation, and metastasis. Tissue-specific evaluation of androgen hormone action demonstrated that epithelial androgen receptor was not necessary for prostate cancer progression, whereas stromal

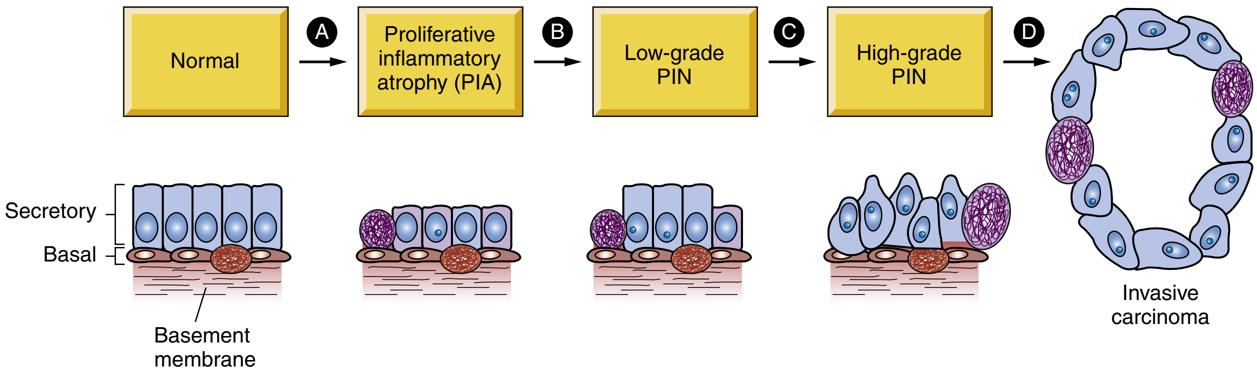

FIGURE 25-18 Cellular and Molecular Model of Early Prostate Neoplasia Progression. **A,** This stage includes infiltration of lymphocytes, macrophages, and neutrophils caused by repeated infections, dietary factors, urine reflux, injury, onset of autoimmunity (which triggers inflammation), and wound healing. **B,** Epigenetic alterations mediate telomere shortening. **C,** Genetic instability and accumulation of genetic alterations. **D,** Continued proliferation of genetically unstable cells leading to cancer progression. *PIN,* Prostatic intraepithelial neoplasia.

androgen receptor was essential for prostate cancer progression, malignant transformation, and metastasis.[96]

Prostate Epithelial Neoplasia. A precursor lesion, prostatic epithelial neoplasia (PIN), has been described. PIN may be more concentrated in prostates containing cancer and is noted in proximity to cancer.[81] However, the final fate of PIN is unknown, including the possibilities of latency, invasion, and even regression. The current working model of prostate carcinogenesis suggests that repeated cycles of injury and cell death occur to the prostate epithelium as a result of damage (i.e., from oxidative stress) from inflammatory responses.[97] The direct injury is hypothesized as a response to infections; autoimmune disease; circulating carcinogens or toxins, or both, from the diet; or urine that has refluxed into the prostate (see Figure 25-16). The resultant manifestation of this injury is focal atrophy or prostatic intraepithelial atrophy (PIA). Biologic responses cause an increase in proliferation and a massive increase in epithelial cells that possess a phenotype intermediate between basal cells and mature luminal cells (Figure 25-18).[97] In a small subset of cells, some may contain "stem cell" or tumor-initiating properties and telomere shortening (see Chapter 12). A subset of PIN cells may activate telomerase enzyme, causing the cells to become immortal.[98] Molecular, genetic, and epigenetic changes can increase genetic instability that might progress to high-grade PIN and early prostate cancer formation. This model of prostate carcinogenesis needs much more research.

Stromal Environment. The prostate gland is composed of secretory luminal epithelium, basal epithelium, neuroendocrine cells, and various cell types comprising supportive tissue or stroma. **Stroma,** or tissue microenvironment, produces autocrine/paracrine factors, as well as structural supporting molecules that help regulate normal cell behavior and organ homeostasis.[99] **Fibroblasts** are the most important cells during the reconstructive phase of wound healing (see Chapter 7). The collagen and connective tissue proteins produced by fibroblasts are deposited in wounded areas after fibroblasts have entered the lesion. Thus their presence is a signature of alterations in the stroma. Reactive tumor stroma is associated with an increased number of fibroblasts, increased capillary density, and collagen and fibrin deposition. These findings suggest that alteration in the prostate microenvironment, mediated by changes associated with aging or senescence, or both, promote epithelial responses that contribute to diseases. In animal studies, investigators have noted that the microenvironment has an increased number of cells that promote inflammation and a collapsed appearance of the smooth muscle cells within adjacent glandular stroma.[99] Fibroblast spreading has been proposed as indicative of decreased mechanical tension because of a lack of direct association of the fibroblasts with aged fragmented collagen fibrils.[100,101] These alterations in mechanical tension and cell shape are suggested as determinants in altering gene expression and cellular function. These alterations in aged prostate stroma for mice and men include significant enhancement for inflammation pathways (e.g., NF-κβ, collagens).[100,101] Inflammation can induce cell stress, and stressed mesenchymal cells can secrete inflammatory mediators (chemoattractants); however, it remains to be determined whether inflammatory infiltrates are a cause of or response to the alterations of aged stroma.[102] Evidence supports that inflammation has a role in the pathogenesis of prostate cancer.[97,103] Investigators have found that disruption of fibroblast growth factor signaling pathways leads to strongly activated and atypical stroma that preceded the development of mice PIN (mPIN).

Epithelial-mesenchymal transition (EMT) was first described in embryonic development, and is observed in a number of solid tumors[104] (also see Chapter 12). Cells that undergo EMT become more migratory and invasive and gain access to vascular vessels.[105] Numerous studies have shown that these transition states (EMT and mesenchymal-epithelial transition [MET]) are a consequence of tumor-stromal interactions.[105,106]

Investigators studying prostate cancer cells in vitro correlated EMT with increased growth, migration, and invasion. These investigators demonstrated that the microenvironment is a critical site for the transition of human prostate cancer cells from epithelial to mesenchymal structure, resulting in increased metastatic potential for bone and adrenal gland.[107]

Prostate cancer is known to be diverse and composed of multiple genetically distinct cancer cell clones. Studies, however,

indicate that most metastatic cancers arise from a single precursor cancer cell.[108] Various research models have been proposed to understand EMT (MET) and invasion and metastases.[109]

In summary, the following multifactorial general hypothesis of prostate carcinogenesis emerges from all of these observations: (1) androgens act as strong tumor promoters through androgen receptor–mediated mechanisms to enhance the carcinogenic activity of strong endogenous DNA toxic carcinogens, including reactive estrogen metabolites and estrogen, and prostate-generated reactive oxygen species; (2) alterations in autocrine/paracrine growth-stimulating and growth-inhibiting factors between the prostate tumor cells and microenvironment influence cancer pathogenesis; and (3) possibly unknown environmental-lifestyle carcinogens may contribute to prostate cancer. All of these factors are modulated by diet and genetic determinants, such as hereditary susceptibility genes and polymorphic genes, which encode receptors and enzymes involved in the metabolism and action of steroid hormones.[64]

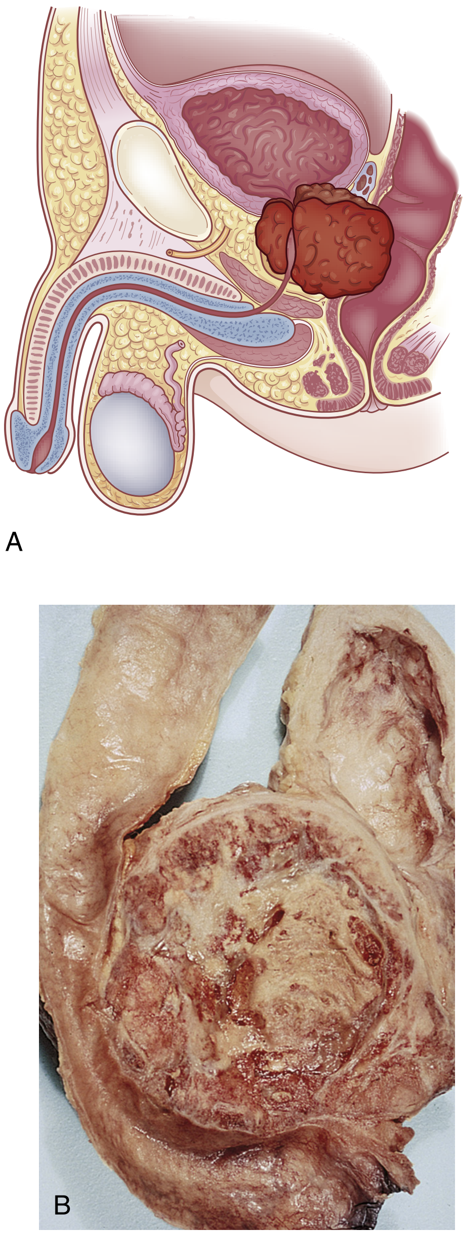

FIGURE 25-19 Carcinoma of the Prostate. **A,** Schematic of carcinoma of the prostate. **B,** Carcinoma of the prostate extending into the rectum and urinary bladder. (**B** from Damjanov I, Linder J, editors: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

The most common sites of distant metastasis are the lymph nodes, bones, lungs, liver, and adrenals. The pelvis, lumbar spine, femur, thoracic spine, and ribs are the most common sites of bone metastasis. Local extension is usually posterior, although late in the disease the tumor may invade the rectum or encroach on the prostatic urethra and cause bladder outlet obstruction (Figure 25-19). The spread of cancer through blood vessels is illustrated in Figure 25-20.

CLINICAL MANIFESTATIONS. Prostatic cancer often causes no symptoms until it is far advanced. The first manifestations of disease are those of bladder outlet obstruction: slow urinary stream, hesitancy, incomplete emptying, frequency, nocturia, and dysuria. Unlike the symptoms of obstruction caused by BPH, the symptoms of obstruction caused by prostatic cancer are progressive and do not remit. Local extension of prostatic cancer can obstruct the upper urinary tract ureters as well. If rectal obstruction occurs, a man may experience a large bowel obstruction or difficulty in defecation. Symptoms of late disease include bone pain at sites of bone metastasis, edema of the lower extremities, enlargement of lymph nodes, liver enlargement, pathologic bone fractures, and mental confusion associated with brain metastases.

EVALUATION AND TREATMENT. Screening for prostatic cancer includes DRE, PSA blood tests, and TRUS. The most significant test used in the diagnosis and management of prostate cancer is **prostate-specific antigen (PSA).** DRE may detect early prostatic carcinomas but is has low sensitivity and specificity.[81] Cancer diagnosis is confirmed through tissue biopsy and microscopic examination of tissue. Lymphography, bone scans, MRI, and CT scans also may be used to determine metastasis to lymph, bone, or other adjacent tissue. Important for treatment is to accurately measure the size of the index (longest) tumor and its percentage Gleason grade of differentiation.[110]

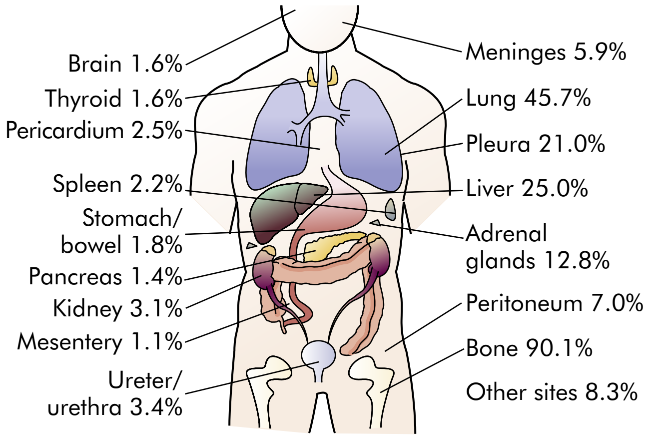

FIGURE 25-20 Distribution of Hematogenous Metastases in Prostate Cancer. Study of 556 individuals with metastatic prostate cancer. (Adapted from Budendorf L et al: *Hum Pathol* 31:578, 2000.)

PSA screening for prostate cancer has led to considerable controversy. A review of the evidence for the U.S. Preventive Services Task Force regarding screening for prostate cancer concluded that PSA-based screening results in small or no reduction in prostate cancer–specific mortality and is associated with harms related to subsequent evaluation and treatments, some of which may be unnecessary (See What's New? Summary of the American College of Physicians (ACP) Guidance Statement on Screening for Prostate Cancer).[111] Convincing evidence demonstrates that the PSA test unfortunately often produces false-positive results. Men who have a false-positive test are more likely to have additional testing, including one or more biopsies. Over a 10-year span, approximately 15% to 20% of men will have a PSA test result that triggers a biopsy, depending on the PSA threshold and testing interval used.[55] In addition, because PSA is organ specific and not cancer specific, it can increase and overlap with BPH, prostatitis, infarct, manipulation from instrumentation, and ejaculation.[81] The annual rate by which PSA rises is known as **PSA velocity** or doubling time (generally described as *PSA kinetics*). Its calculation has been judged to be far from straightforward. More than 20 different methods for calculation have been proposed, and many of these give divergent results. Evidence clearly shows that PSA kinetics are critical for understanding prognosis in advanced or relapsed prostate cancer. However, PSA kinetics have questionable value for men with an untreated prostate; neither PSA velocity nor doubling time has an established role in diagnosing prostate cancer or providing a prognosis for men before treatment.[112] In fact, investigators recently evaluated guidelines on the use of PSA velocity in prostate cancer detection and found that change in PSA levels over time is such a poor predictor of prostate cancer (in a previously untreated prostate) that it is highly likely many unnecessary biopsies have been performed.[113] It is thus somewhat doubtful at this juncture that PSA velocity adds any additional predictive accuracy to PSA alone or positive digital rectal examination, or both, for purposes of prostate cancer screening.

Older age is the strongest risk factor for the development of prostate cancer. However, neither screening nor treatment trials show benefit in men older than 70 years. Across age ranges, black men and men with a family history of prostate cancer have an increased risk of developing and dying of prostate cancer. Black men are approximately twice as likely to die of prostate cancer than other men in the United States and the reason for this disparity in unknown. Black men represent a very small minority of participants in randomized clinical trials of screening and, thus, no firm conclusions can be made about the balance of benefits and harms of PSA-based screening in this population. As such, it is a questionable practice to selectively recommend PSA-based screening for black men in the absence of data that support a more favorable balance of risks and benefits.[55] The ability to predict cancer rises significantly when TRUS is added to the annual DRE and PSA testing. Researchers are studying microRNAs as potential new biomarkers for prostate cancer.

Prostate cancer is now detected in greater numbers at lower stages of disease and is amenable to multiple forms of efficacious treatment. However, there is a lack of conclusive data demonstrating a definitive mortality benefit from this earlier diagnosis and treatment of prostate cancer. This is likely because of the treatment of a large proportion of indolent cancers that would have had little adverse effect on health or life span if left alone (Box 25-7).

Because of this "overtreatment" phenomenon, active surveillance with delayed intervention is gaining traction as a viable management approach in contemporary practice. The ability to distinguish clinically insignificant cancers from those with a high risk of progression or lethality, or both, is critical to the appropriate selection of surveillance protocols versus immediate intervention[114] (Box 25-8). The most important observation for pathologists to make to facilitate cure of any individual of prostate cancer is that of accurately measuring the size of the index (longest) tumor and Gleason score (degree of differentiation) (see Box 25-6).[115]

Treatment of prostatic cancer depends on the stage of the neoplasm (see Box 25-6); the anticipated effects of treatment; and the age, general health, and life expectancy of the individual. Options include no treatment; surgical treatments such as total prostatectomy, transurethral resection of the prostate (TURP), or cryotherapy; nonsurgical treatments such as radiation therapy, hormone therapy, or chemotherapy; watchful waiting; and any combination of these.[55] In addition, new approaches are using immunotherapy. Palliative treatment is aimed at relieving urinary, bladder outlet, or colon obstruction; spinal cord compression; and pain. Prognosis and survival rates have improved steadily since the early 1960s. According to the most recent data, 10- and 15-year relative survival rates are 98% and 91%, respectively.[1]

Treatment for prostate cancer may lead to loss of urinary control, which may or may not return to normal after several weeks or months. Stress incontinence can occur after surgery, and mild urge incontinence can occur after radiation therapy. Prostate cancer and its treatment can affect sexual functioning. Sensation of orgasm is not usually affected, but smaller amounts of ejaculate will be produced or men may experience a "dry" ejaculate because of retrograde ejaculation.

BOX 25-7 RETHINKING SCREENING FOR PROSTATE CANCER AND BREAST CANCER

In essence, it has become necessary to rethink screening for both prostate and breast cancer because since screening was introduced, the incidence of both prostate and breast cancer increased and never returned to prescreening levels, and the absolute number of advanced prostate and breast cancers diagnosed during this period has not decreased as predicted. Furthermore, whereas colon and cervical cancer screening detects precancerous treatable conditions, prostate and breast cancer screening detects so-called early cancers that may not be destined to grow or become lethal. Thus it is possible that prostate and breast cancer screening may be increasing the burden of low-risk cancers without any significant reduction of burden associated with aggressive lesions, thereby not resulting in the anticipated reduction in breast and prostate cancer mortality.

Data from Esserman L, Shieh Y, Thompson I: *J Am Med Assoc* 302(15):1685–1920, 2009.

WHAT'S NEW?

Summary of the American College of Physicians (ACP) Guidance Statement on Screening for Prostate Cancer

Disease or condition	Prostate cancer
Target audience	Internists, family physicians, other clinicians
Target patient population	All men
Screening tests	DRE and PSA
Interventions	Strategies to manage prostate cancer
Outcomes	Mortality and morbidity
Indications for discussing screening	• Men between the age of 50 and 69 years of age • Earlier age in men who are at increased risk for prostate cancer (African American race and first-degree relative (father or brother diagnosed with prostate cancer, especially before age 65 years)
Frequency of screening	• No clear evidence guides the periodically or frequency of screening • No clear evidence that PSA screening more frequently than every 4 years produces any additional benefit • PSA levels of 2.5 μg/L or greater may warrant yearly evaluation
Benefits of screening	Reduction in mortality
Harms of screening	• False alarms related to number of high false-positive results associated with DRE and especially PSA • High false-negative rates • Overdiagnosis (detection of cancer that is not destined to cause future morbidity and mortality) • Overtreatment and associated harms, including bleeding, pain, and hospitalization • Anxiety and discomfort • Positive screening results may lead to further testing, such as biopsies, which not only can be painful but also can lead to complications, such as infections
Recommendations	• *Guidance statement 1:* ACP recommends that clinicians inform men between the age of 50 and 60 years about the limited potential benefits and substantial harms of screening for prostate cancer. ACP recommends that clinicians base the decision to screen for prostate cancer using the prostate-specific antigen test on the risk for prostate cancer, a discussion of the benefits and harms of screening, the man's general health and life expectancy, and preferences. ACP recommends that clinicians should not screen for prostate cancer using the prostate-specific antigen test in men who do not express a clear preference for screening. • *Guidance statement 2:* ACP recommends that clinicians should not screen for prostate cancer using the prostate-specific antigen test in average-risk men under the age of 50 years, over the age of 69 years, or men with a life expectancy of less than 10 to 15 years. • Prostate cancer screening with the PSA test is controversial.

Talking points with patients	• PSA screening can detect prostate cancer, but for most men, the chances of harm from screening with the PSA test outweigh the chances of benefit.
	• A small number of prostate cancer cases are serious and can cause death; however, the vast majority of prostate cancer is slow-growing and does not cause death.
	• Most men who choose not to have PSA testing will not be diagnosed with prostate cancer and will die of something else.
	• Men who choose PSA testing are much more likely than those who decline PSA testing to be diagnosed with prostate cancer.
	• The PSA test often does not distinguish between cancer cases that are serious and those cases that are not serious; however, men with markedly elevated PSA levels (>10μg/L) may have a reduced chance of dying from prostate cancer by having surgical treatment.
	• The small potential benefit of prostate cancer screening corresponds to preventing, at most, 1 death caused by prostate cancer per 1000 men screened after 11 years of follow-up.
	• The potential harms of screening include:
	  • Problems interpreting test results: the PSA test result may be high because of an enlarged prostate but not because of cancer, or it may be low even though cancer is present.
	  • If a prostate biopsy is needed, it, too, is not free from risk—the biopsy involves multiple needles being inserted into the prostate under local anesthesia, and there is a risk for infection or significant bleeding as well as risk for hospitalization (1.4%).
	  • If cancer is diagnosed, it will often be treated with surgery or radiation, which are associated with risks; there is a small risk for death with surgery, loss of sexual function (approximately 37% higher risk), and loss of control of urination (approximately 11% higher risk) compared with no surgery; these risks may vary depending on the man's and surgeon's characteristics and treatment method.
	  • The PSA test is not "just a blood test;" it is a test that can open the door to more testing and treatment that a man may not actually want and that may actually harm him; a man's chances of being harmed are much greater than his chances of benefitting from the PSA test; thus, each man should have the opportunity to decide for himself whether to have the PSA screening test.
	  • Studies are ongoing, so clinicians expect to learn more about the benefits and harms of screening, and recommendations may change over time; men also are welcome to change their minds at any time by asking for screening that they have previously declined or discontinue screening that they have previously requested.

DRE, digital rectal examination; *PSA*, prostate-specific antigen
Data from Qaseem A et al: *Ann Intern Med* 158(1):761, 2013.

BOX 25-8 PROSTATE SPECIFIC ANTIGEN–BASED SCREENING FOR PROSTATE CANCER

Why not screen for prostate cancer?

Screening may benefit a small number of men but will result in harm to many others. A person choosing to be screened should believe that the possibility of benefit is more important than the risk for harm. The U.S. Preventive Services Task Force assessment of the balance of benefits and harms in a screened population is that the benefits do not outweigh the harms.

What are the benefits and harms of screening 1000 men ages 55 to 69 years[1] with a prostate specific antigen (PSA) test every 1 to 4 years for 10 years?

Possible benefit of screening:	**Men, *n***
Reduced 10-year risk for dying of prostate cancer:	
Die of prostate cancer with no screening	5 in 1000
Die of prostate cancer with screening	4-5 in 1000
Do not die of prostate cancer because of screening	0-1 in 1000
Harms of screening:	
At least one false-positive screening PSA test result:	
Most positive test results lead to biopsy. Of men having biopsy, up to 33% will have moderate or major bothersome symptoms, including pain, fever, bleeding, infection, and temporary urinary difficulties; 1% will be hospitalized	100-120 in 1000
Prostate cancer diagnosis:	
Although a diagnosis of prostate cancer may not be considered a harm, currently 90% of diagnosed men are treated and thus are at risk for the harms of treatment. A large majority of the men who are being treated would do well without treatment. A substantial percentage of these men would have remained asymptomatic for life.	110 in 1000
Complications of treatment (among persons who are screened):[2]	
Develop serious cardiovascular events because of treatment	2 in 1000
Develop deep venous thrombosis or pulmonary embolus because of treatment	1 in 1000
Develop erectile dysfunction because of treatment	29 in 1000
Develop urinary incontinence because of treatment	18 in 1000
Die because of treatment	<1 in 1000

Data from Moyer VA, U.S. Preventive Services Task Force: *Ann Intern Med* 157(2):120–134, 2012. Also see Esserman L, Shieh Y, Thompson I: *J Am Med Assoc* 302(15):1685–1920, 2009 for further reading on this matter. A brief summary of the thinking of Esserman and colleagues is provided in the prostate cancer evaluation and treatment section (p. 908).

Calculations of the estimated benefits and harms rely on assumption and are, by nature, somewhat imprecise. Estimates should be considered in the full context of clinical decision making and used to stimulate shared decision making.

[1]The best evidence of possible benefit of PSA screening is in men ages 55 to 69 years.

[2]The rate of complications depends on the proportion of men having treatment and the method of treatment. The above reflects a distribution of 60% surgical treatment, 30% radiation treatment, and 10% observation. Other harms of radiation, such as bowel damage, are not shown.

Sexual Dysfunction

In men the normal sexual response involves three processes: erection, emission, and ejaculation. **Sexual dysfunction** is the impairment of any or all of these processes. Impairment can be caused by a number of physiologic and psychologic factors.

Until the late 1970s, most cases of male sexual dysfunction were thought to be psychogenic. Studies of this problem indicate that in men older than 40 years, organic factors are involved in more than 50% of cases. The causes of organic sexual dysfunction include: (1) vascular, endocrine, and neurologic disorders; (2) chronic disease, including renal failure and diabetes mellitus; (3) penile diseases and penile trauma; and (4) iatrogenic factors, such as surgery and pharmacologic therapies. Most of these disorders cause erectile dysfunction.

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS. Vascular disorders can prevent erection. Some arterial diseases diminish or interrupt circulation to the penis. This prevents engorgement of erectile tissues in the corpora cavernosa and corpus spongiosum. Rarely, excessive venous drainage of the corpora cavernosa prevents erection.

Endocrine disorders that reduce testosterone production affect sexual function and libido. The reduction may be caused by inadequate secretion of the gonadotropins caused by pituitary dysfunction or hyperprolactinemia. Feminizing tumors and estrogen therapy reduce relative levels of testosterone. Testicular atrophy from any cause also decreases testosterone levels and contributes to sexual dysfunction.

Neurologic disorders can interfere with the important sympathetic, parasympathetic, and CNS mechanisms required for erection, emission, and ejaculation. They include spinal cord injury or tumor, multiple sclerosis, and disorders that cause peripheral neuropathies, such as diabetes mellitus and chronic renal failure. Spinal cord injuries or tumors can alter one or more components of the sexual response, depending on the location of the lesion. For example, in most men with upper motor neuron lesions, reflexogenic erection is possible but emission and ejaculation (i.e., orgasm) are not possible. Lesions affecting the lower motor neurons usually prevent erection. In approximately 40% of such cases, emission and ejaculation are prevented.

Many chronic diseases are associated with sexual dysfunction. In some conditions the sexual dysfunction has a specific physiologic cause. Diabetes mellitus, for example, causes peripheral vascular and neurologic pathology that can lead to erectile dysfunction. Impotence occurs in about 50% of men

undergoing dialysis due to decreased testosterone levels, autonomic neuropathy, accelerated vascular disease, multiple medications, worsening of primary disease, and psychologic stress. Potency may be restored by successful renal transplantation, except in bilateral transplantation if arterial flow is diminished or interrupted. Cirrhosis of the liver, scleroderma, chronic debilitation, and cachexia also are known to cause impotence. Emotional and psychologic response to chronic illness, such as anxiety, depression, and loss of self-esteem, can affect sexual functioning. In other chronic conditions, sexual dysfunction is associated with low energy levels and loss of libido. The pathophysiologic mechanisms responsible for such changes are not known.

Priapism causes fibrosis of trabeculae (erectile tissues) within the corpora cavernosa, making erection difficult. The penile curvature caused by Peyronie disease does not make erection impossible but may make it extremely painful and intercourse impossible. Penile trauma can damage the erectile tissue, disrupt the posterior urethra, and disrupt the pudendal arteries or nerves.

Iatrogenic factors, including drugs and surgery, have a significant effect on erectile function. The following surgical procedures carry the risk of erectile dysfunction: radical pelvic surgery; radical prostatectomy; transurethral, suprapubic, or simple retropubic prostatectomy; and aortoiliac surgery. Erectile dysfunction is caused by the severing of small nerve branches that are essential for erection. Aortoiliac surgery, retroperitoneal lymphadenectomy, and sympathectomy cause the loss of ejaculation capacity in some individuals.

A few pharmacologic agents enhance the sexual response, but most have the opposite effect. Men who are taking antihypertensives, antidepressants, antihistamines, antispasmodics, sedatives or tranquilizers, barbiturates, diuretics, sex hormone preparations, narcotics, or psychoactive drugs may experience some degree of sexual dysfunction. Drug-induced sexual dysfunction consists of decreased desire, decreased erectile ability, or decreased ejaculatory ability. Ethyl alcohol may induce alcoholic neuropathy or increased estrogens because of hepatic dysfunction; marijuana depresses testosterone levels; and cigarette smoking contributes to vasoconstriction and venous leakage. A number of pharmacologic agents also diminish the quality or quantity of sperm. A few may cause priapism. Drugs can assist in maintaining an erection.

EVALUATION AND TREATMENT. Evaluation of sexual dysfunction includes a physical examination, with particular attention to the genitalia, prostate, and nervous system, and basic laboratory tests to identify the presence of endocrinopathies or other underlying disorders that can cause the dysfunction. If no physiologic cause is found and the condition does not improve with psychotherapy, the man is referred for further investigation of organic causes. Psychologic evaluation is indicated for younger men with a sudden onset of sexual dysfunction or men of any age who are able to achieve but not maintain an erection.

Sophisticated diagnostic techniques can be used to assess penile blood flow, erectile tissue anatomy, nervous system function, and occurrence of erection or emission during sleep (nocturnal emission). Penile blood flow is measured by Doppler techniques and penile arteriography. Corpus cavernosography, in which contrast material is injected into the corpora cavernosa, provides anatomic information about the erectile tissue of the penis. Neuropathic causes of sexual dysfunction are evaluated by measuring the speed of the bulbocavernosus reflex. Nocturnal penile tumescence monitoring measures the frequency of nocturnal erections. Depending on the equipment used, this information may be correlated to rapid eye movement (REM) or non-REM sleep.

Treatments for organic sexual dysfunction include medical and surgical interventions. Nonsurgical interventions include correction of underlying disorders, particularly drug-induced dysfunction and endocrinopathy-related (e.g., reduced testosterone associated with chronic renal failure) dysfunction. Vasodilators and cessation of smoking can benefit individuals with vasculogenic erectile dysfunction. Surgical interventions include penile implants, penile revascularization, and correction of other anatomic defects contributing to sexual dysfunction.

Impairment of Sperm Production and Quality

Spermatogenesis requires adequate secretion of FSH and LH by the pituitary; sufficient secretion of testosterone by the Leydig cells; sufficient function of the Sertoli cells, including secretion of androgen-binding protein, growth factors, inhibin B, and a number of other important (but poorly understood) peptides; and adequate spermatogonia.[32,116] The Leydig cells are located in the testicular interstitium *between* the tubules, and the Sertoli cells and spermatogonia are located *within* the seminiferous tubules. The Sertoli cells extend from the basement membrane to the lumen, display tight junctions between adjacent cells, and form the blood-testis barrier. Inadequate secretion of gonadotropins may be caused by hypothyroidism, hyperadrenocortisolism, hyperprolactinemia, or hypogonadotropic hypogonadism. In these situations gonadotropin levels are low because of feedback inhibition or idiopathic hyposecretion. In the absence of adequate gonadotropin levels, the Leydig cells are not stimulated to secrete testosterone and sperm maturation is not promoted in the Sertoli cells. Spermatogenesis depends not only on appropriate stimulation by the gonadotropins but also an appropriate response by the testes. Defects in testicular response to the gonadotropins result in decreased secretion of testosterone and inhibin B and, as a result of normal feedback mechanisms, high levels of circulating gonadotropins. In the absence of adequate testosterone levels, spermatogenesis is impaired. Newer research demonstrates the significance of inhibin B as an important marker of the competence of Sertoli cells and spermatogenesis. Inhibin B is strongly correlated with severity of spermatogenic effects. A positive correlation exists between serum inhibin B levels and sperm concentration and testicular volume, and lower levels have been associated with azoospermia, testicular disorders, and infertility.[116]

Impaired spermatogenesis also can be caused by genetic disorders (such as Klinefelter syndrome), myotonic dystrophy, or testicular trauma. Other conditions associated with impaired spermatogenesis include systemic illness, such as renal failure, hepatic disease, or sickle cell disease; exposure to gonadotoxins, such as chemotherapy or radiation; varicocele; and cryptorchidism.

Fertility is adversely affected if spermatogenesis is normal but the sperm are chromosomally or morphologically abnormal or are produced in insufficient quantities. Chromosomal abnormalities are caused by genetic factors and by external variables, such as exposure to radiation or toxic substances. Ongoing research using small ribonucleic acids (RNAs) is elucidating the molecular mechanisms regulating spermatogenesis.[117] A sperm count of 20 million sperm per milliliter of semen has been suggested as the minimum concentration required for fertility. Average fertile men have 50 to 100 million sperm per milliliter.[32]

Sperm motility is another important variable affecting fertility. Motility appears to be affected by the sperm's chemical environment, that is, the characteristics of semen. Prostatic dysfunction, excessive semen viscosity, presence of drugs or toxins in the semen, and presence of antisperm antibodies are associated with impaired sperm motility. Approximately 3% to 7% of infertile males have antisperm antibodies in their semen. Antisperm antibodies may develop as a result of epididymitis or other inflammation of the genitourinary tract, testicular injury or torsion, a previous vasectomy or biopsy, and cryptorchidism. Antisperm antibodies may be (1) cytotoxic antibodies, which attack sperm and reduce their number in the semen; or (2) sperm-immobilizing antibodies, which impair sperm motility and reduce their ability to traverse the endocervical canal. Intrinsic, biologic factors leading to the production of antisperm antibodies seem to play a greater role than extrinsic factors. The exact mechanism remains unclear.[32]

A male factor contributes to the cause of up to 50% of cases of infertility. As understanding of the male factor in infertility increases, evaluation becomes more complex and essential to appropriate treatment (Box 25-9). Treatment for impaired spermatogenesis involves correction of any underlying disorders and avoidance of radiation or toxins. Androgens, human gonadotropins, and antiestrogens (e.g., clomiphene citrate, tamoxifen citrate) may enhance spermatogenesis. Semen can be modified to improve sperm motility. If conception is desired, the semen is obtained by masturbation (or mechanical device),[32] after which it can be diluted, concentrated, or washed to remove antisperm antibodies. These alterations are followed by artificial insemination.

BOX 25-9 EVALUATION OF MALE PARTNER OF INFERTILE COUPLES

- Thorough history and physical, including imaging for varicocele
- Two semen analyses and quantification of serum FSH, LH, testosterone levels, and prolactin if indicated
- Semen and urethral cultures
- Serum assays or monoclonal antibody testing for white blood cells
- Immunobead monoclonal antibody test
- Postcoital testing of semen activity and function
- Sperm penetration assay
- Inhibin B assays or testicular biopsy
- Vasogram, TRUS, or other imaging studies

FSH, Follicle-stimulating hormone; *LH,* luteinizing hormone; *TRUS,* transrectal ultrasonography.

DISORDERS OF THE MALE BREAST

Gynecomastia

Gynecomastia is the overdevelopment of breast tissue in a male. Gynecomastia accounts for approximately 85% of all masses that develop in the male breast and affects 32% to 40% of the male population. If only one breast is involved, it is typically the left. Incidence is greatest among adolescents and men older than 50 years.

Gynecomastia results from hormonal alterations, which may be idiopathic or caused by systemic disorders, drugs, or neoplasms. It usually involves an imbalance of the estrogen/testosterone ratio, which can be altered in one of two ways. First, estrogen levels may be excessively high, although testosterone levels are normal, as in drug-induced and tumor-induced cases of hyperestrogenism. Second, testosterone levels may be extremely low although estrogen levels are normal, as is the case in hypergonadism. Gynecomastia also can be caused by alterations in breast-tissue responsiveness to hormonal stimulation. Breast tissue may have increased responsiveness to estrogen or decreased responsiveness to androgen. Alterations of responsiveness may cause many cases of idiopathic gynecomastia.

Besides puberty and aging, estrogen-testosterone imbalances are associated with hypogonadism, Klinefelter syndrome, and testicular neoplasms. Hormone-induced gynecomastia is usually bilateral. Pubertal gynecomastia is a self-limiting phenomenon that usually disappears within 4 to 6 months. Senescent gynecomastia usually regresses spontaneously within 6 to 12 months.

Systemic disorders associated with gynecomastia include obesity, cirrhosis of the liver, infectious hepatitis, chronic renal failure, chronic obstructive lung disease, hyperthyroidism, tuberculosis, and chronic malnutrition. It may be that these disorders ultimately alter the estrogen/testosterone ratio, initiating gynecomastia.

Gynecomastia is often seen in men receiving estrogen therapy, either in preparation for a sex-change operation or for prostatic carcinoma. Other drugs that can cause gynecomastia include digitalis, cimetidine, spironolactone, reserpine, thiazide, isoniazid, ergotamine, tricyclic antidepressants, amphetamines, vincristine, and busulfan. Gynecomastia is usually unilateral in these instances.

Malignancies of the testes, adrenals, or liver can cause gynecomastia if they alter the estrogen/testosterone ratio. Pituitary adenomas and lung cancer also are associated with gynecomastia.

PATHOPHYSIOLOGY. The breast enlargement consists of hyperplastic stroma and ductal tissue. Hyperplasia results in a firm, palpable mass, at least 2 cm in diameter located beneath the areola.

EVALUATION AND TREATMENT. The diagnosis of gynecomastia is based on physical examination. Identification and treatment of the cause are likely to be followed by resolution of the gynecomastia. The man should be taught to perform breast self-examination and is examined at 6- and 12-month intervals if the gynecomastia persists. All unilateral breast enlargement in men warrants an evaluation for malignancy; workup includes fine-needle aspiration, cytology, mammography, ultrasound, and biopsy.

Cancer

Male breast cancer (MBC) accounts for 1% of all male cancers and less than 1% of all breast cancers. Global incidence rates were generally less than 1 per 100,000 man-years in contrast to much higher rates in females (see Chapter 24). The highest incidence rate for MBC is in Israel with 1.24 per 100,000, and the lowest incidence rates for males (0.16) and females (18.0) were observed in Thailand.[118] It occurs most commonly after age 60, with the peak incidence between 60 and 69 years (men tend to be diagnosed at an older age than women). It has, however, been reported in males as young as 6 years and in adolescents. Klinefelter syndrome is the strongest risk factor for developing male breast carcinoma. Other risk factors include germline mutation in *BRCA1* or *BRCA2*, but familial cases usually have *BRCA2* rather than *BRCA1* mutations.[119-121] Obesity increases the risk of MBC. Testicular disorders, including cryptorchidism, mumps, orchitis, and orchiectomy are related to risk.[122] The relationship between these factors and risk of disease is not clearly defined.

Recent data on most frequent molecular subtypes of male breast cancer appear to be different than female breast cancers with Luminal A and Luminal B the most common subtypes and basal-like, unclassifiable triple-negative, and HER2-driven male breast cancer subtypes are rare.[123-125] The majority of MBCs express estrogen and progesterone receptors.[126] The malignant male breast lesion is usually a unilateral solid mass located near the nipple. Because the nipple is commonly involved, crusting and nipple discharge are typical clinical manifestations. Other findings include skin retraction, ulceration of the skin over the tumor, and axillary node involvement. Patterns of metastasis are similar to those in females.

The diagnosis of cancer is confirmed by biopsy. Because of delays in seeking treatment, male breast cancer tends to be advanced at the time of diagnosis and therefore tends to have a poor prognosis. Treatment protocols are similar to those for female breast cancer, but endocrine therapy is used more often for males because a higher percentage of male tumors are hormone dependent. The mainstay of treatment is modified mastectomy with axillary node dissection to assess stage and prognosis. Because 90% of tumors are hormonal receptor positive, tamoxifen is standard adjuvant therapy. For metastatic disease, hormonal therapy is the main treatment but chemotherapy also can provide palliation.[119]

SUMMARY REVIEW

Alterations of Sexual Maturation

1. Sexual maturation, or puberty, should begin in boys between 9 and 14 years of age. Delayed puberty is the onset of sexual maturation after these ages; precocious puberty is onset before these ages.
2. Alterations of sexual maturation can be idiopathic or caused by a disease or congenital anomaly. In most cases of delayed puberty, the hypothalamic-pituitary-gonadal (HPG) axis is intact but the surge of activity that stimulates puberty is delayed. This situation is common in boys. Precocious puberty also can be caused by mistiming of the stimulatory surge in a child whose HPG system is otherwise normal.
3. Precocious puberty can be complete (sex appropriate), mixed (not sex appropriate), or partial (development of one secondary sex characteristic only). Causes of delayed or incomplete puberty can be divided into categories based on gonadotropic secretion: hypergonadotropism (increased levels of FSH and LH), and hypogonadotropism (decreased LH and FSH levels).

Disorders of the Male Reproductive System

1. Disorders of the urethra include urethritis (inflammation of the urethra) and urethral strictures (narrowing or obstruction of the urethral lumen caused by scarring).
2. Although noninfectious urethritis can occur, most cases of urethritis result from sexually transmitted pathogens. Symptoms of urethritis include dysuria, frequency, urgency, urethral tingling or itching, and clear or purulent discharge. Treatment consists of appropriate antibiotic therapy and avoidance of future chemical or mechanical irritation.
3. Acquired or congenital scarring that causes urethral stricture can be caused by trauma or by severe or untreated urethral infection. The primary symptom is diminished force and caliber of the urinary stream; other symptoms include urinary frequency and hesitancy, mild dysuria, double urine stream or spraying, and postvoiding dribbling. Treatment is usually surgical.
4. Phimosis and paraphimosis are penile disorders involving the foreskin (prepuce). In phimosis the foreskin cannot be retracted over the glans. In paraphimosis the foreskin is retracted and cannot be returned to its normal anatomic position over the glans. Phimosis is caused by poor hygiene and chronic infection and can lead to paraphimosis. Paraphimosis can constrict the penile blood vessels, preventing circulation to the glans.
5. Peyronie disease consists of fibrosis, affecting the corpora cavernosa, which causes penile curvature during erection. Fibrosis prevents engorgement on the affected side, causing a lateral curvature that can prevent intercourse.
6. Priapism, a prolonged painful erection not stimulated by sexual arousal, is a urologic emergency. The corpora cavernosa (but not the corpus spongiosum) fills with blood that does not drain out, probably because of venous obstruction. Priapism is associated with spinal cord trauma, sickle cell disease, leukemia, and pelvic tumors. It can also be idiopathic and can occur with cocaine use.
7. Balanitis is an inflammation of the glans penis and usually occurs in conjunction with posthitis. It is associated with phimosis, inadequate cleansing under the foreskin, skin disorders, and infections.
8. Cancer of the penis is rare; major risk factors include HPV, smoking, and consequences of treatment for psoriasis. Penile carcinoma in situ tends to involve the glans; invasive carcinoma of the penis involves the shaft as well.

SUMMARY REVIEW—cont'd

9. A varicocele is an abnormal dilation of the veins within the spermatic cord caused by either congenital absence of valves in the internal spermatic vein or acquired valvular incompetence.
10. A hydrocele is a collection of fluid between the testicular and scrotal layers of the tunica vaginalis. Hydroceles can be idiopathic or caused by trauma or infection of the testes.
11. A spermatocele is a cyst located between the testis and epididymis that is filled with fluid and sperm.
12. Cryptorchidism is a congenital condition in which one or both testes fail to descend into the scrotum. Uncorrected cryptorchidism is associated with infertility and a significantly increased risk of testicular cancer.
13. Testicular torsion is the rotation of a testis, which twists blood vessels in the spermatic cord. This interrupts blood supply to the testis, resulting in edema and, if not corrected within 4 to 6 hours, necrosis and atrophy of testicular tissues.
14. Orchitis is an acute infection of the testes. Pathogenic organisms may reach the testes through the blood or the lymphatics; most commonly, they reach the testes by ascending through the vas deferens and epididymis. Complications of orchitis include hydrocele and atrophy. Granulomatous orchitis, an autoimmune disease, is a nonspecific, noninfectious, inflammatory process that occurs in middle-aged men.
15. Testicular cancer is the most common malignancy in males ages 15 to 35 years. Although its cause is unknown, high androgen levels, genetic predisposition, and a history of cryptorchidism, trauma, or infection may contribute to tumorigenesis. Most testicular neoplasms are germ-cell tumors.
16. Epididymitis, an inflammation of the epididymis, is usually caused by a sexually transmitted pathogen that ascends through the vasa deferentia from an already infected urethra or bladder.
17. BPH is enlargement of the prostate gland. This condition becomes symptomatic as the enlarging prostate compresses the urethra, causing symptoms of bladder outlet syndrome and urine retention.
18. Prostatitis is inflammation of the prostate. Prostate syndromes have been classified by the National Institutes of Health as: (a) acute bacterial prostatitis (ABP), (b) chronic bacterial prostatitis (CBP), (c) chronic pelvic pain syndrome (CPPS), and (d) asymptomatic inflammatory prostatitis.
19. Prostate cancer is the most common cancer in American men, and the incidence varies greatly worldwide. Possible causes include genetic predisposition, environmental and dietary factors, inflammation, and alterations in levels of hormones (testosterone, dihydrotestosterone, and estradiol) and growth factors. Incidence is greatest among northwestern European and North American men (particularly blacks) older than 65 years of age.
20. Most cancers of the prostate are adenocarcinomas that develop at the periphery of the gland.
21. Sexual dysfunction in males can be caused by any physical or psychologic factor that impairs erection, emission, or ejaculation.
22. Spermatogenesis (sperm production by the testes) can be impaired by disruptions of the HPG axis that reduce testosterone secretion and by testicular trauma or atrophy from any cause. Sperm production is also impaired by neoplastic disease, cryptorchidism, or any factor that causes testicular temperature to rise.
23. Sperm quality is impaired by chromosomal abnormalities resulting from genetic factors, irradiation, or toxins. Sperm motility can be impaired by unfavorable constituents or characteristics of semen.

Disorders of the Male Breast

1. Gynecomastia is the overdevelopment (hyperplasia) of breast tissue in a male resulting from hormonal alterations, which may be idiopathic or caused by systemic disorders, drugs, or neoplasms. It usually involves an imbalance of the estrogen/testosterone ratio.
2. Gynecomastia affects 32% to 40% of the male population. The incidence is greatest among adolescents and men older than 50 years.
3. Gynecomastia is caused by hormonal or breast tissue alterations that cause estrogen to dominate. These alterations can result from systemic disorders, drugs, neoplasms, or idiopathic causes.
4. Breast cancer is relatively uncommon in males, but it has a poor prognosis because men tend to delay seeking treatment until the disease is advanced. The incidence is greatest in men in their 60s.
5. Most breast cancers in men are estrogen positive.

- Review Questions and Answers

CHAPTER OUTLINE

Throughout recorded history, infectious diseases have threatened humans. Even into the twentieth century, epidemics of diphtheria, typhoid, tuberculosis, cholera, and other catastrophic infections have decimated entire communities almost overnight (see Chapter 10). Despite medical advances, improved living standards, and better nutrition, epidemics still arise as major public health problems, and some pose lethal threats to individuals and communities. Some of these epidemics are caused by sexually transmitted infections (STIs). At this time, many people consider the number of individuals with acquired immunodeficiency syndrome (AIDS), human immunodeficiency virus (HIV), and human papillomavirus (HPV) infections to be at epidemic levels.

Sexually contracted infections affect more than 19 million Americans per year (see What's New? Sexually Transmitted Infection [STI] Statistical Summary from 2010 CDC Report), and half of those are younger than 25 years[1] and account for about one third of the reproductive mortality in the United States. They have been called the "hidden epidemic" by the Centers for Disease Control and Prevention (CDC)[2] because of their stigma and overall lack of knowledge of the prevalence and consequences of sexually transmitted infections. Complications of STIs include pelvic inflammatory disease, infertility, ectopic pregnancy, chronic pelvic pain, neonatal morbidity and mortality, and genital cancers. Long-term sequelae of untreated or undertreated STIs can affect a person's physical, emotional, and financial well-being.

In the past an infection transmitted through sexual intercourse was called a *venereal disease.* Because of its limited scope, the term venereal disease has been replaced with *sexually transmitted infection (STI).* STIs are contracted by intimate, as well as sexual, contact and include systemic infections, such as tuberculosis and hepatitis, that can be spread to a sexual partner. The etiology of an STI may be bacterial, viral, protozoal, parasitic, or fungal (Table 26-1). Although the majority of STIs can be treated, viral STIs cannot be cured, only treated naturally or pharmacologically. Many infected individuals do not seek treatment because symptoms are absent, minor, or transient or because health services are inaccessible, unaffordable, or culturally insensitive. High-risk sexual behaviors (e.g., multiple partners) and poor health habits (e.g., failure to use a condom in nonmonogamous or new relationships, drug use) increase an individual's risk of exposure or the severity of infection if exposed. Perhaps partly

WHAT'S NEW?

Sexually Transmitted Infection (STI) Statistical Summary from 2010 CDC Report

Each year in the United States:

- 19 million individuals contract a sexually transmitted infection; half of those infected are younger than 25 years
- 17 billion dollars are spent on STIs, not including long-term healthcare costs
- Only half of people who need STI screening receive needed services

Chlamydia cases:

- 1.3 million cases were reported and treated but an estimated 2.6 million additional cases remain untreated

Gonorrhea cases increased in 2010 and have become resistant to many previous treatments and may soon become resistant to remaining antibiotics

Syphilis cases have decreased for the first time in a decade:

- There was a 134% increase in the syphilis rate among young black men
- The syphilis rate is highest among men who have sex with men

Viral STIs affect more than 70 million people in the United States:

- 20 million currently infected with human papillomavirus; more than half of all sexually active people will get HPV in their lifetime
- 50 million with genital herpes
- 1 million with HIV

Data from Centers for Disease Control and Prevention: *Sexually transmitted disease surveillance, 2010,* Atlanta, 2011, U.S. Department of Health and Human Services. Available at www.cdc.gov/std/stats.

because of risk-taking behavior (unprotected intercourse or selection of high-risk partners), adolescents have the greatest risk for STI exposure and infection. In addition, adolescent women may have a physiologically increased susceptibility to infection because of cervical immaturity. Rates of gonorrhea, chlamydia, vaginitis, cervical condyloma, genital warts, and pelvic inflammatory disease (PID) are highest in adolescents and young women and decline exponentially with increasing age (Figure 26-1). The health consequences of STIs are both immediate and long-term. Women and infants bear the greatest health burden from STIs.

STIs are stereotyped as occurring only among urban poor and minority populations. Because the CDC does not require that all STIs be reported, private physicians may not report them. Thus reported STIs often are provided by public health clinics, giving the impression that a greater number of the urban poor and minority populations are infected with STIs. In fact, STIs are prevalent in all socioeconomic and racial/ethnic groups.

TABLE 26-1 CURRENTLY RECOGNIZED SEXUALLY TRANSMITTED INFECTIONS

CAUSAL MICROORGANISM	INFECTION
Bacteria	
Campylobacter	Campylobacter enteritis
Calymmatobacterium granulomatis	Granuloma inguinale
Chlamydia trachomatis	Urogenital infections; lymphogranuloma venereum
Polymicrobial	
Gardnerella vaginalis interaction with anaerobes (*Bacteroides* and *Mobiluncus spp.*) and genital mycoplasmas	Bacterial vaginosis
Haemophilus ducreyi	Chancroid
Mycoplasma	Mycoplasmosis
Neisseria gonorrhoeae	Gonorrhea
Shigella	Shigellosis
Treponema pallidum	Syphilis
Viruses	
Cytomegalovirus	Cytomegalic inclusion disease
Hepatitis B virus (HBV)	Hepatitis
Hepatitis C virus (HCV)	Hepatitis
Herpes simplex virus (HSV)	Genital herpes
Human immunodeficiency virus (HIV)	Acquired immunodeficiency syndrome (AIDS)
Human papillomavirus (HPV)	Condylomata acuminata, cervical dysplasia, and cervical cancer
Molluscum contagiosum virus	Molluscum contagiosum
Protozoa	
Entamoeba histolytica	Amebiasis; amebic dysentery
Giardia lamblia	Giardiasis
Trichomonas vaginalis	Trichomoniasis
Ectoparasites	
Phthirus pubis	Pediculosis pubis
Sarcoptes scabiei	Scabies
Fungus	
Candida albicans	Candidiasis

SEXUALLY TRANSMITTED UROGENITAL INFECTIONS

Bacterial Infections

Gonorrhea

Gonorrhea is caused by **gonococci** (singular, *gonococcus*), which are microorganisms of the species *Neisseria gonorrhoeae.* Neisser first identified gonococci in stained smears of vaginal, urethral, and conjunctival exudate in 1879. Until 1994 gonorrhea was the most commonly reported communicable infection in the United States. After reaching a record low in 2009, the rates for gonorrhea increased 2% between 2009 and 2010. Although the number of reported cases in 2010 was 309,341,[2] the actual number of cases is estimated to be twice as high.

Infection rates are highest in the southern region of the United States.[2] Other demographic and lifestyle risk factors may include transient or urban residence, early onset of sexual activity, multiple serial or consecutive sex partners, drug use, prostitution, and previous gonorrheal or concurrent STI.[2] The risk of developing gonorrhea from intercourse with an infected male partner is 50% to 80% for women, and with an infected female partner, it is 20% to 30% for men. The risk increases threefold to fourfold for men after four exposures to an infected partner. Men who have sex with infected men have a greater risk of contracting gonorrhea if they are the receptive partner in oral or anal intercourse.[2]

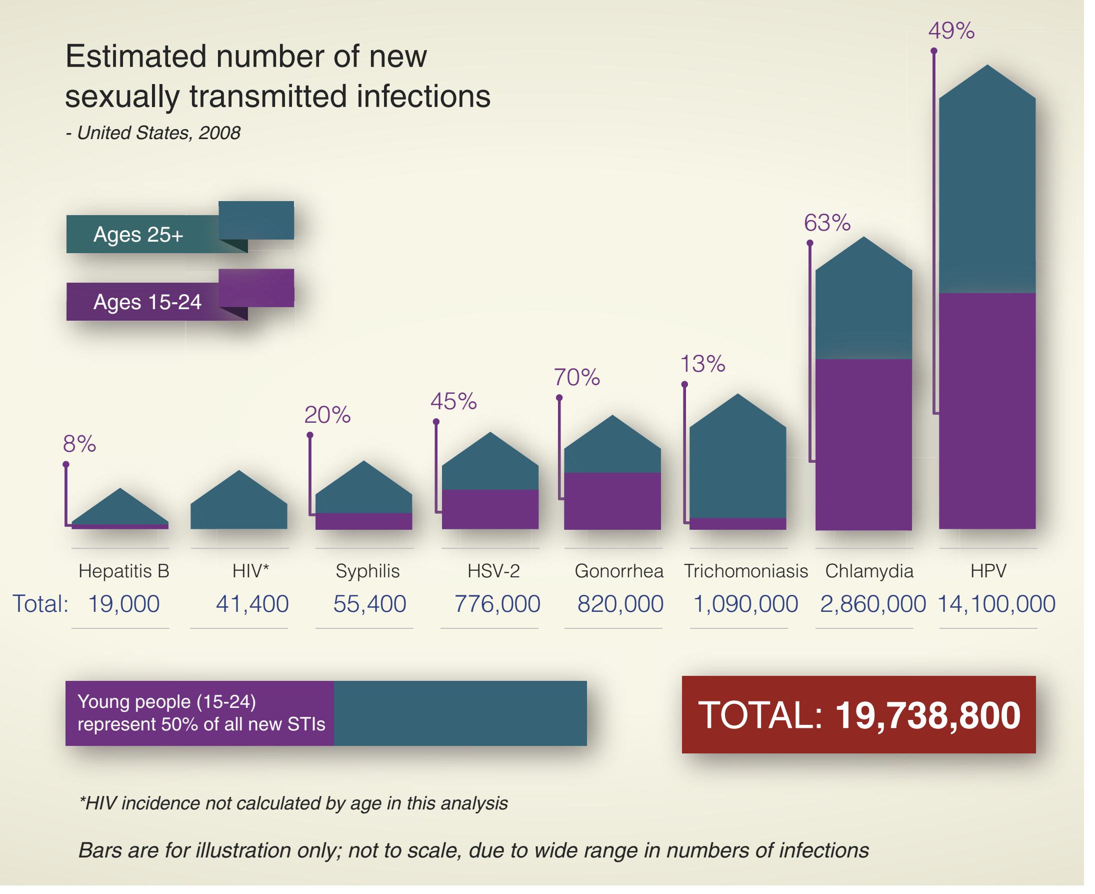

FIGURE 26-1 **Incidence and Prevalence of Sexually Transmitted Infections.** (From Centers for Disease Control and Prevention: *CDC fact sheet: incidence, prevalence, and cost of sexually-transmitted infections in the United States,* 2013. Available at www.cdc.gov/std/stats/STI-Estimates-Fact-Sheet-Feb-2013.pdf. Accessed February 24, 2013, using data from Satterwhite CL et al: *Sex Transm Dis* 40[3]:187–193, 2013.)

Transmission of gonococcal infection generally requires contact of epithelial (mucosal) surfaces, such as occurs during sexual, oral, or anal intercourse. A pregnant woman also can transmit gonorrhea to her fetus. The infection passes from mother to child predominantly through infected cervical and vaginal secretions. **Fomites** (contaminated objects) are rarely involved in the transmission of *N. gonorrhoeae,* primarily because the gonococcus requires a rich medium (e.g., body fluids) and an environment high in carbon dioxide (5% to 10%) for growth.

Treatment for gonorrhea is becoming more difficult because of rapidly developing resistance to available antibiotics. The CDC states that it is reasonable to expect that gonorrhea may become resistant to all known antibiotics in the near future.[3]

PATHOPHYSIOLOGY. Humans are the only natural hosts for *N. gonorrhoeae,* which is an aerobic, non–spore-forming, oxidase-positive gram-negative coccal (round) microorganism that usually appears in pairs (diplococci), with the adjacent sides slightly flattened. Hairlike filaments, called *pili,* appear to help the microorganisms attach themselves to host cells: the epithelial cells of mucous membranes (Figure 26-2). Columnar, transitional, and stratified squamous epithelial cells are infected most often. First the microorganisms become attached to the plasma membranes (cell walls) of these cells, and then they

FIGURE 26-2 **Gonococci.** Scanning electron microscopy showing gonococci attaching to the nonciliated cells of human fallopian tube mucosa. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 3, London, 2003, Mosby.)

invade the cells and begin to damage the mucosa. Generally a quick leukocytic (inflammatory) response and exudation at the site of infection occur.

In women the endocervical canal (inner portion of the cervix) is the usual site of initial gonococcal infection, although urethral colonization and infection of glands (paraurethral [Skene glands] and greater vestibular [Bartholin glands]) near the urethra and vagina also are common. Several factors can facilitate ascent of gonococci into the uterus and the fallopian tubes, where they cause PID. Among these factors are: (1) disintegration of the cervical mucous plug and an increase in vaginal pH to greater than 4.5 during menstruation, (2) uterine contraction that may cause retrograde menstruation into the fallopian/uterine tubes, and (3) various microbes that possess virulent potentiating factors for chlamydia or gonococcal PID. Bacteria *(N. gonorrhoeae, Chlamydia trachomatis)* also may adhere to sperm and be transported to the fallopian/uterine tubes. In the fallopian/uterine tubes, progressive mucosal and submucosal invasion and sloughing of normal, ciliated tubal epithelium are accompanied by a marked inflammatory response, causing the tubes to fill with exudate (see Chapter 25 for more on PID). In men the gonococci typically infect the urethra or rectum. Untreated urethral infection can cause epididymitis in men, and, if untreated, urethral stricture, fistula, and sterility.[4] Concurrent oropharyngeal and anorectal infection can be found in infected men and women.[2] Virulence is determined by variations in the bacterial properties and host response.

CLINICAL MANIFESTATIONS. The clinical manifestations of gonorrhea can be categorized as local or systemic and uncomplicated or complicated. Uncomplicated local infections are seen as urethral infections in men and urogenital infections in women. The majority of infected men will have sudden onset of painful urination or purulent penile discharge, or both, within a week of infection.[4] These severe symptoms encourage most men in developed countries to seek treatment.[2,4] However, some men have little discharge or urethral itching (i.e., pruritus) only, and 5% to 10% never have signs or symptoms. Most cases of untreated gonococcal urethritis resolve spontaneously after several weeks, and more than 95% of individuals are asymptomatic by 6 months after infection (although they may still be infectious). Some men develop urethritis even after being appropriately treated. If untreated, gonorrhea can cause penile abscesses, fistulae, and strictures.[4]

In women, the incubation period varies, but those who develop symptoms usually manifest within 10 days of exposure or within 1 to 2 days after the next menstrual period. More than half of gonorrhea infections in women are initially asymptomatic. Symptoms often do not appear until the infection has spread to the upper reproductive tract (uterus, fallopian/uterine tubes, and ovaries). Symptoms can include dysuria, increased vaginal discharge, abnormal menses (increased flow or dysmenorrhea), dyspareunia, lower abdominal/pelvic pain, and fever. Physical examination may disclose cervical friability and erythema (redness) and mucopurulent discharge from the cervical os (Figure 26-3). There may be a discharge from the paraurethral (Skene) or greater vestibular (Bartholin) glands if these sites are involved.

FIGURE 26-3 **Gonococcal Cervicitis.** The cervix is involved in 85% to 90% of cases in women, but the resultant discharge is profuse enough to be recognized in only 10%. (From Centers for Disease Control and Prevention: *STD clinical slides (website).* Available at www.cdc.gov/std/training/clinicalslides/slides-dl.htm. Accessed March 5, 2013.)

Anal and rectal gonococcal infection is found in 30% to 50% of women diagnosed with urogenital gonorrhea. In women, anorectal infection is usually asymptomatic and not necessarily related to anal intercourse. Symptomatic anorectal gonorrhea occurs more commonly in men who have sex with men.[2] Symptoms of anorectal gonorrhea range from mild anal pruritus (itching), mucopurulent rectal discharge, and slight rectal bleeding to severe rectal pain, tenesmus (painful and ineffectual straining at stool), and constipation. Physical examination findings include anal erythema and discharge and evidence of mucosal damage to the anus and rectum, such as friability, edema, and purulent exudate.

Gonococcal pharyngitis occurs after oral sexual contact with an infected partner. Symptomatic pharyngitis is indistinguishable from any other bacterial pharyngitis and can include fever, lymphadenopathy, and tonsillitis. Approximately 60% of these infections are asymptomatic.

Other sites of uncomplicated local infections include the eye, leading to conjunctivitis; however, this is rare in adults. Primary cutaneous infection also has been reported and is usually manifested as a localized ulcer of the genitalia, perineum, proximal lower extremities, or fingers. It is important to determine whether such infections are the result of *N. gonorrhoeae* or secondary colonization by a preexisting lesion.

Complicated gonococcal infections include prostatitis, epididymitis, lymphangitis, and urethral stricture in men and salpingitis, PID, and bartholinitis in women. Chronic salpingitis or perididymitis can cause scarring and adhesions that lead to sterility in men and women. Approximately 10%[2] of women with untreated cervical gonorrhea develop salpingitis or PID. Importantly, salpingitis has the potential for long-term sequelae, especially infertility and ectopic pregnancy.

The onset of symptoms for women may be rapid and usually occurs during menses. Women may experience chills, fever, nausea, vomiting, and lower abdominal/pelvic pain that worsen with movement, such as walking, coughing, sneezing, or intercourse. Abdominal palpation often discloses bilateral lower quadrant tenderness and rebound tenderness resulting from peritoneal irritation caused by tubal exudate. Marked

tenderness of the internal genitalia is often noted during pelvic examination. Enlargement or masses may be palpable in the upper genital tract. Tubal infertility is found in 12% of women after one episode of PID. If a woman has three or more episodes of PID, she has a 50% risk of tubal infertility.[5] **Disseminated gonococcal infection (DGI)** is a rare systemic complication caused by the spread of infection through the bloodstream. Symptoms of this life-threatening condition include a generalized rash and severe joint pain. Proliferation of *N. gonorrhoeae* to the liver causes a condition known as **perihepatitis** or Fitz-Hugh–Curtis syndrome. *C. trachomatis* also has been identified as a causative agent of this condition. Inflammation of the capsule of the liver produces sudden and intense right upper quadrant pain.[6] This complication usually develops after acute salpingitis in women and is very rare in men.

If a mother has untreated gonorrhea at the time of birth, she can transmit the infection to her child, regardless of whether the baby is delivered vaginally or by cesarean section. Most states require all infants to receive prophylactic ophthalmic antibiotics to prevent gonococcal eye infection (**ophthalmia neonatorum**) (Figure 26-4) and risk for associated blindness. Newborns born to infected mothers also may develop gonorrheal rhinitis, anorectal infection, or an abscess at the site of electrode placement for fetal monitoring. Onset of symptoms generally occurs 1 to 12 days after birth, with a mean of 4 to 6 days. Affected newborns usually are born to mothers who have suffered from prolonged ruptured membranes. In these cases, immediate treatment with a topical antibiotic is not effective because the infection is already established. Established infection causes bilateral corneal ulceration, with a profuse yellow or gray purulent exudate, and is followed by necrosis, scarring, and permanent blindness.

EVALUATION AND TREATMENT. Clinical signs and symptoms are not sufficient for the differential diagnosis of gonococcal infections. Microscopic evaluation of Gram-stained slides of clinical specimens is deemed positive for *N. gonorrhoeae* if gram-negative diplococci with typical "kidney bean" morphology are seen inside polymorphonuclear leukocytes. Such a finding is considered adequate for the diagnosis of gonococcal urethritis in a symptomatic man. For women, the Gram-stain technique is less accurate and reliable and is replaced with a single sample of endocervical secretions. Most clinic settings now use nucleic acid hybridization tests because these samples do not require an anaerobic incubation, are highly sensitive, and can be easily transported to a laboratory for testing. Because of the large percentage of infected women without symptoms, routine screening for at-risk women (i.e., those younger than age 25 or with a new sexual partner) is recommended. Samples can be obtained from the urine or the vagina, endocervix, urethra, rectum, or oropharynx. Although nucleic acid hybridization is acceptable for screening, the CDC prefers direct culture for testing because this will provide information about antibiotic susceptibility and help provide a cure.[3]

N. gonorrhoeae has developed resistance to many antibiotics and has the potential to become resistant to all current treatment drugs.[3] Several types of drug-resistant strains have been identified, including penicillinase-producing *N. gonorrhoeae* (PPNG), which is resistant to penicillin; tetracycline-resistant *N. gonorrhoeae* (TRNG), which is resistant to tetracycline; chromosomal control of mechanisms of resistance of *N. gonorrhoeae* (CMRNG), which is resistant to penicillin and tetracycline; and increasingly a fluoroquinolone-resistant *N. gonorrhoeae* (QRNG).[7,8] Until 2007 fluoroquinolones were the first-line treatment recommended by the CDC. In 2010 more than 27% of CDC-monitored samples were resistant to one or more antibiotics.[2] The only class of drugs still recommended for treatment of gonorrhea are the cephalosporins; however, there is increasing resistance to this type of medication in the United States, Canada, and around the world. There is currently only one CDC recommended drug, ceftriaxone, to treat gonorrhea although less-effective alternatives are available.[3] To prevent further drug resistance, the CDC recommends a multidrug treatment for gonorrhea that also is effective against chlamydia.[3]

FIGURE 26-4 Gonococcal Ophthalmia Neonatorum. Examiner would be gloved. (From McMillan A, Scott GR: *Sexually transmitted infections,* ed 2, London, 2000, Churchill Livingstone.)

The CDC is closely observing the drug resistance of gonorrhea through monitoring of samples obtained at sexually transmitted disease (STD) clinics around the country.[3] Treatment for gonorrhea is influenced by three factors: (1) the spread of infection caused by drug-resistant strains, (2) the high frequency of chlamydia infection accompanying gonorrhea, and (3) the recognition of the serious complications of chlamydia and gonorrhea infections. CDC treatment guidelines are updated regularly, and the most recent edition should be used. Current CDC treatment guidelines for uncomplicated gonorrheal infections are listed in Box 26-1; complicated infections require intravenous antibiotic therapy and possibly hospitalization.

Sexual partners also are assessed and treated according to these protocols, and sexual contact is avoided until treatment is completed. Condoms are strongly recommended to prevent future infection.

Syphilis

Syphilis, a disease with local and systemic manifestations, has been well-known throughout history. Many famous figures

bid, Twice per day; *IM,* intramuscularly; *PO,* orally.

from the ancient world and from the royal families of Europe were thought or known to have had syphilis.[9] In the early half of the 1900s, an estimated 1 in 4 to 1 in 20 Americans were infected.[9] With the advent of antibiotics and intensive public health efforts during and after World War II, the prevalence of syphilis declined sharply. Rates of syphilis declined in the 1990s and reached a record low in 2000 (2.2 cases per 100,000). However, between 2000 and 2009, the syphilis rate in the United States increased. In 2010, the rate of syphilis infection was 7.9 cases per 100,000 population for men and 1.1 cases per 100,000 for women.[2] The rate of primary and secondary syphilis has risen dramatically among men. Data suggest this increase is driven by increased transmission of syphilis among men who have sex with men (MSM), and accounts for 67% of these cases. The rate of primary and secondary syphilis is now nearly six times greater in men than women, whereas rates were almost equivalent a decade ago. Syphilis remains a problem in certain geographic regions, particularly in the South. Syphilis facilitates the transmission of human immunodeficiency virus (HIV) infection and seems to contribute to HIV transmission in those parts of the United States where rates of both infections are high. From 2003 to 2009, the rates have increased for all groups; in 2010 the reported rate among non-Hispanic whites was 2.1 per 100,000, among Hispanics the rate was 4.6 per 100,000, among Asian/Pacific Islanders the rate was 1.3 per 100,000, among Native American/Alaskan Natives the rate was 2.5 per 100,000, and among blacks the rate was 16.8 per 100,000.

While rates in men have increased dramatically, rates in women have decreased slightly from a recent high in 2008.[2] There also has been a slight decline in the rate of congenital syphilis, currently reported as 8.7 cases of congenital syphilis per 100,000 live births.[2] During pregnancy, untreated early syphilis results in perinatal death in as many as 40% of cases and may lead to fetal infection in more than 70% of cases because the spirochete that causes syphilis can cross the placental membrane to infect the fetus.[10]

Race, ethnicity, and gender alone do not alter STI risk but rather act as risk markers that correlate with other more fundamental determinants of health status, such as poverty, access to quality care, and health-seeking behavior. Higher infection rates have been associated with urban areas, with the exchange of sex for drugs, and with prison populations.[2,11] A growing concern is the incidence of co-infection with HIV among MSM.[2] Since a syphilitic chancre is an open wound, it greatly increases the risk of acquiring other STIs such as HIV.

BOX 26-2 PROGRESSION OF UNTREATED SYPHILIS

Stage I, primary syphilis—local invasion: *Treponema pallidum* multiplies in epithelium, producing granulomatous tissue reaction (chancre); lymph-containing microorganisms drain into adjacent lymph nodes and stimulate immune responses

Stage II, secondary syphilis—systemic disease: blood-borne bacteria spread to all major organ systems; immune system suppresses infection and symptoms regress spontaneously

Stage III, latent syphilis—silent infection: transmission of infection possible even though there are no clinical signs of infection

Stage IV, tertiary syphilis—noninfectious disease: significant morbidity and mortality occur; destructive skin, bone, and soft tissue lesions, or gummas, result from severe hypersensitivity; cardiovascular complications (aneurysms, heart valve insufficiency, heart failure) and neurosyphilis develop

PATHOPHYSIOLOGY. *Treponema pallidum,* the cause of syphilis, is an anaerobic bacterium that cannot be cultured in vitro. The treponema (individual microorganism) resembles a corkscrew, with regular, tight spirals and a rotary motion; it can infect any organ or tissue. Because the bacterium is present in exudate from moist mucosal or cutaneous lesions, the spirochete is usually transmitted to others during the first few years of infection. Transmission generally occurs through minor abrasions during sexual intercourse but can occur extragenitally as well. Approximately 30% to 50% of partners who have sexual intercourse with an individual in early stage syphilis develop the disease.[2] Although condoms can decrease the likelihood of infection, syphilis can be easily transmitted by contact with areas not covered by the condom.

Syphilis becomes a systemic disease shortly after infection and can be transmitted from a pregnant woman to her fetus as early as the ninth week of gestation. The risk of transmission to the fetus gradually declines with each subsequent pregnancy; therefore, a mother who has given birth to several children with severe congenital syphilis may later have a healthy child.[12] The course of untreated syphilis consists of four stages: primary, secondary, latent, and tertiary (Box 26-2).

Primary syphilis begins at the site of bacterial invasion (Figure 26-5), where *T. pallidum* multiplies in the epithelium and produces a granulomatous tissue reaction called a **chancre.** Some microorganisms drain with lymph into adjacent lymph nodes. Within the nodes and at the site of the chancre, the cell-mediated and humoral immune responses are stimulated.

Secondary syphilis is systemic. During this stage, blood-borne bacteria spread to all major organ systems. The secondary stage is followed by a period during which the immune system is able to suppress the infection. Even without treatment, spontaneous resolution of the skin lesions occurs and the individual enters the latent stage of infection.

Latent syphilis may be subdivided into early and late stages; however, no specific criteria delineate one from the other.[11]

FIGURE 26-5 Primary Syphilis. **A,** Penile chancre. **B,** Vulval chancres; the labia and perineum show induration and edema of chancres. (**A** from McMillan A, Scott GR: *Sexually transmitted infections,* ed 2, London, 2000, Churchill Livingstone; **B** courtesy Barbara Romanowski, MD, from Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2013, Saunders.)

FIGURE 26-6 Secondary Syphilis. Secondary syphilis to the palms and plantar surfaces. (From Morse S et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2013, Saunders.)

Medical history and serologic studies show that syphilis is present, but the individual has no clinical manifestations. Transmission is possible during the late and early latent stages.

Tertiary syphilis is the most severe stage, involving significant morbidity and mortality. The pathogenesis of syphilitic manifestations at this stage remains unclear. The destructive skin, bone, and soft tissue lesions (called **gummas**) of tertiary syphilis probably are caused by a severe hypersensitivity reaction to the microorganism. Within the cardiovascular system, infection with *T. pallidum* may cause aneurysms, heart valve insufficiencies, and heart failure. Within the central nervous system (CNS), the presence of *T. pallidum* in cerebrospinal fluid may cause the manifestations of neurosyphilis, which can occur within any stage of syphilis infection.[11]

Congenital syphilis is estimated to cause a half million fetal and neonatal deaths every year worldwide.[12] The risk of acquiring congenital syphilis (CS) is estimated at up to 80% in primary syphilis and declines with advancing stages of the disease. Intrauterine infection causes fetal or perinatal death in 40% of affected infants and many live-born infants have permanent lifelong morbidity.[12]

CLINICAL MANIFESTATIONS

Primary Stage. In adults, the incubation period of syphilis ranges from 12 days to 12 weeks after exposure and averages 3 weeks. A sore, or *hard chancre,* develops at the site of treponemal entry. Typically the chancre is an eroded, painless, firm, and indurated (hard) ulcer that may be a few millimeters to 2 cm in diameter. Firm, enlarged, and nontender regional lymph nodes accompany chancres. Figure 26-5 shows typical chancres of the penis and vulva. Syphilitic chancres are not always typical, however, and syphilis should be considered in the presence of any open lesion. Secondary infection can cause chancres to become necrotic and painful, and lesions on the fingers may be dry, scaly, and papular or moist and vegetative. If left untreated, the chancre of primary syphilis heals in 2 to 8 weeks and then spontaneously disappears, usually without leaving a scar.

Secondary Stage. Clinical manifestations of secondary syphilis usually develop 6 weeks after the first appearance of the chancre but may overlap with those of the primary stage. Typically this stage presents with variable systemic symptoms, including low-grade fever, malaise, sore throat, hoarseness, anorexia, generalized adenopathy, headache, joint pain, and skin or mucous membrane lesions or rashes. Cutaneous (skin) rashes are generally papulosquamous (raised and scaly), but any variation or combination of macular (flat), papular (raised), and pustular (pus-filled) lesions may be seen. Often lesions are widespread and bilateral and appear on the palms and soles (Figure 26-6). Some lesions become hypertrophied, flat, moist, and wartlike or vegetative (e.g., cauliflower-like). These lesions, called **condylomata lata,** are highly contagious and develop on the perineum, vulva, and groin of women (Figure 26-7) and around the inner thigh and the anal area in men and women. Besides skin sores, oral mucous membrane lesions (known as mucous patches), lymphadenopathy, pruritus, and alopecia are common. Some individuals develop anemia, leukocytosis, increased sedimentation rate, hepatitis, transitory proteinuria,

FIGURE 26-7 Condylomata Lata. Broad-based, moist, darkfield-positive condylomata lata of the perineum. (From McMillan A, Scott GR: *Sexually transmitted infections,* ed 2, London, 2000, Churchill Livingstone.)

arthritis, electrocardiographic abnormalities, and central nervous system (CNS) symptoms. Regardless of whether treatment is given, the cutaneous lesions generally heal in 2 to 10 weeks, but relapses may occur for several years.[11]

Latent and Tertiary Stages. The asymptomatic, latent stage of syphilis may be as short as 1 year or as long as a lifetime. After the latent stage, tertiary syphilis may present with gummas, cardiovascular lesions, and neurosyphilis. These manifestations of tertiary syphilis are quite rare because antibiotics can cure syphilis.

Congenital Syphilis. **Congenital syphilis (CS)** is characterized by vasculitis, necrosis, fibrosis, and distribution of *T. pallidum* throughout the tissues; it is divided into early and late stages. Signs and symptoms of early CS manifest in the first 2 years of life, and clinical manifestations of the late stage often occur near puberty. Affected newborns often are premature and have growth abnormalities, hepatosplenomegaly, bone marrow depression, destructive bone and skin lesions (see Figure 26-6), retinal inflammation, glaucoma, blood dyscrasia, nephrotic syndrome, and varying degrees of CNS involvement.[9] Late manifestations of classic congenital syphilis are rare and are similar to those of tertiary syphilis in the adult.

EVALUATION AND TREATMENT. Because *T. pallidum* cannot be cultured in vitro, early definitive diagnosis of primary or secondary syphilis depends on darkfield microscopy of a specimen taken from an infected site. If the initial result is negative, the darkfield examination is repeated on 2 successive days. In addition to darkfield microscopy, serologic testing is useful in diagnosis. An algorithmic approach to the diagnosis of genital ulcers is presented in Figure 26-8.

Two categories of serologic testing exist: nontreponemal antigen tests and treponemal antibody tests.[9] Nontreponemal antigen tests, which demonstrate the presence of *reagin* (a group of antibodies present in syphilis) in serum, provide indirect evidence of infection. Examples of nontreponemal analysis are the Venereal Disease Research Laboratory (VDRL) antigen and the rapid plasma reagin (RPR) tests (Box 26-3). These tests yield a positive result (presence of reagin) in more than 50% of individuals with primary syphilis and in 100% of individuals in the secondary phase of disease. Because the VDRL and RPR tests have high rates of false positives, a treponemal test is performed if the screening test is positive. Treponemal tests are serologic-specific tests that are used to assess antibody response to *T. pallidum* and include the fluorescent treponemal antibody absorption (FTA-ABS) test and the passive particle agglutination (TP-PA) assay.[9]

Numerous dermatologic disorders can mimic the skin lesions of secondary syphilis, making differential diagnosis difficult. Again, laboratory confirmation is important; darkfield microscopy of scrapings from condylomata lata or other skin lesions is diagnostic for the disease. Serologic blood tests are almost always strongly positive in this stage.

During the latent stage, individuals continue to have serologic evidence of untreated disease, but confirmation through darkfield microscopy is difficult. Examination of cerebrospinal fluid may confirm that the treponemata are present.

Preferred treatment for all stages of syphilis is parenteral injection of benzathine penicillin G. If the individual has manifested signs of the disease for less than 1 year, a single intramuscular dose is appropriate. If signs have been present for more than 1 year, the treatment is three weekly injections. This therapy is also appropriate for pregnant women.[9] There is no evidence to date that *T. pallidum* has developed resistance to penicillin. In fact, it is highly sensitive; but because of the slow replication time, serum levels must be maintained for 7 to 14 days. Nonpregnant women who are allergic to penicillin may receive oral doxycycline, 100 mg twice daily for 14 days. Pregnant women with a penicillin allergy should be desensitized and then treated with benzathine penicillin G as recommended by the CDC because tetracycline will cause permanent, lifelong discoloration of the forming teeth of the fetus.[9] Repeated assessment of VDRL or RPR titers is used to determine effectiveness of treatment. Titers should decrease fourfold if treatment has been successful. Sexual partners also are examined and treated, and the use of condoms is recommended until effective treatment is verified.

Newborns of mothers with documented syphilis need careful evaluation after birth. Definitive diagnosis of congenital syphilis is made by microscopic identification of *T. pallidum* in material from skin lesions, nasal discharge, or placental tissue. Nontreponemal tests are performed on the infant's blood and compared with maternal levels.[9] In all cases of maternal syphilis, the goal is to treat the mother to prevent congenital syphilis through early maternal treatment with penicillin. If the infant requires treatment, penicillin is the drug of choice. Such infants are then given serologic tests for syphilis every 2 to 3 months until the test becomes nonreactive or the titer has decreased fourfold.[9]

Chancroid

Chancroid, or soft chancre, is an acute infectious disease that was first differentiated from syphilis in 1852. It is caused by *Haemophilus ducreyi,* a gram-negative bacillus. The incidence of

BOX 26-3 FALSE-POSITIVE SEROLOGIC TESTS FOR SYPHILIS

Reasons for False-Positive, Nontreponemal Reactions (VDRL, RPR)

Transient Reactions (<6 Months)

Technical error (low titer)
Mycoplasma pneumonia
Enterovirus infections
Infectious mononucleosis
Pregnancy
Narcotic abuse
Advanced tuberculosis
Scarlet fever
Viral and atypical pneumonia
Brucellosis
Rat-bite fever
Leptospirosis
Measles
Mumps
Lymphogranuloma venereum
Malaria
Trypanosomiasis
Varicella

Chronic Reactions (>6 Months)

Malaria
Leprosy
Systemic lupus erythematosus
Narcotic abuse
Other connective tissue diseases
Elderly population
Hashimoto thyroiditis
Rheumatoid arthritis
Reticuloendothelial malignancy
Familial false-positive reaction
Idiopathic

Reasons for False-Positive, Treponemal-Specific Reactions (FTA-ABS)

Technical error
Inefficient sorbents
Healthy individuals without syphilis
Genital herpes simplex
Pregnancy
Lupus erythematosus (skin only or systemic)
Alcoholic cirrhosis
Scleroderma
Mixed connective tissue disease

FTA-ABS, Fluorescent treponemal antibody absorption; *RPR,* rapid plasma reagin; *VDRL,* Venereal Disease Research Laboratory.

chancroid is decreasing worldwide. The incidence in the United States is low; 24 cases were reported to the CDC in 2010.[2] Sporadic outbreaks occur throughout the world and tend to be associated with conditions such as poverty, prostitution, and illicit drug use, in which individuals continue to engage in intercourse in spite of the presence of a painful lesion.[2]

PATHOPHYSIOLOGY. *H. ducreyi* is a gram-negative bacillus with rounded ends. Under a microscope it is commonly observed in small chains or clusters along mucous strands. Transmission can occur through sexual contact and autoinoculation. There is no evidence of maternal-fetal transfer before or after delivery. Chancroid lesions usually are found throughout the genital region, most commonly on the internal surface of the foreskin or at its point of attachment to the penis (the frenulum) in men and on the labia, clitoris, or fourchette in women. Initially the papule enlarges; it then erodes into a soft, circumscribed ulcer containing a superficial exudate. Beneath the ulcer is a lesion characterized by edema, endothelial proliferation, and a base of granulation tissue that is full of lymphocytes and plasma cells. Adjacent lymph nodes are acutely inflamed and full of polymorphonuclear leukocytes and necrotic cells.[13]

CLINICAL MANIFESTATIONS. Chancroid has an incubation period of 3 to 10 days.[13] Generally, women are asymptomatic, but depending on the site of infection, can present with less obvious symptoms (dysuria, dyspareunia, vaginal discharge, pain on defecation, or rectal bleeding). Constitutional symptoms are unusual. At the site of inoculation, an initial vesicopustule lesion forms and erodes into a soft ulcer with a necrotic base, surrounding erythema, and a ragged, serpiginous (spreading) border (Figure 26-9). Unilateral, painful, local lymphadenopathy presents in about half of infected individuals—primarily men. (Women tend to have multiple lesions.) Inguinal **buboes** (unilocular abscess of the inguinal lymph nodes) develop 7 to 10 days after the initial chancre and fill with exudate. In 25% to 60% of cases, the buboes spontaneously rupture out onto the skin, spreading the infection through autoinoculation.

Ulcers on the prepuce may lead to phimosis or paraphimosis. Other complications of chancroid include balanitis, secondary infections, necrosis, and fistula formation. Recalcitrant, serpiginous lesions may take months or years to heal.

EVALUATION AND TREATMENT. Chancroid is easily confused with other types of genital ulcers, particularly those of syphilis, genital herpes, and granuloma inguinale (see Figure 26-9). Unlike the syphilitic ulcer, chancroidal ulcer is painful, tender, and nonindurated. Microscopic analysis of a Gram-stained smear from the chancroid helps to identify the microorganism. Definitive diagnosis depends on recovery of *H. ducreyi* from cultured specimens; however, the culture medium is not widely available.[9] Because 10% of infected individuals are coinfected with syphilis or herpes simplex virus (HSV), testing includes serologic examination for syphilis and viral culture for HSV. In addition, HIV testing is recommended: chancroid is a cofactor for transmission of HIV.

Resistance to recommended antibiotics has emerged in isolated instances worldwide. Recent treatment recommendations include a single intramuscular injection of ceftriaxone (250 mg) or a single dose of oral azithromycin (1 g). Effective oral multiple-dose regimens include ciprofloxacin, 500 mg orally twice daily for 3 days; or erythromycin, 500 mg three times daily for 7 days. Persons infected with HIV have higher rates of treatment failure with single-dose therapy and may require a longer treatment regimen. As a palliative measure, buboes can be aspirated through adjacent, healthy skin. In approximately 5% of cases, relapses at the site of original ulcer have occurred.[9] Simultaneous treatment of sexual partners and use of condoms are recommended to prevent reinfection.

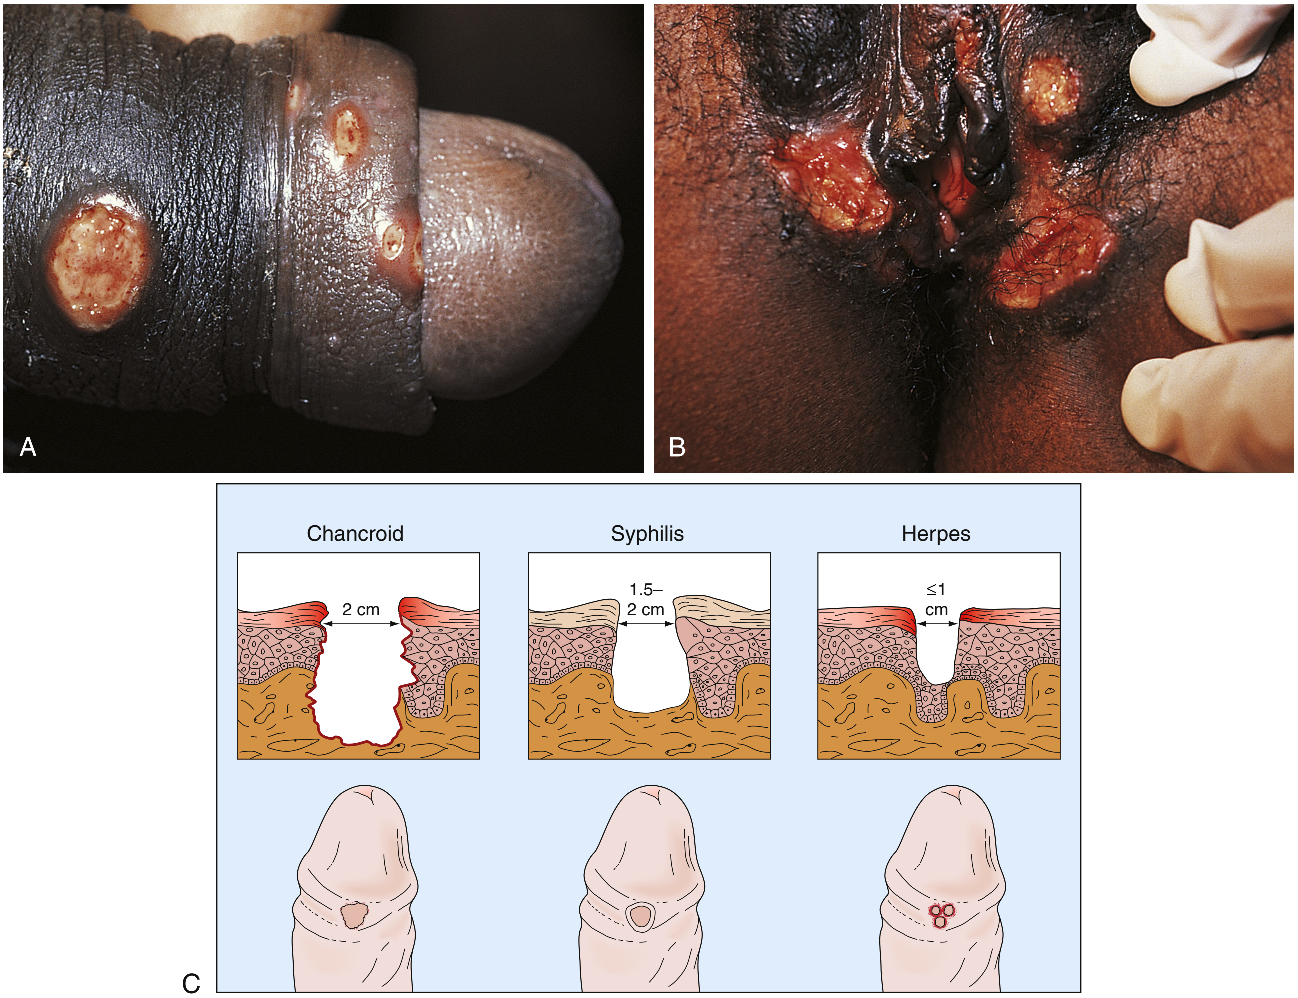

FIGURE 26-9 **Chancroid. A,** Ulcers on the penile shaft. **B,** Multiple vulvar lesions. **C,** Differences in clinical appearance among chancroid, syphilis, and genital herpes. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2013, Saunders.)

Granuloma Inguinale

Granuloma inguinale (**donovanosis**) is a chronic, progressively destructive bacterial infection caused by *Calymmatobacterium granulomatis,* recently reclassified as *Klebsiella granulomatis.*[14] Although sexually transmissible, granuloma inguinale is only mildly contagious and repeated exposure is necessary to cause disease. Often, individuals are coinfected with syphilis.[15]

Granuloma inguinale very rarely occurs in the United States.[2] Yet it is more prevalent in some tropical and subtropical parts of the world (India, New Guinea, Africa, central Australia, and to a lesser extent the Caribbean and Brazil). Infection is usually acquired through sexual intercourse with an individual who has active disease or asymptomatic rectal infection. As with all genital ulcerative diseases, granuloma inguinale plays a role in HIV transmission.[2]

PATHOPHYSIOLOGY. *C. granulomatis* is a gram-negative, nonsporing, nonmotile, encapsulated rod that is not easily isolated in the laboratory. After exposure the bacteria survive and multiply within vacuoles of large histiocytic cells or polymorphonuclear leukocytes. The bacteria reproduce within these cells until a vacuole may contain 20 to 30 microorganisms. These bacteria-filled vacuoles were identified by Donovan in 1905 and are termed **Donovan bodies.** The presence of Donovan bodies in tissue smears of material from the lesions is considered the gold standard for diagnosis of lymphogranuloma inguinale, but this test is difficult even in well-equipped labs.[15,16]

The initial lesion is an indurated subcutaneous nodule that is often preceded and accompanied by itching. The primary sites for development of the lesions are the distal penis in men and the introitus in women. Single lesions often coalesce with nearby lesions or form new lesions by autoinoculation of nearby skin surfaces. Progression from the initial nodule to a large, granuloma-heaped ulcer occurs slowly. Secondary infection may occur, increasing tissue damage and residual scarring. The disease may spread to the bones, joints, and liver.

CLINICAL MANIFESTATIONS. The incubation period of granuloma inguinale is 8 to 80 days. The initial lesion is an indurated, sharply defined, painless, subcutaneous nodule that is often preceded and accompanied by itching. Nodules bleed easily and contain abundant red, beefy-looking granulation tissue.

Progression to a large granuloma-heaped ulcer occurs slowly; single lesions coalesce or form new lesions by autoinoculation of nearby skin surfaces. Secondary infection may occur, increasing tissue damage and residual scarring. Although systemic symptoms are rare, the disease may spread to the bones, joints, and liver. In some cases, infection spreads to the inguinal area and produces **pseudobuboes.** In these instances, the affected lymph nodes are not directly affected, but the surrounding area may be infected and abscessed.

EVALUATION AND TREATMENT. Although the clinical manifestations of this disease are important for diagnosis, confirmation in the developed world involves microscopic examination in which Donovan bodies are found in a smear or biopsy specimen. No FDA-cleared polymerase chain reaction (PCR) tests for the detection of *K. granulomatis* DNA exist.[13]

Many antibiotics have been used successfully against *K. granulomatis.* Because other STIs frequently coexist, individuals should be tested for chlamydia, gonorrhea, syphilis, hepatitis B, and HIV. Because of the persistent nature of the disease, duration of therapy tends to be relatively long. With effective antibiotic treatment, lesions begin to heal in 7 days, but treatment is continued for at least 3 weeks and until all lesions are completely healed. Oral therapy includes doxycycline, 100 mg twice a day; azithromycin, 1 g once a week for 3 weeks and until lesions are healed; ciprofloxacin, 750 mg twice a day for at least 3 weeks; erythromycin base, 500 mg four times a day for at least 3 weeks; or trimethoprim-sulfamethoxazole, 160 mg/800 mg, double-strength tablet twice a day for at least 3 weeks.[9] Relapses can occur 6 to 18 months later despite effective initial therapy, so prolonged follow-up is necessary, as is treatment of sexual partners.

Bacterial Vaginosis

Bacterial vaginosis (BV)—previously called nonspecific vaginitis; nonspecific vaginosis; or *Haemophilus, Corynebacterium,* or *Gardnerella* vaginitis—is a sexually associated condition, but is not necessarily considered an STI. The condition is associated with sexual contact including genital touching and digital penetration, oral sex, and penile penetration. Although BV occurs mostly in sexually active women of reproductive age, it can affect women, especially menopausal women, who are not sexually active. BV is diagnosed by the presence of characteristic symptoms and clinical findings. Prevalence rates vary from 17% among women in family planning clinics to 37% among some groups of pregnant women.[1] Fifty percent of women with signs of BV are asymptomatic.

PATHOPHYSIOLOGY. The exact etiology of BV is unknown but is thought to be a dysbiosis of normal vaginal flora that is associated with sexual contact. *Gardnerella vaginalis* and various anaerobes, including *Mycoplasma hominis, Bacteroides,* and *Mobiluncus,* interact and proliferate when lactobacilli (the normal predominant vaginal flora) are decreased or absent. Bacteria adhere to vaginal epithelium, and massive overgrowth occurs and causes a noninflammatory response. Catabolic enzymes degrade proteins into amines. In turn, amines elevate the vaginal pH and produce the characteristic fishy odor associated with BV. BV has been implicated in PID, chorioamnionitis, preterm labor, and postpartum endometritis. In addition, BV increases a woman's risk of contracting other STIs, such as HIV.

CLINICAL MANIFESTATIONS. BV is characterized by a thin, gray, homogeneous, and malodorous discharge that adheres to the vaginal walls but is often copious enough to drain into the vulva. Occasionally the discharge is bubbly or frothy. Usually the vaginal pH is 5 to 5.5, and women often complain of a strong, foul, fishy vaginal odor, particularly after intercourse and during menses. Odor is caused by contact with alkaline secretions, including semen and menstrual discharge. Male and female partners of infected women may harbor the microorganisms responsible for BV but have no signs or symptoms.

EVALUATION AND TREATMENT. Diagnosis of BV can be made on the basis of three of four of the following criteria, known as Amsel's criteria: (1) presence of adherent gray vaginal discharge, (2) vaginal pH greater than 4.5, (3) positive amine odor in the presence of an alkali such as potassium hydroxide, and (4) presence of clue cells on wet mount.[17] Clue cells are considered pathognomonic for BV. The saline wet mount also may show absence of lactobacilli and few or no leukocytes. Clue cells are vaginal epithelial cells that are covered with bacteria and look as if pepper has been sprinkled on them. A Gram stain is considered the "gold standard" for diagnosis but is difficult to perform quickly in a clinic laboratory.[18] Cultures for BV are not recommended; however, high-risk individuals should be screened for gonorrhea and chlamydia.

The most commonly used treatment for BV is a course of oral metronidazole (Flagyl), 500 mg twice daily for 7 days, or 0.75% vaginal gel once daily for 5 days.[9] Alternative regimens include tinidazole 2 g once daily for 2 days or 1 g orally for 5 days. Oral clindamycin, 300 mg twice daily for 7 days; or 2% vaginal cream, once daily for 7 days, is another choice for treatment.[9] Clindamycin vaginal suppositories are a 3-day treatment regimen in nonpregnant women. Clindamycin cream is oil based, and for up to 72 hours after completing therapy, it may weaken latex condoms and diaphragms. BV treatment in women infected with HIV is the same as that in individuals who are HIV-negative. In pregnancy, treatment decisions are more complex because even though the presence of BV is associated with preterm labor, the risk of preterm labor is actually increased with treatment. The CDC recommends that practitioners consider delaying treatment until 36 weeks and provide women with informed consent about the risk of preterm birth with treatment.[9] Treatment of sexual partners is not recommended.[9,19]

Chlamydial Infections

Urogenital Infections

Chlamydia is the common name for infections caused by *Chlamydia trachomatis* (CT). *C. trachomatis* is responsible for a variety of syndromes, including acute urethral syndrome, nongonococcal urethritis (NGU), mucopurulent cervicitis, and PID. Chlamydia, the most common reportable STI in the United States, affects about 3 million individuals annually and is a leading cause of preventable infertility and ectopic pregnancy.[2] In 2010, more than 1.3 million cases of chlamydial infections were reported, which was an increase of 5% from

2 years earlier.[2] Rates of chlamydia are increasing in all age groups, areas of the country, and racial/ethnic groups. This increase probably reflects the continued expansion of screening efforts and increased use of more sensitive diagnostic tests as well as an actual increase in incidence.[2] The majority of reported cases of chlamydia are in people less than 26 years old but the incidence in older adults is increasing.[2,20] Up to 90% of women with CT infection are asymptomatic, which can delay diagnosis and increase the risk of long-term health sequelae.[2]

Risk groups for chlamydia include age younger than 26 (with highest rates in people younger than 20 years old), recent new sexual partner, and drug use or other risky behaviors.[2] The incidence of CT infection in pregnancy has been estimated at between 2% and 21%.[2] Like gonorrhea, *Chlamydia* infection can be transmitted from mother to infant during birth and can cause eye infections and pneumonia in affected newborns.[9]

PATHOPHYSIOLOGY. *C. trachomatis* is an obligate, gram-negative intracellular bacterium that lacks the ability to reproduce independently. Like viruses, *Chlamydia* can reproduce only within host cells. It is differentiated from other bacteria by its unique two-part growth cycle. The first part consists of an elementary body that is small, resilient, metabolically inert, and able to survive extracellularly. Once this elementary body attaches itself to a receptor host cell, it is able to enter by endocytosis. Once inside the cell, the second part of the cycle begins and the microorganism becomes a metabolically active parasite, reproducing within the cell until the cell is destroyed and ruptures, disseminating up to 1000 new elementary bodies. Rarely does this cause a secondary infection. Infection with *C. trachomatis* produces a mononuclear inflammatory reaction rather than a polymorphonuclear inflammatory reaction. The mononuclear inflammatory reaction produces permanent scarring of tissues.[2]

Chlamydia microorganisms are always pathogens; they are not part of the normal flora of the urogenital tract, despite the fact that infection is often asymptomatic. Numerous serotypes, or strains, of *C. trachomatis* have been identified. Some cause urogenital infection; some, ocular trachoma; and others, lymphogranuloma venereum, which is discussed in the next section.

The strains of *C. trachomatis* that cause urogenital infection apparently require squamous-columnar and columnar-epithelial cells as hosts. *C. trachomatis* infects and disrupts epithelial tissues but does not seem to invade or destroy deeper tissues or organs.[21]

In newborns, several sites may be inoculated with *Chlamydia* during passage through the infected maternal cervix. These include the eye, nasopharynx, rectum, and vagina. The infant also may aspirate infected secretions with its first breaths, resulting in chlamydial pneumonitis and substantial newborn morbidity.

CLINICAL MANIFESTATIONS. Asymptomatic chlamydial infection in adults is common. Urogenital infections caused by *Chlamydia* closely parallel those caused by gonorrhea. Both microorganisms infect superficial genital tract tissues, such as mucosa of the urethra and cervix, and both can invade the epididymides, fallopian/uterine tubes, and (rarely) the hepatic capsule. Table 26-2 lists the pathophysiologic similarities of chlamydial and gonococcal infections.

TABLE 26-2 SIMILARITY OF CLINICAL SYNDROMES CAUSED BY *NEISSERIA GONORRHOEAE* AND *CHLAMYDIA TRACHOMATIS*

SITE OF INFECTION	CLINICAL SYNDROME: *N. GONORRHOEAE*	CLINICAL SYNDROME: *C. TRACHOMATIS*
Men		
Urethra	Urethritis	Nongonococcal urethritis; postgonococcal urethritis
Epididymis	Epididymitis	Epididymitis
Rectum	Proctitis	Proctitis
Conjunctiva	Conjunctivitis	Conjunctivitis
Systemic	Disseminated gonococcal infection	Reiter syndrome
Women		
Urethra	Acute urethral syndrome	Acute urethral syndrome
Bartholin gland	Bartholinitis	Bartholinitis
Cervix	Cervicitis	Cervicitis; cervical atypia
Fallopian tube	Salpingitis	Salpingitis
Conjunctiva	Conjunctivitis	Conjunctivitis
Liver capsule	Perihepatitis	Perihepatitis
Systemic	Disseminated gonococcal infection	Arthritis-dermatitis syndrome

Data from Stamm WE, Holmes KK: *Chlamydia trachomatis* infections in the adult. In Holmes KK et al, editors: *Sexually transmitted diseases*, ed 2, New York, 1990, McGraw-Hill.

Chlamydial infection accounts for 50% to 60% of cases of nongonococcal urethritis in men. Clinically, urethritis caused by gonorrhea and chlamydia cannot be differentiated: both have a 7- to 21-day incubation period and cause dysuria. Although urethral discharge in men may be similar in the two infections, chlamydial discharge tends to be more clear and gonococcal discharge more purulent. Men might note a clear, mucous discharge or mild burning with urination. Chlamydial urethritis is generally milder than gonorrheal urethritis and more likely to be asymptomatic. Gram-stained smears of the urethral discharge show numerous polymorphonuclear leukocytes, which indicate ongoing inflammation.

Chlamydial epididymitis can accompany chlamydial urethritis in men and is characterized by fever and a unilaterally painful, swollen scrotum. Chlamydial infection also causes proctitis (rectal inflammation) in people who have receptive anal intercourse. Chlamydial proctitis is generally mild, although it may, like gonorrheal proctitis, cause rectal bleeding, mucous discharge, and diarrhea. Reiter syndrome (urethritis, conjunctivitis, arthritis, and characteristic mucocutaneous lesions) is also associated with untreated chlamydial infections of the urogenital tract.

Chlamydia infection is the leading cause of tubal infertility in women. Risk factors for infertility include numbers of chlamydial infections and duration and severity of infection. Even

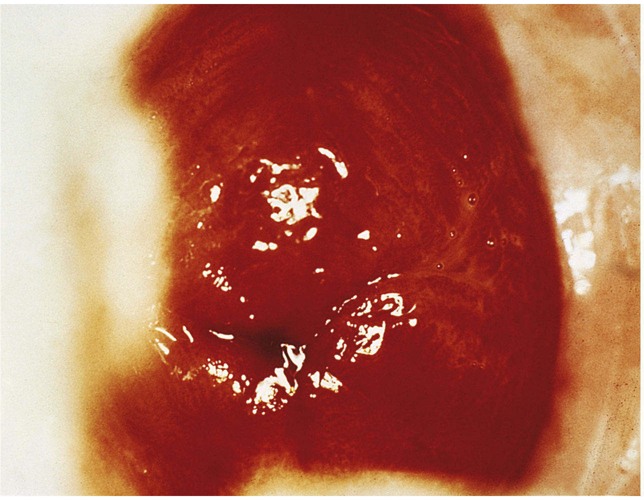

FIGURE 26-10 **Chlamydial Cervicitis.** Beefy red mucosa of columnar epithelium of cervix. (Courtesy Paul Weisner. From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2013, Saunders.)

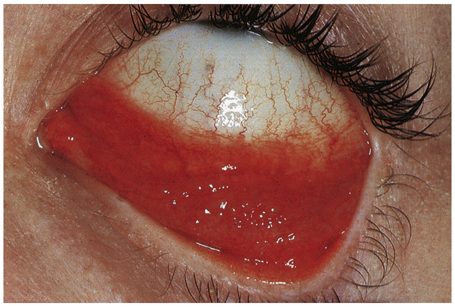

FIGURE 26-11 **Chlamydial Ophthalmia.** (From McMillan A, Scott GR: *Sexually transmitted infections,* ed 2, London, 2000, Churchill Livingstone.)

women with asymptomatic salpingitis have a risk of subsequent infertility. This may reflect an antigen-antibody response rather than inflammatory damage.[22]

In sexually active women, *C. trachomatis* can cause **acute urethral syndrome** (dysuria, urinary frequency, and presence of sterile pus in the urine). *C. trachomatis* also causes asymptomatic urethral infection in women. Chlamydial infection of Bartholin/greater vestibular glands can cause purulent discharge and formation of a Bartholin cyst. Women with chlamydial cervicitis may be asymptomatic or may have a yellow mucopurulent discharge from the cervical os and a hypertrophic, edematous, and friable area of cervical ectopy. The woman also may report intermenstrual or postcoital spotting. Although ectopy alone does not indicate a pathologic condition, an erythematous, raw, and friable cervix is suggestive of chlamydial cervicitis (Figure 26-10).

The most common clinical manifestations of chlamydial infections in the newborn are conjunctivitis and pneumonia. Prophylactic treatment with antibiotic eye ointment at birth does not provide complete protection against neonatal conjunctivitis and does not protect against neonatal pneumonia. Chlamydial conjunctivitis begins between 5 and 14 days after delivery, when the infant's eyes begin to water. This discharge may become purulent, and both eyes may become red and swollen (Figure 26-11).

Scarring of the conjunctivae may result, but this infection does not cause blindness, as does the ophthalmia neonatorum caused by *N. gonorrhoeae.* The pneumonia is mild or severe and may accompany the conjunctivitis. Infants with chlamydial pneumonia develop staccato coughing spells, nasal congestion, dyspnea, and minimal fever at 3 to 11 weeks of age. Affected infants may have persistently abnormal pulmonary function tests into childhood.[9]

EVALUATION AND TREATMENT. Methods for diagnosing chlamydial infections include tissue culture, direct chlamydial enzyme immunoassay, fluorescein-labeled monoclonal antibody tests, and nucleic acid amplification testing (NAAT). Currently, tests using chlamydia-specific nucleic acid sequences are the most sensitive and cost-effective tests available.[9] Concurrent testing for gonorrhea can be done using the same swab. NAAT can be performed on samples taken from the vagina, endocervix, urethra, or urine specimens. The ease of use means that screening can be performed without a clinician if needed.[9]

C. trachomatis is susceptible to inexpensive, readily accessible antibiotics. Treatment includes antibiotic therapy for infected individuals and all sexual contacts; abstinence or use of condoms during treatment and for 7 days after treatment is recommended. Azithromycin is given 1 g orally, as a single dose, or a 7-day course of oral doxycycline, 100 mg twice daily. Single-dose azithromycin is preferred if adherence to a multiple-dose, multiple-day regimen may not be feasible for the individual. Alternative regimens include a 7-day course of oral erythromycin, 500 mg four times a day; or erythromycin E, 800 mg four times daily for 7 days. Ofloxacin, 300 mg twice daily; and levofloxacin, 500 mg once daily for 7 days, are also effective alternatives.[9] Azithromycin is the drug of choice in pregnancy. Because of the asymptomatic nature of *Chlamydia* and the potential sequelae of untreated infection, the CDC recommends routine annual screening for chlamydia for all sexually active women who are less than 26 years old. In addition, the CDC recommends that all women, regardless of age, be screened if they have a new sexual partner or their partner is not monogamous.[9] Pregnant women should be routinely screened for *Chlamydia* at least once during pregnancy.[9]

Lymphogranuloma Venereum

C. trachomatis (invasive serovars of strains L1, L2, or L3) can cause a chronic STI known as **lymphogranuloma venereum (LGV),** which may be confused with syphilis, herpes, or chancroid. LGV was previously rare in the developed world but now is increasingly found in men who have sex with men and may spread to other populations. The infection is acquired during sexual intercourse or through contact with contaminated exudate from active lesions.[9]

PATHOPHYSIOLOGY. The strain of *C. trachomatis* that causes LGV probably penetrates skin and mucous membranes through tiny abrasions. LGV spreads to genital and rectal lymphatic tissue, where it causes marked inflammation, necrosis, buboes, abscesses of inguinal lymph nodes, and infection of surrounding tissues. Healing occurs by fibrosis after several weeks or months and results in scarring, damaging the lymph nodes and disrupting their function. LGV can cause permanent lymphatic

disruption and genital disfigurement. Affected nodes become chronically swollen, hardened, and enlarged. *C. trachomatis* also spreads systematically through the bloodstream and can enter the CNS.[23]

CLINICAL MANIFESTATIONS. The primary lesion of LGV appears after an incubation period of 5 to 21 days. The lesion is most commonly a herpetiform (multivesicular) ulcer, but it can assume various forms. The ulcer generally is asymptomatic and inconspicuous and heals rapidly, leaving no scar. In men, the lesion is found most commonly on the penis or scrotum; in women, it is found on the vaginal wall, cervix, or labia. Other signs of primary LGV include a large, tender lymphatic nodule or bubo, urethritis, and cervicitis.

The secondary stage of untreated LGV in men is characterized by inflammation and swelling of the lymph nodes. At first the inguinal bubo is a firm, somewhat painful mass. As the bubo gradually enlarges, it becomes very painful, thereby restricting mobility, and is deep blue in color. This color change signals impending rupture of the bubo through the skin. Thick yellow pus may drain from the site for weeks or months. Healing is slow and results in scar formation. Systemic manifestations of secondary LGV include meningitis, pneumonitis, and other major infections. In some cases the bubo does not rupture but rather involutes and becomes firm. Bubo formation is most common in men and may result in a distinctive inguinal swelling, known as the "groove sign."[13] In women the path of pelvic lymph drainage is different and the inguinal lymph nodes are involved in less than one third of cases.

Anorectal LGV may be caused by direct inoculation during anal intercourse, or it may be a chronic or late manifestation of lymphatic spread from the inguinal area. Most individuals with anorectal LGV have had receptive anal intercourse with males. Clinical symptoms include multiple ulcerations of the rectal mucosa, chronic inflammation, mucopurulent rectal discharge, and rectovaginal fistulae in women. Individuals may have fever, rectal pain, and tenesmus. Rectal strictures, perirectal abscesses, and anal fissures may develop and are the cause of most of the severe morbidity associated with LGV.

EVALUATION AND TREATMENT. Clinical manifestations and laboratory tests are used to diagnose LGV. Tests include the LGV complement-fixation test, isolation of the microorganism in tissue culture, and monoclonal antibody tests. The diagnosis usually is made serologically and by excluding other causes of genital ulcers or inguinal lymphadenopathy. LGV is treated with oral doxycycline, 100 mg twice daily for 21 days. A 21-day course of erythromycin is also effective. Sexual partners also should be treated regardless of symptoms.[9]

Nongonococcal or Nonspecific Urethritis

Nongonococcal urethritis (NGU), also known as *nonspecific urethritis,* is a nonreportable STI. This terminology is slightly antiquated since it was originally developed to describe all forms of urethritis not associated with gonorrhea. At the time this term was first used, it was difficult to test for many microorganisms. However, with current lab tests clinicians are better able to diagnosis the exact cause of urethritis when test results are available. This diagnosis remains in use in part because it is clinically useful until definitive test results can be obtained. In student health centers and STI clinics, more than 50% of individuals with urethritis have NGU. Approximately 2 million men are affected each year. NGU may be complicated by epididymitis in men younger than 35 years or in men who have proctitis or Reiter syndrome, or both.

PATHOPHYSIOLOGY. Nongonococcal urethritis is a syndrome caused by a variety of microbes, including *C. trachomatis* and *Ureaplasma urealyticum.* Chlamydial infections are discussed earlier in this chapter (see p. 929).

C. trachomatis is the most common cause of NGU (15% to 55%). *Trichomonas vaginalis* and herpes simplex virus (HSV) sometimes cause NGU. However, *Mycoplasma genitalium* is implicated in as many as one third of the cases of NGU. Enteric bacteria also may cause NGU, especially if the man has had insertive anal intercourse.[9]

CLINICAL MANIFESTATIONS. Clinically, NGU infection caused by CT cannot be differentiated from NGU caused by another microbe. In both cases, men present after a 7- to 21-day incubation period with complaints of dysuria and mild to moderate white or clear urethral discharge. Discharge may be absent, and urethral itching may be the only symptom. Asymptomatic infection is common.

EVALUATION AND TREATMENT. NGU is a diagnosis of exclusion. Urethral exudate is Gram-stained, and an endourethral swab or a urine NAAT test may be taken for testing or culture. Urine sediment also may be examined. All individuals who have urethritis should be evaluated for the presence of gonococcal and chlamydial infection. A treatment of a single 1-g oral dose of azithromycin should be initiated as soon as possible after diagnosis. Doxycycline, 100 mg orally twice a day for 7 days, is also effective. Single-dose regimens have the advantage of improved compliance and of directly observed therapy.[9] These regimens have the advantage of providing coverage for a wide array of potential causes of urethritis, including *Trichomonas* and enteric bacteria. However, if improvement does not occur, the man should be evaluated again to rule out other pathologies.[9]

Viral Infections

Genital Herpes

Genital herpes, which causes blisters (cold sores), is the most common infectious cause of genital ulcerations in the United States. In fact, genital infection with HSV is an epidemic in the United States. Herpes simplex virus is not a reportable disease so national statistics are not available. However, HSV infections are estimated to affect 1 million new individuals each year. Recurrent infections are mostly asymptomatic (50% to 70%) and affect an estimated 50 million Americans annually.[2] Eighty percent of infected individuals do not know they have herpes.[2] Genital herpes can be caused by either of the two serotypes of HSV: HSV-1 or HSV-2. Although infections caused by the serotypes are clinically indistinguishable, serologic studies show that more than 80% of initial and 98% of recurrent genital HSV infections are caused by HSV-2.

The seroprevalence of HSV-2 is estimated to range from 16% to 20% of the total adult population to 50% for subgroups, for example, individuals treated at STI clinics and black women.

Genital herpes can be caused by either the HSV-1 or the HSV-2 subtype but HSV-2 has more virulent and frequent outbreaks.[9]

Herpes simplex virus infection is transmitted through genital skin or mucosal contact with a person who is shedding the virus. Persons without symptoms probably transmit most infections. Transmission rates are not well identified. However, women are more susceptible than men to contracting herpes related to prolonged semen contact with the vaginal or rectal mucosa. It is estimated that a woman has an 80% to 90% risk of developing genital herpes after being exposed to an infected man. In 1992 Mertz and colleagues[24] studied monogamous heterosexual couples in which one partner had HSV-2 infection. The noninfected partner seroconverted in 10% of couples over a 1-year period. As many as 70% of such infections seem to be acquired during periods of asymptomatic shedding. Uninfected female partners were at greater risk than men, especially if they were seronegative for HSV-1 antibodies as well. Both HSV-1 and HSV-2 can be transmitted through genital-genital contact or orogenital contact. The likelihood of nonsexual transmission of genital herpes, through aerosolized secretions of other fomites, is unlikely.[2,21]

Condoms do not fully protect against HSV infection because there is still contact between genital skin not covered by the latex. Female condoms offer a bit more protection from HSV since they cover and protect the vulva but they do not eliminate the risk of transmission.[25] HSV infection greatly increases the risk of HIV acquisition. People with HSV are four times more likely to contract HIV if exposed, potentially because of small skin splits that occur as a result of HSV infection.[2] Prevention of the spread of HIV and HSV through safer sex practices is essential for infected people.

Neonatal infections can begin in utero or, more commonly, during the intrapartum or postpartum period. The risk of transmission of HSV to the neonate varies from <3% among women with recurrence of known herpes at term who acquired HSV during the pregnancy to up to 30% to 60% in women who are exposed and acquire HSV near term.[26] Perinatal transmission can cause extensive morbidity and mortality.

Intrauterine transmission is rare but can occur through transplacental or ascending infection and can cause fetal malformations.[27] Eighty-five percent of infections are transmitted intrapartally. Infants are at greatest risk if the mother has a primary infection acquired near the time of delivery rather than a recurrent infection or an infection acquired during the first half of pregnancy. Ruptured membranes have a role in the development of HSV. Rupture of membranes for more than 4 hours increases the risk of the fetus for contracting HSV. Internal fetal monitoring devices also increase the risk of vertical transmission because they break the skin.[28] Infants also may be exposed after birth through mouth-to-mouth kissing by family members; there have been several cases of infants exposed during ritual circumcision involving direct orogenital suction.[29]

PATHOPHYSIOLOGY. After initial exposure and entry of the virus at mucocutaneous sites or abraded skin, the virus undergoes replication locally in the dermis and epidermis. This leads to cell destruction, transudation, and vesicle formation. The virus spreads to contiguous cells and eventually into sensory nerves. Eventually the virus is transported intra-axonally to the dorsal root, where it remains in a latent stage until it becomes reactivated. During the latent period the genome for the virus is maintained in the host cell nucleus without causing the death of the cell. After oral infection the latent virus resides in the trigeminal ganglion; after genital infection it resides in the dorsal sacral nerve roots.

Latent infections can become reactivated, often during times of physical or emotional stress, and cause a recurrent infection with similar manifestations. Reactivation of the HSV-2 infection is twice as common as HSV-1 infections, and the likelihood of HSV-2 recurrent infections is 8 to 10 times. Reactivation of HSV is not well understood but may be attributable to physical, hormonal, and immunologic stimuli. Other triggering events may be menstruation, stress, and sun exposure.[30] During reactivation the viral genomes are transported through the peripheral sensory nerves back to the dermal surface.

CLINICAL MANIFESTATIONS. Three distinct syndromes associated with HSV infection are first-episode primary genital infection, first-episode nonprimary HSV, and recurrent infections. The manifestations of each one depend on the individual's immune state. First-episode primary genital infection occurs when an individual has no antibodies to HSV-1 or HSV-2. Up to 60% of primary infections with HSV-2 and one third of primary infections with HSV-1 are asymptomatic.[31] If symptoms occur, the individual may have small (1 to 2 mm), multiple, vesicular lesions at the site of infection, usually on the labia minora, fourchette, penis, or mouth (Figure 26-12). They also may appear on the cervix, buttocks, and thighs and are often painful and pruritic. These lesions usually last about 10 to 20 days. The lesions of HSV-1 and HSV-2 are indistinguishable to the naked eye. These wet lesions actively shed virus for about 10 to 14 days, after which they heal by reepithelialization. Small lesions may coalesce into larger ulcers and become secondarily infected.

Systemic manifestations often accompany primary HSV infection, and an individual may experience fever, malaise, myalgias, lymphadenopathy, and urinary retention. Pharyngitis, aseptic meningitis, and hepatitis also may accompany primary HSV infection. Figure 26-13 illustrates the clinical course of primary genital HSV.

First-episode non-primary HSV occurs in individuals who have preexisting antibodies. In some individuals the primary infection may not have had any clinical manifestations, but the HSV virus has become latent in the nerve root and can reactivate later in life. Compared with primary infection, the first episode of nonprimary HSV is often milder with fewer lesions that are less painful and heal faster. Fewer systemic manifestations occur and viral shedding is of shorter duration.

Recurrent infections produce mild local symptoms. The number of lesions is greatly reduced, and the lesions are less painful. Lesions are often unilateral, with crusting within 4 to 5 days. Recovery and healing are usually complete within 10 days. Asymptomatic viral shedding can occur with both HSV-1 and HSV-2, but is more common with HSV-2.[9]

Individuals affected with HSV-2 are more likely to experience recurrent infections. Recurrent infections occur an average

FIGURE 26-12 **Herpes Lesions. A,** Herpetic vesicles on the penis. **B,** Herpetic ulceration of the vulva. (From McMillan A, Scott GR: *Sexually transmitted infections,* ed 2, London, 2000, Churchill Livingstone.)

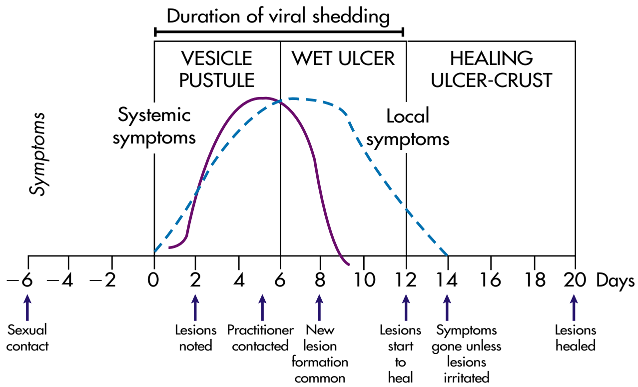

FIGURE 26-13 **Clinical Course of Primary Genital Herpes.** (From Corey L: Genital herpes. In Holmes KK et al, editors: *Sexually transmitted diseases,* ed 2, New York, 1990, McGraw-Hill.)

of five to eight times per year but may be as frequent as every month for many years. Individuals may experience prodromal symptoms (e.g., pruritus, tingling, dysesthesias) a few hours to 2 days before the eruption of lesions. Women may experience a vaginal discharge and dysuria, and 44% of men have dysuria.

Symptomatic HSV infection of the newborn may occur any time in the first month of life. Manifestations range from a local infection of the eyes, skin, or mucous membranes to a severe disseminated infection with CNS involvement. About 70% of affected infants present with skin lesions. CNS involvement includes seizures and is associated with a mortality of more than 50% and extensive neurologic sequelae in survivors. Eighty-five percent of untreated infants with disseminated disease will die.[27]

EVALUATION AND TREATMENT. Genital HSV infection is suggested if typical genital lesions are present. Diagnosis can be made after viral culture, but these cultures have a low sensitivity especially when lesions are healing. The CDC recommends serologic testing for diagnosis and to determine the virus subtype because the prognosis and the risk of transmission differ.[9]

There is no cure for HSV, only symptom management and viral suppression treatments. Oral acyclovir, valacyclovir, penciclovir, and famciclovir are used for primary and periodic outbreaks and to prevent recurrences. Acyclovir has a better safety profile for pregnant and nursing women, but there is ongoing research supporting the safety of valacyclovir as well.[26] Intravenous acyclovir is reserved for pregnant or severely immunocompromised individuals.[32] Suppressive treatment is recommended for individuals with more than six recurrences per year and pregnant women at term with a history of herpes. Suppressive treatment also may reduce asymptomatic viral shedding, decreasing transmission to sexual partners and vaginally-born infants. Although condoms offer some protection, individuals with HSV should refrain from all genital contact when prodromal or symptomatic and understand that an undetermined risk of transmission exists even during asymptomatic periods.

Human Papillomavirus Infection

Human papillomavirus (HPV) infection is the most common symptomatic viral STI in the United States. Although more than 5.5 million cases are diagnosed yearly, prevalence is considered underestimated because HPV infection is often subclinical. More sensitive measures of HPV indicate that 50% of all sexually active people are infected with the virus at some point in their lives.[9]

More than 120 different types of HPV have been identified. More than 40 serotypes are unique to the stratified squamous epitheliums of the genital area. These are divided into serotypes that have a high risk of causing cervical cancer and low-risk serotypes, which are associated with benign genital lesions or warts: *condylomata acuminata* of the vulva, vagina, penis, and perianal areas. High-risk types 16 and 18 are the most common, causing up to 70% of anogenital cancers.[9] Serotypes 6 and 11 are associated with 90% of genital warts. Low-risk subtypes can coexist with the high-risk types, but do not cause cancer. Although rare, these types also may cause oral lesions. It is now known that infection with persistent, high-risk serotypes of HPV is

necessary for the development of cervical or anal cancer (see also Chapters 10 and 24). Fortunately, most cases of HPV are transient and resolve on their own within 2 years.[9] Persistence of the virus, immune response, and the presence of cofactors, including smoking and hormonal contraceptive exposure, may play a role in the development of cervical dysplasia and cancer following HPV exposure.[33] HPV infection is closely associated with multiple sexual partners and early onset of sexual activity and is most common in teens and young adults, 16 to 25 years of age.

Genital warts are very contagious, with transmission rates among individuals estimated to be between 38% and 95%. Such a wide range is attributable to the subclinical nature of some infections and various influencing factors that include number of exposures, HPV type, location of lesions, and cellular immunity response. Infants and children also have been identified as being infected with HPV. Infants can be infected in utero and by passage through an infected birth canal. HPV infection in children has been traced to child sexual abuse; however, reports vary in making this connection.[34,35]

A vaccine against HPV serotypes 6, 11, 16, and 18 is available and has shown to be effective in prevention of HPV acquisition. Approved for use in males and females age 11 to 26 years, the three-dose vaccine offers protection from the most dangerous HPV strains to young adults.[36,37] Prevention of HPV acquisition in young adults is important because they are more likely than older adults to contract STIs and the cervixes of younger women are more vulnerable to HPV. Although there has been widespread resistance to the vaccine, public health officials are hopeful that vaccination in boys and girls before they become sexually active will decrease the burden of HPV infection in the future (see What's New? HPV Vaccine).

The immune system is prepared to eliminate the virus through immune response when previously vaccinated. When an individual has not been vaccinated, he or she may or may not be able to clear this viral infection. Although most HPV subtypes are not associated with abnormal cellular growth, high-risk HPV subtypes cause cellular changes that can lead to cell proliferation, causing warts or cancer.

PATHOPHYSIOLOGY. HPV is a nonenveloped, circular, double-stranded DNA virus, one of the papovaviruses, that belongs to the Papovaviridae family.[38] Transmission of the virus is believed to occur through sexual contact; however, the exact transmissibility of the virus into the cell is unknown. The initial infection follows trauma to the epithelium that allows the virus to reach and infect the basal cells of the epithelium, which appear to be supportive of viral propagation. Such minor trauma may occur during sexual intercourse. Epithelial cells that are infected with HPV undergo transformation, proliferate, and may form a warty growth. HPV manifestations may appear in about 2 to 3 months or may not be noticed for years.

CLINICAL MANIFESTATIONS. **Condylomata acuminata** are soft, skin-colored, whitish pink to reddish brown discrete growths. They may occur singly or in clusters and may be broad based or pedunculated and feathery or smooth (Figure 26-14). Sometimes the warts enlarge to form cauliflower-like masses on the male frenulum, glans, foreskin, urinary meatus, shaft, scrotum, or anus and on the female labia, clitoris, perineum, vagina, or anus (Figure 26-15). Although the lesions are usually not painful, they may cause dyspareunia (painful intercourse) and may be friable and bleed easily. Some individuals complain of pruritus. Cervical lesions are generally flattened and may not be seen easily without colposcopy.[2] Urethral condylomata may occur in men, are always preceded by skin lesions, and can become

WHAT'S NEW?

HPV Vaccine

Every year in the United States:
- About 12,000 women are diagnosed with HPV-related cervical cancer
- Almost 4000 women die from this disease
- About 1900 men get HPV related penile or anal cancer

Gardasil is available in the United States to vaccinate against four types of high-risk human papillomavirus (HPV):
- Recommended for females and males as early as age 9 or 10 years and up to age 26 years
- Given in a series of three injections over 6 months; administration of all three doses recommended; efficacy not established if series not completed
- Highly effective in preventing high-risk HPV types associated with cervical cancer; proven safe and effective by the Centers for Disease Control and Prevention (CDC), ongoing safety monitoring
- Not recommended for pregnant women because safety is not yet established
- Women still need cervical cancer screening at regular intervals because the vaccine will not protect against all HPV types
- The vaccine costs approximately $125 per shot, or $375 total, and is covered by most insurance plans, Medicaid, and the Vaccines for Children (VFC) program if individuals meet eligibility requirements, including age and financial need

For more information, visit the Centers for Disease Control and Prevention's STD website at www.cdc.gov/std. Data from Centers for Disease Control and Prevention: *HPV vaccine information, 2012,* Atlanta, 2012, U.S. Department of Health and Human Services. Available at www.cdc.gov/std/Hpv/STDFact-HPV-vaccine.htm.

FIGURE 26-14 **Condylomata Acuminata—Penile.** Asymptomatic, flesh-colored papules are present on the shaft of the penis. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2013, Saunders.)

FIGURE 26-15 Condylomata Acuminata—Vulva and Perineum. The clinical diagnosis was giant condylomata of Buschke and Löwenstein. Such large and confluent lesions should be carefully examined and multiple biopsies obtained to rule out underlying malignancy. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2013, Saunders.)

cancerous.[39] Ninety percent of lesions are found in the distal urethra.

Laryngeal papillomas can occur in infants whose mothers had genital warts at the time of delivery. Clinical manifestations of laryngeal warts include stridor, hoarseness, abnormal cry, cough, and respiratory distress.[40]

EVALUATION AND TREATMENT. Generally, diagnosis of condylomata acuminata is made on the basis of clinical manifestations. Verrucose, fleshy pink lesions caused by HPV must be differentiated from condylomata lata (the whitish gray, flat lesions) of secondary syphilis. Because HPV infection often accompanies other STIs, gonorrhea culture, chlamydia culture, serologic test for syphilis, and wet mount for other vaginal microorganisms also should be performed.

Treatments for external genital warts are considered cosmetic—not curative—and include patient-applied therapies (podofilox, imiquimod, and sinecathechins) and provider-administered therapies (cryotherapy, podophyllin resin, trichloroacetic acid [TCA], bichloroacetic acid [BCA], and surgery). Vaginal, urethral, or anal warts are treated in the clinic using TCA, BCA, cryotherapy, or surgical excision. Success of treatment depends on response of the immune system. Warts resolve in approximately one third of individuals and another one third of patients experience a decrease in wart size.[41] Surgical excision is the treatment for laryngeal warts in infants.

HPV infection, especially with high-risk strains, is a risk factor for the development of cancer. Before the development of adequate tests for screening for cervical cancer, it was a leading cause of death among older women. This is caused in part by the poor innervation of the upper pelvis, allowing cancerous masses to grow large before causing symptoms. The development of the Papanicolaou or "Pap" smear helped reduce deaths from cervical cancer by 70% since the 1950s.[42] Ideally, infections and cellular changes can be detected early so preventive measures and early treatment can begin.

The appropriate interval for screening for HPV and genital cancers has been controversial. Following the development of the Pap smear, women were advised to have yearly Pap tests to detect cancer. Over time, however, it became apparent that while younger women often had abnormal Pap tests, they were often able to clear HPV infection and resolve cellular changes without any treatment. Recent systematic reviews of the research support that treatment of women less than 20 years of age provides little to no benefit in reducing later rates of cervical cancer but results in pain, anxiety, and increased health care costs. In addition, the procedures used on the cervix to treat abnormal cells may increase the risk of the woman giving birth preterm.[43] Therefore, in 2012 the United States Preventive Services Health Task Force, the American College of Obstetricians and Gynecologists, and many other national cancer agencies recommended that Pap smear and HPV testing begin only after 21 years of age.

Women ages 21 to 29 should receive Pap testing alone every 3 years. Women 30 to 66 years of age may receive Pap testing with HPV screening every 5 years[44] (preferred) or Pap testing alone every 3 years.[45] After 65 years of age, Pap testing and HPV screening are no longer recommended since the risk of malignancy is low. Women who have had a hysterectomy with removal of the uterine cervix for a noncancerous condition do not need Pap smears or HPV testing for the rest of their life. Although the HPV vaccine does reduce the risk for cervical cancer, it does not change the frequency or need for Pap and HPV testing.

If the results of a Pap test are abnormal, the woman's cervix will be further evaluated using colposcopy, which involves applying acetic acid (vinegar) and using magnification to examine the cervix for changes indicative of cancer or precancerous lesions. HPV-infected cells will appear white when exposed to acetic acid. In some developing countries with limited laboratory facilities, this test alone is used to screen for cervical cancer (see What's New? Cervical Cancer Screening in the Developing World, Chapter 24, p. 826). Following visual investigation of the cervix during colposcopy, the clinician can take biopsies of suspicious areas for further investigation. Treatment of precancerous and cancerous lesions varies and involves removal or destruction of the affected cells through excision or ablation so they cannot continue to divide.

Although infection with high-risk HPV strains is a risk factor for development of anogenital cancers, as well as cervical cancer, there is no consensus on screening for rectal and anal cancers. Anyone who engages in receptive anal intercourse is at risk for rectal acquisition of HPV and subsequent development of anal cancers. Women are about twice as likely as men to develop anal cancer, but men who have sex with men also are at risk.[46] Hopefully the need for treatment of HPV-related genital conditions will decrease as more children and young adults receive the HPV vaccine before becoming sexually active.

FIGURE 26-16 Molluscum Contagiosum. Flesh-colored papules of molluscum may be distinguished by their umbilicated centers. The papules contain a white cheesy substance that may be stained for the presence of viral inclusion bodies. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2013, Saunders.)

Molluscum Contagiosum

Molluscum contagiosum is a benign viral infection of the skin in children and adults. Primarily the face, hands, lower abdomen, and genitalia are affected; papules found on other parts of the skin or widely distributed are not uncommon. Molluscum contagiosum also is a symptom of immunosuppression in HIV-positive individuals.[47]

Molluscum contagiosum occurs throughout the world and has been a common childhood disease in the developing world. It is much less common in the United States, where the incidence is highest among young adults. The childhood disease is transmitted by skin-to-skin contact and fomites (e.g., towels, wet surfaces and equipment) and affects the face, trunk, and limbs. Adult disease is more commonly sexually transmitted and affects the lower abdomen, genitalia, and perianal area.[47] Molluscum contagiosum in adults is most common in men 20 to 29 years of age and in those with multiple sexual partners. The molluscum contagiosum virus is taken into epithelial cells by phagocytosis and replicates within the cytoplasm, where it produces superficial cytoplasmic inclusions (**molluscum bodies**) and cellular hyperplasia. After an incubation period of 2 to 7 weeks, white or flesh-colored, round or oval dome-shaped papules appear. The lesions are relatively small (2 to 5 mm) but occasionally may coalesce to form larger lesions up to 15 mm. The surface has a characteristic central umbilication, from which a thick, creamy core material can be expressed (Figure 26-16). Generally the lesions are not painful or pruritic unless secondarily infected. The papules usually resolve in 6 to 12 months but may last several years and spread by autoinoculation.[47]

The appearance of the lesions is generally all that is needed to make the diagnosis, although direct microscopic examination of stained material from the core of the papule discloses molluscum bodies within the swollen and rounded epithelial cells. The lesions often heal spontaneously after several months but are contagious until completely healed. Other effective means of removing the lesions include curettage or application of liquid nitrogen (cryotherapy), silver nitrate, or topical creams; however, these treatments may cause scarring. Individuals tend to have lifetime immunity once lesions are healed.

Parasitic Infections

Trichomoniasis

Originally discovered in 1836, *T. vaginalis* was at first thought to be a harmless commensal microorganism. *T. vaginalis* is now known to be a common cause of sexually transmitted lower genital tract infection and urethritis.

Because **trichomoniasis** (infection by *T. vaginalis*) is not a reportable disease, its prevalence can only be estimated. The latest estimates suggest that as many as 3 million cases of trichomoniasis occur each year in the United States,[1,2] and that *T. vaginalis* accounts for one of four cases of infectious vaginitis. Although sexual transmission is clearly the most common means of disease spread, transmission through fomites is theoretically possible. To cause infection, the warm, moist fomite would have to introduce an inoculum of about 10,000 microorganisms directly into the vagina.[48]

PATHOPHYSIOLOGY. *T. vaginalis* is an anaerobic, unicellular, flagellated, parasitic protozoan that adheres to and damages squamous epithelial cells. Because this protozoan selectively affects squamous epithelia, vaginal and urethral tissue is often infected, as are periurethral (Skene) and greater vestibular (Bartholin) glands. The endocervical canal is not affected because it is lined with columnar epithelium. In men, the urethra is the most common site of infection, although the protozoa, called **trichomonads,** also can infect the epididymis and (rarely) the prostate.

Trichomoniasis is most common in men and women of reproductive age, and it is primarily an infection of the vagina. *T. vaginalis* can induce a marked inflammatory response in the vagina, causing a copious discharge that contains large numbers of polymorphonuclear neutrophils. Trichomonads adhere to but do not invade the squamous epithelial cells.

CLINICAL MANIFESTATIONS. Manifestations of vaginal trichomoniasis range from none to severe, with some women reporting an increase in distressing symptoms immediately after menses. Vaginal discharge and internal pruritus are the most common complaints. Dyspareunia and dysuria are also fairly common. Secretions are usually copious, frothy, malodorous, and yellow-green to gray-green. The vaginal walls may appear erythematous and sore. Small, punctate red marks, sometimes called *strawberry spots,* are sometimes visible on the vaginal walls and cervix. Vaginal pH is usually more than 4.5.[9] Most men with trichomoniasis are asymptomatic but may have scant intermittent discharge, slight pruritus, and mild dysuria.[9]

EVALUATION AND TREATMENT. History and symptoms are inadequate for diagnosis of trichomoniasis. Microscopic or laboratory confirmation of the presence of the trichomonads in vaginal secretions or urine provides a definitive diagnosis. In a fresh wet mount preparation that has been warmed slightly, the epithelial cells have relatively clean and sharp edges, the ratio

of polymorphonuclear leukocytes to epithelial cells exceeds 1:1, and the trichomonads are visible. The ovoid microorganism is slightly larger than a polymorphonuclear leukocyte and has one rounded, flagellated end and one slightly pointed, flagellated end. The flagella give the trichomonads their characteristic twisting motility. Fresh secretions have a pH higher than 4.5 and a positive amine odor when mixed with 10% KOH (positive "whiff test"). In an acidic environment, such as urine, the trichomonads assume a "balled-up" or spherical shape and become less motile.

There are a variety of clinical tests for trichomoniasis, including microscopic examination of vaginal discharge and pH testing, as well as laboratory tests, such as an immunochromatographic dipstick (e.g., OSOM Trichomonas Rapid Test) and a nucleic acid probe (e.g., Affirm VPIII).[9] Many tests have a high false-negative rate that can delay adequate treatment of infected individuals.

The treatment of choice for trichomoniasis is a single 2-gram dose of metronidazole (Flagyl) or tinidazole. The single-dose therapy is effective, has fewer side effects than multiple-dose therapy, and eliminates the need for individual compliance with longer regimens. Sexual partners, even if asymptomatic, also should be treated for trichomoniasis. The 2-gram single dose of metronidazole can be used to treat pregnant women. However, lactating women should suspend breast-feeding for 12 to 24 hours after single-dose therapy.[9]

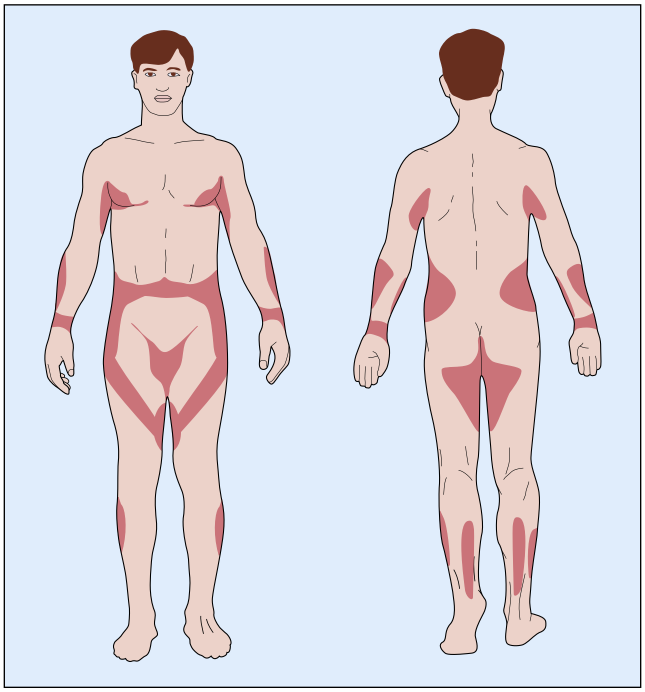

FIGURE 26-17 Distribution of Skin Lesions of *Sarcoptes scabiei* Infestation. Unshaded areas are rarely affected in healthy adults. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 3, London, 2003, Mosby.)

Scabies

Scabies is a common parasitic infection that can be spread by skin-to-skin and sexual contact. Discovered by Bonomo in 1687, it is considered to be the first human disease with a known cause.[49]

Scabies has a worldwide distribution, but actual prevalence is unknown.[14] Outbreaks are common in childcare centers, nursing homes, and prisons and are often spread to the larger community through familial contact. Transmission of scabies requires prolonged close skin-to-skin contact, which occurs within families or between sexual partners. Mites also can be transferred through infested bedding, clothes, and other fomites. Nonsexual transmission is common in residential institutions and hospitals, especially when crusted scabies, a highly contagious variant of scabies, is present.[50]

PATHOPHYSIOLOGY. Only 5 to 10 mites are needed to establish infection in a previously uninfected individual. The adult female itch mite, *Sarcoptes scabiei,* is 0.3 to 0.4 mm long and has a life span of about 30 days. Once deposited on human skin, it burrows through the horny layer of the stratum granulosum. Within hours of burrowing, the female begins laying two or three large eggs per day, each of which progresses through larval and nymphal stages to become an adult itch mite in about 10 days. The most common places for scabies to burrow are on the hands (between the fingers) and on the flexor surfaces of the wrists and the extensor surfaces of the elbows. The groin is a common location for sexually transmitted scabies. Lesions may occur on the penile shaft, glans, scrotum, and buttocks.[51,52] Figure 26-17 shows the typical sites of scabies burrows.

FIGURE 26-18 Scabies Burrow. An S-shaped burrow with a tiny vesicle at one end. (From Marks JG, Miller JJ: *Lookingbill and Marks' principles of dermatology,* ed 4, St Louis, 2006, Saunders.)

CLINICAL MANIFESTATIONS. The classic symptom of scabies is intense pruritus, which may increase at night. Pruritus is a result of a reaction to the presence of the *S. scabiei* mite. This reaction may take weeks to develop with initial infection, but only 24 hours if the person has been previously infected. The typical burrow of the *S. scabiei* is a short, linear, curved, or S-shaped line (Figure 26-18). There may be small, erythematous, excoriated larval papules near the burrows. Secondary infections are common and are caused by scratching. In some individuals a

hypersensitivity reaction occurs a month or more after the infestation and causes multiple, reddish brown, pruritic nodules on the covered portions of the body—most commonly, the upper thighs, buttocks, male genitalia, and axillary regions. These nodules may persist for more than 1 year despite treatment with a scabicide. Even after successful treatment, some individuals will continue to experience pruritus for several weeks.[51]

EVALUATION AND TREATMENT. Although the diagnosis of scabies is often made clinically, microscopic identification of the mite or its eggs, larvae, or feces is recommended because the symptoms of scabies can imitate those of many other dermatologic conditions. Superficial scrapings from a recently developed unexcoriated papule or burrow can be observed easily under the microscope; the addition of KOH allows easier visualization of the mite.

Preferred treatment is topical application of 5% permethrin massaged into the skin and left for 8 to 14 hours, or ivermectin 1% dosed at 200 mcg/kg orally and repeated again in 2 weeks. Lindane (1%) lotion or cream also is effective if applied thinly to all areas of the body below the neck and washed thoroughly at 8 hours.[9] Close household and sexual contacts should be treated even if they are not yet symptomatic. Permethrin has been used safely in infants as young as 2 months and is the treatment of choice for children. Pregnant women should be treated with permethrin only if infestation with scabies can be documented. For population-based outbreaks, such as those in residential institutions, the CDC recommends treating the entire population; ivermectin has advantages in these settings because it is easy to administer and is not dependent on thorough topical treatment and bathing.[9] To prevent reinfestation, clothing and bed linens should be machine washed and dried at high temperatures, or kept away from body contact for 72 hours.[9]

Pediculosis Pubis

Phthirus pubis, the crab louse, is one of three species of lice that infest humans. *P. pubis* is commonly transmitted sexually and causes **pediculosis pubis,** or "crabs." Adolescents and young children are most commonly infected.

P. pubis is transmitted primarily by intimate sexual contact or contact with infected bed linens or clothing. It is highly contagious; there is a 95% chance of contracting the disease during a single sexual encounter. Fomites are another common method of infection because crabs can live away from the body for several days. The transfer of lice from pubic hair is probably mechanical, assisted by scratching, fingernails, towels, and other similar means rather than by self-propulsion. Pubic lice usually infect the perineal and axillary hair and occasionally the hair of the trunk, beard, scalp, and eyelashes.

PATHOPHYSIOLOGY. The crab louse has a 25- to 30-day life cycle from egg to egg that consists of five stages: an egg (or nit) stage, three nymphal stages, and an adult stage, all of which occur in the host. The nits of crab lice are found "glued" to hairs; they are oval, 0.8 by 0.3 mm, and whitish, and they hatch in 5 to 10 days (Figure 26-19). In the adult stage, pubic lice are grayish, are approximately 1 mm in length, and have a segmented body and claws particularly designed for clinging to pubic hairs. Because lice depend on blood for nutrition, they bite into the skin to obtain food.

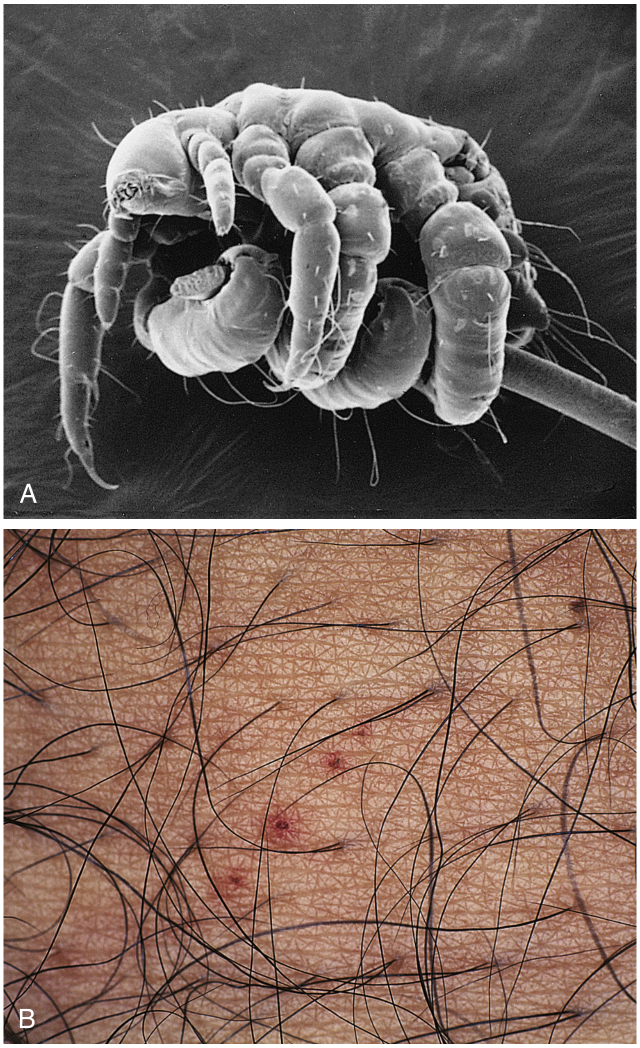

FIGURE 26-19 **Pubic Louse and Crab Louse. A,** Pubic louse *(Phthirus pubis)* encircling a pubic hair; the clawlike legs produce a firm grip. **B,** Crab louse bites *(P. pubis).* (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2013, Saunders.)

CLINICAL MANIFESTATIONS. Symptoms range from mild pruritus to severe, intolerable itching, depending on the individual's sensitivity to louse bites. Allergic sensitization occurs in about 5 days, when itching, erythema, and inflammation may worsen. Excessive scratching may lead to secondary infection.

EVALUATION AND TREATMENT. The individual usually presents with a history of localized itching in the infected area. Because the lice and nits are visible to the naked eye, a thorough clinical examination permits definitive diagnosis. Pediculosis pubis is treated with 1% permethrin cream rinse or 1% lindane lotion, cream, or shampoo or with over-the-counter pyrethrin or piperonyl butoxide. Infection of the eyelashes should be treated with occlusive ophthalmic ointment for 10 days.[9] For nonocular infections, the pediculicide is applied to infested and adjacent hairy areas and removed after a specified length of time by thorough washing. Remaining nits can be removed with a fine-toothed comb. Permethrin is recommended for young children and pregnant women and has less potential toxicity

with inappropriate use. On the other hand, lindane is the least expensive and nontoxic if used correctly. Lindane should not be used after a bath, or by persons with extensive dermatitis, by pregnant or lactating women, or by children less than 2 years of age.[53] Sexual contacts from the past month should be treated regardless of symptoms, and any other intimate household contacts also should be examined and treated if needed. Clothing and bed linens should be machine washed and dried at high temperatures or kept away from body contact for 72 hours. Treatment can be repeated in 7 days to eradicate any newly hatched lice.

Resistance to treatment is increasing and is widespread. If initial treatment fails, malathion 0.5% lotion is a second-line treatment but has an unpleasant odor and must be kept on the body for 8 to 12 hours.[9]

SEXUALLY TRANSMITTED INFECTIONS OF OTHER BODY SYSTEMS

There are a variety of infectious diseases, including some enteric bacterial and systemic viral diseases, in which the main mode of transmission is not through sexual contact. Some, however, are transmitted through sexual contact, more so among men who have sex with men. Although the major mode of transmission may be by ingestion (i.e., gastrointestinal system through hand-to-mouth or water or food consumption), respiratory exposure (i.e., hand to nose or eye, or inhalation), or direct contact with blood or body fluids (i.e., sharing of needles among drug users, blood transfusions, vertical transmission from mother to baby, health worker exposures), infection can be transmitted through intimate sexual contact as well. Among the most serious of these infections is acquired immunodeficiency syndrome (AIDS) caused by the human immunodeficiency virus (HIV) and hepatitis (all types). Worldwide, the main mode of transmission of HIV and hepatitis B is through sexual intercourse (primarily heterosexual), but nonsexual exposure to infected blood and body fluids contributes significantly to infection rates for both. The epidemiology, modes of transmission, pathophysiology, clinical manifestations, and evaluation and treatment of AIDS and hepatitis are discussed in detail in Chapters 10 and 41. Less serious, but often debilitating, are gastrointestinal infections, such as shigellosis and giardiasis, and systemic diseases, such as Epstein-Barr virus and cytomegalovirus infections. Table 26-3 provides a list of several gastrointestinal and systemic infections that are known to be transmitted by intimate sexual contact, but in which the mode of transmission is primarily through other routes.

Hepatitis B Virus

Hepatitis is a liver infection that can be caused by six types of viruses: hepatitis A, hepatitis B, hepatitis C, hepatitis D, hepatitis E, and hepatitis G. Each virus causes a syndrome of acute, icteric (jaundice-producing) liver inflammation. Of the three types, the **hepatitis B virus (HBV)** is known to be sexually transmitted. (Hepatitis A, like most other predominantly enteric infections, may be considered an STI because of anal-oral transmission.) Although hepatitis C virus (HCV) is not recognized as an STI, the CDC has listed sexual exposure, particularly for individuals with multiple partners, as a potential HCV risk factor (Figure 26-20). Data indicate sexual transmission may occur in approximately 1% of HCV cases; however, the virus is inefficiently spread through this manner.[54] Additional information about hepatitis is found in Chapter 41.

The prevalence of HBV infection varies dramatically worldwide. Widespread screening of pregnant women and

TABLE 26-3 INFECTIONS WITH KNOWN SEXUAL TRANSMISSIBILITY: MAIN MODE OF TRANSMISSION BY OTHER MEANS

INFECTION/DISEASE	MAIN ROUTE OF TRANSMISSION
Gastrointestinal Infections	
Shigellosis caused by the *Shigella* bacteria	Contact with infected feces Hand-to-mouth
Campylobacter enteritis caused by the *Campylobacter jejuni* bacteria	Primarily an animal pathogen Hand-to-mouth
Giardiasis caused by the *Giardia lamblia* protozoa	Contaminated drinking water Hand-to-mouth
Amebiasis caused by the *Entamoeba histolytica* protozoa	Contaminated drinking water Hand-to-mouth
Hepatitis (liver infection and inflammation) A, C	Hepatitis A: contact with infected feces; hand-to-mouth Hepatitis C: blood-borne pathogen; direct exposure to contaminated blood; sexual transmission very uncommon
Systemic Diseases	
Epstein-Barr virus	Mucous membrane (oral) exposure
Cytomegalovirus	Body fluids; exposure via close interpersonal contact or direct transfer

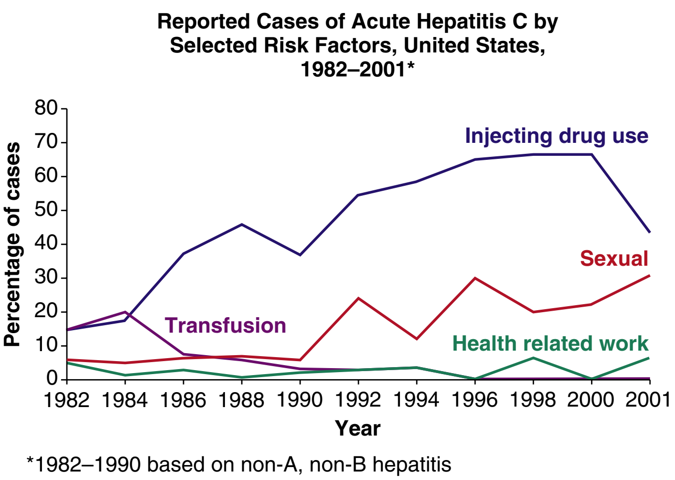

FIGURE 26-20 Risk for Hepatitis C Exposure. Comparison of injecting drug use *(blue)*, transfusions *(purple)*, health-related work *(green)*, and sexual exposure *(red)*. Note the rise in sexually transmitted incidences. (From Centers for Disease Control and Prevention: *Hepatitis C: What clinicians and other health professionals need to know, 2000.* Available at www.cdc.giv/ncid/diseases/hepatitis/c_training/edu/intro).

vaccination of all infants since 1991 has decreased the rate of infection in the United States by more than 80% and is expected to have lasting effects into future decades.[55] In the United States, approximately 5% to 20% of the general population has evidence of HBV infection, and more than 1.4 million are chronically infected.[2] Seropositivity generally increases with age. Serologic tests of STI clinic patients show evidence of past infection in 28% of individuals ages 25 years and older and 7% in those younger than 25 years.[53] Those at risk for HBV infection in the United States are infants born to hepatitis-infected mothers, healthcare workers, individuals who have sexual contact with HBV-infected persons, and immigrants from areas of high HBV prevalence. However, larger portions of the population are at risk in developing countries. For example, 60% to 80% of the population in Southeast Asia and Africa may harbor serologic evidence of past or current infection.

Transmission of HBV can occur through needle puncture, blood transfusion, cuts or abrasions in the skin, and absorption by mucosal surfaces. Direct contact with infected body fluids, such as tears, cerebrospinal fluid, synovial fluid, gastric juices, pleural fluid, semen, and urine, may pass the infection. The hepatitis B virus can survive dry and outside the body for up to 1 week, making it easily infectious on fomites, such as medical equipment. Only very high temperatures or bleach can kill the hepatitis virus.[9] Perinatal transmission of HBV is relatively common. Neonates whose mothers are infectious have a 90% chance of becoming chronically infected with HBV during labor or delivery if they do not receive treatment.[55] Infants of infected mothers should receive HBV vaccine and immunoglobulin against hepatitis within 12 hours of birth to reduce risk. The vaccine and immunoglobulin combination successfully prevents chronic carrier status 85% of the time.[55] Although HBV is in many maternal body fluids, it is not found in breast milk and breast-feeding is still encouraged for mothers with HBV.[56]

Hepatitis delta agent is a defective virus that is similar to HBV antigen but cannot cause hepatitis B by itself, requiring the presence of HBV to cause hepatitis. Hepatitis delta infection is rare in the United States, but cases have been documented in intravenous drug users and their sexual contacts and in recipients of contaminated blood. It is most commonly found in men who have sex with men, persons requiring kidney dialysis, and healthcare workers.

PATHOPHYSIOLOGY. After exposure, HBV passes through the bloodstream to the liver, where it infects liver cells and multiplies. The infection is usually self-limiting, with most patients mounting an effective immune response. Approximately 6% to 10% of infected adults cannot eradicate the virus and become chronic carriers of HBV. There is an inverse relationship between age and chronic carrier status, with younger individuals at greater risk for infection.[9]

CLINICAL MANIFESTATIONS. Most HBV infections are clinically asymptomatic and result in permanent immunity. Symptoms of hepatitis usually develop only after an HBV antigen has been circulating in the blood for 3 to 6 weeks. Approximately 15% to 20% of individuals develop a prodromal syndrome characterized by an erythematous rash, urticaria, polyarthralgias, and arthritis. Symptoms of infection also may include lassitude, anorexia, nausea, vomiting, headache, fever, dark urine, jaundice, and moderate liver enlargement with tenderness. Long-term sequelae include chronic persistent and chronic active hepatitis, cirrhosis, hepatocellular carcinoma, hepatic failure, and death. In neonates who contract HBV, the disease may be manifested in many ways from mild illness to a severe infection with liver damage.

EVALUATION AND TREATMENT. HBV infection is clinically indistinguishable from other types of hepatitis. Diagnosis can be made only through serologic testing. No specific therapy exists for HBV infection in adults. Treatment consists of supportive care and relief of symptoms. Since 1991, the CDC has promoted an aggressive vaccination campaign and recommends vaccination for all infants, children, and adolescents and a diversity of high-risk adults. The three-injection vaccine series is begun at birth for all infants.

Acquired Immunodeficiency Syndrome

Epidemiology, modes of transmission, pathophysiology, clinical manifestations, and evaluation and treatment of AIDS are discussed in detail in Chapter 10.

SUMMARY REVIEW

Sexually Transmitted Urogenital Infections

1. Gonorrhea is a sexually transmitted communicable disease that can be local or systemic. Complications include PID, sterility, and disseminated infection.
2. Gonorrhea passed to the fetus from the mother typically manifests as an eye infection and develops 1 to 12 days after birth. Usually ophthalmic antibiotic prophylaxis is not sufficient to prevent infection.
3. Gonorrhea is rapidly becoming resistant to available antibiotics. Multidrug therapy is now recommended to decrease drug resistance.
4. Syphilis is an STI that becomes systemic shortly after infection. The four stages of the disease are: (a) primary syphilis with a chancre at the site of infection; (b) secondary syphilis with systemic spread to all body systems; (c) latent syphilis with minimal symptoms or the development of skin lesions; and (d) tertiary syphilis, the most severe stage, with destruction of bone, skin, and soft and neurologic tissues.
5. Congenital syphilis contributes to prematurity of the newborn with bone marrow depression, CNS involvement, renal failure, and intrauterine growth retardation.
6. Syphilis is diagnosed by darkfield microscopy and serologic testing and is treated with injectable penicillin. Sexual partners also are treated.
7. With chancroid infection, women are generally asymptomatic and men may develop inflamed, painful genital ulcers

SUMMARY REVIEW—cont'd

and inguinal buboes. Incubation period is 1 to 14 days. Single-dose therapy with injectable ceftriaxone or oral azithromycin for both partners is recommended. Persons with HIV may require a longer treatment regimen.

8. Granuloma inguinale (donovanosis) is rare in the United States. The bacteria are gram negative and survive within macrophages. Localized nodules coalesce to form granulomas and ulcers on the penis in men and labia in women. Antibiotics provide effective treatment. Although rare and mildly infectious, granuloma inguinale is a chronic, progressively destructive bacterial infection.
9. Bacterial vaginosis (BV) is a sexually-associated condition caused by an overgrowth of anaerobic bacteria that produce aromatic amines and raise the pH of the vagina, promoting further bacterial growth (without an inflammatory response) and a fishy odor. "Clue cells" are found on the wet mount. Metronidazole (Flagyl) provides effective treatment. BV has been associated with PID, chorioamnionitis, preterm labor, and postpartum endometritis. Treatment of male sexual partners is not recommended.
10. Chlamydia is the most common bacterial STI in the United States and a leading preventable cause of infertility and ectopic pregnancy. The causative organism, *C. trachomatis,* localizes to epithelial tissue and can spread throughout the urogenital tract or pass from infected mother to the eyes and respiratory tract of newborn infants during birth. *C. trachomatis* is susceptible to inexpensive, readily accessible antibiotics. Single-dose azithromycin is the drug of choice. Antibiotic therapy for infected individuals and all sexual contacts is recommended. Because of the asymptomatic nature of chlamydia and the potential sequelae of untreated infection, extensive and widespread screening is recommended by the CDC.
11. Lymphogranuloma venereum is a chronic STI uncommon in the United States. The lesion begins as a skin infection and spreads to the lymph tissue, causing inflammation, necrosis, buboes, and abscesses of the inguinal lymph nodes. Primary lesions appear on the penis and scrotum in men and on the cervix, vaginal wall, and labia in women. Secondary lesions involve inflammation and swelling of the lymph nodes with formation of large blue buboes that rupture and form draining ulcerative lesions. A 21-day or longer course of oral doxycycline or erythromycin is needed for treatment. Treatment of sexual partners is recommended.
12. Genital herpes is the most common genital ulceration in the United States and is caused by either HSV-1 or HSV-2. Lesions initially appear as groups of vesicles that progress to ulceration with pain, lymphadenopathy, and fever. Herpes simplex virus passes from mother to fetus; thus, women with active lesions should give birth by cesarean section to avoid vertical transmission. Acyclovir reduces symptoms but does not cure the disease.
13. Herpes simplex virus (HSV) infection is lifelong and can result in an initial outbreak and subsequent outbreaks. Individuals are contagious during outbreaks and episodes of asymptomatic viral shedding. Recurrent infections are most often attributable to HSV-2 and are generally milder and of shorter duration.
14. Human papillomavirus (HPV) is associated with the development of cervical dysplasia and cancer as well as condylomata acuminata. The high-risk strains of HPV (HR-HPV) that are precursors to the development of cervical cancer do not cause genital warts. Testing is available to detect HR-HPV and a vaccine is now available for HPV types 16 and 18, which have the highest risk for cervical cancer.
15. Condylomata acuminata (genital warts) are sexually transmitted and highly contagious. The velvety cauliflower-like lesions occur in the genital and anal areas, vagina, and cervix and are painless. They can be transmitted to the infant at birth.
16. Molluscum contagiosum is a benign viral infection of the skin. It is transmitted by skin-to-skin contact in children and adults. In adults, it tends to occur on the genitalia and to be transmitted by sexual contact.
17. Trichomoniasis *(T. vaginalis)* causes vaginitis in women, and urethritis in men. Both partners usually are infected. Women usually have a copious, malodorous, gray-green discharge with pruritus. Men usually are asymptomatic. Metronidazole is the treatment for both partners.
18. Scabies is a common parasitic infection that can be spread by skin-to-skin contact and sexual contact. The scabies mite burrows through the skin, depositing two or three large eggs per day. Intense pruritus, especially at night, is the most pronounced clinical manifestation. Treatment consists of topical application of a pediculicide.
19. Pediculosis pubis (crabs) is commonly transmitted sexually and is caused by the crab louse, *P. pubis.* The lice bite into the skin for nutrition. Symptoms include mild and severe pruritus. Topical application of prescription or over-the-counter pediculicides is effective treatment.

Sexually Transmitted Infections of Other Body Systems

1. Systemic diseases known to be sexually transmitted include AIDS (see Chapter 9), cytomegalovirus infection, and Epstein-Barr virus.
2. Transmission of HBV can occur through needle puncture, blood transfusion, cuts in the skin, and contact with infected body fluids.
3. Hepatitis B infection poses significant health risks including chronic liver disease and hepatocellular cancer. Immunization against hepatitis B is the most effective means of preventing transmission. Universal vaccination of infants and children is recommended, as well as vaccination of high-risk adults.
4. The risk of perinatal transmission of HBV is high for infants of HBV-infected mothers unless they receive immunoglobulin and vaccination.
5. Hepatitis C is generally transmitted percutaneously but sexual transmission appears possible.

CHAPTER OUTLINE

All the body's tissues and organs require oxygen and nutrients to survive. These essential needs are provided by the blood that flows through miles of vessels throughout the human body. The red blood cells provide the oxygen and remove carbon dioxide, and the fluid portion of the blood carries the nutrients and ions for proper acid-base balance. The blood also cleans discarded waste from the tissues; transports hormones; conveys cells (white blood cells), platelets, and other ingredients that are necessary for protecting the entire body from injury and infection and initiating healing; and provides thermal regulation to maintain organs and tissues within an acceptable range of temperatures.

COMPONENTS OF THE HEMATOLOGIC SYSTEM

Composition of the Blood

Blood consists of various cells that circulate in the cardiovascular system suspended in a solution of protein and inorganic materials (plasma), which is approximately 92% water and 8% dissolved substances (solutes) (Figure 27-1). The blood volume amounts to about 6 quarts (5.5 L) in adults. The continuous movement of blood guarantees that critical components are available to all parts of the body to carry out their chief functions: (1) delivery of substances needed for cellular metabolism in the tissues, (2) removal of the wastes of cellular metabolism, (3) defense against invading microorganisms and injury, and (4) maintenance of acid-base balance.

Plasma and Plasma Proteins

In adults, plasma accounts for 50% to 55% of blood volume. **Plasma** is a complex aqueous liquid containing a variety of organic and inorganic elements (Table 27-1). The concentration of these elements varies depending on diet, metabolic demand, hormones, and vitamins. Plasma differs from serum in that **serum** is plasma that has been allowed to clot in the laboratory in order to remove fibrinogen and other clotting factors that may interfere with some diagnostic tests.

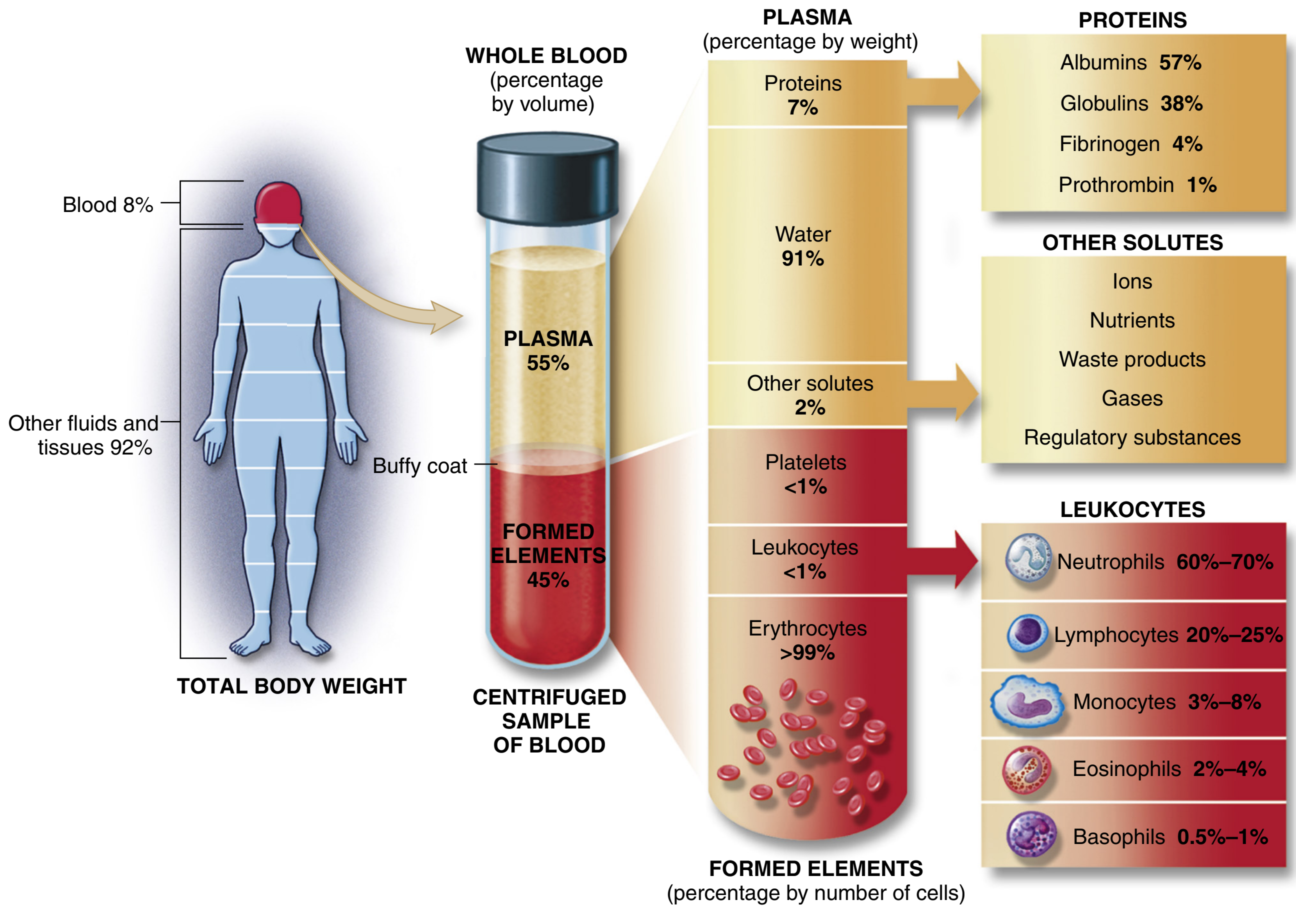

FIGURE 27-1 Composition of Whole Blood. Approximate values for the components of blood in a normal adult. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

The plasma contains a large number of proteins (**plasma proteins**) that constitute about 7% of the total plasma weight. These vary in structure and function and can be classified into two major groups, albumin and globulins. Most plasma proteins are produced by the liver. The major exception is antibodies (immunoglobulins), which are produced by plasma cells in the lymph nodes and other lymphoid tissues (see Chapter 8).

Albumin (about 60% of total plasma protein at a concentration of about 4 g/dl) serves as a carrier molecule for normal components of blood as well as drugs that have low solubility in water (e.g., free fatty acids, lipid-soluble hormones, thyroid hormones, bile salts). Its most essential role is regulation of the passage of water and solutes through the capillaries. Albumin molecules are large and do not diffuse freely through the vascular endothelium, and thus they maintain the critical colloidal osmotic pressure (or oncotic pressure) that regulates the passage of water and solutes into the surrounding tissues (see Chapters 1 and 3). Water and solute particles tend to diffuse out of the arterial portions of the capillaries because the blood pressure is greater in arterial than in venous blood vessels (see Chapter 3). Water and solutes move from tissue cells into the venous portions of the capillaries where the pressures are reversed, oncotic pressure being greater than intravascular pressure or hydrostatic pressure. In the case of decreased production (e.g., cirrhosis, other diffuse liver diseases, protein malnutrition) or excessive loss of albumin (e.g., certain kidney diseases, extensive burns), the reduced oncotic pressure leads to excessive movement of fluid and solutes into the tissue and decreased blood volume.

The remaining plasma proteins, or **globulins,** are often classified by their properties in an electric field (serum electrophoresis). Under the normal conditions used to perform serum electrophoresis, albumin is the most rapidly moving protein. The globulins are classified by their movement relative to albumin: alpha (α) globulins (those moving most closely to albumin), beta (β) globulins, and gamma (γ) globulins (those with the least movement). Depending on the electrophoretic procedure the alpha and beta globulins may be subdivided into subregions (α_1-, α_2-, β_1-, or β_2-globulins). Fibrinogen is a major plasma protein (about 4% of total plasma protein) that would move between the beta and gamma regions but is removed during the formation of serum. The gamma-globulin region consists primarily of immunoglobulin G (IgG) (see Chapter 8).

Plasma proteins can also be classified into groups by function: clotting, defense, transport, or regulation. The **clotting factors** promote coagulation and stop bleeding from damaged blood vessels. Fibrinogen is the most plentiful of the clotting factors and is the precursor of the fibrin clot. Proteins involved in defense, or protection, against infection include antibodies and complement proteins (see Chapters 7 and 8). Transport proteins

TABLE 27-1 ORGANIC AND INORGANIC COMPONENTS OF ARTERIAL PLASMA

CONSTITUENT	AMOUNT/CONCENTRATION	MAJOR FUNCTIONS
Water	93% of plasma weight	Medium for carrying all other constituents
Electrolytes	Total <1% of plasma weight	Maintain H_2O in extracellular compartment; act as buffers; function in membrane excitability
Na^+	142 mEq/L (142 mM)	
K^+	4 mEq/L (4 mM)	
Ca^{2+}	5 mEq/L (2.5 mM)	
Mg^{2+}	3 mEq/L (1.5 mM)	
Cl	103 mEq/L (103 mM)	
HCO_3^-	27 mEq/L (27 mM)	
Phosphate (mostly)	2 mEq/L (1 mM)	
Sulfate	1 mEq/L (0.5 mM)	
Proteins	7.3 g/dl (2.5 mM)	Provide colloid osmotic pressure of plasma; act as buffers; bind other plasma constituents (lipids, hormones, vitamins, minerals, etc.); clotting factors; enzymes; enzyme precursors; antibodies (immunoglobulins); hormones; transporters
Albumin	4.5 g/dl	
Globulins	2.5 g/dl	
Fibrinogen	0.3 g/dl	
Transferrin	250 mg/dl	
Ferritin	15-300 mcg/L	
Gases		
CO_2 content	22-32 mmol/L plasma	Byproduct of oxygenation, most CO_2 content is from HCO_3 and acts as a buffer
O_2	$Pa{O_2}$ 80 torr or greater (arterial); $Pv{O_2}$ 30-40 torr (venous)	Oxygenation
N_2	0.9 ml/dl	Byproduct of protein catabolism
Nutrients		Provide nutrition and substances for tissue repair
Glucose and other carbohydrates	100 mg/dl (5.6 mM)	
Total amino acids	40 mg/dl (2 mM)	
Total lipids	500 mg/dl (7.5 mM)	
Cholesterol	150-250 mg/dl (4-7 mM)	
Individual vitamins	0.0001-2.5 mg/dl	
Individual trace elements	0.001-0.3 mg/dl	
Iron	50-150 mcg/dl	
Waste products		
Urea (blood urea nitrogen [BUN])	7-18 mg/dl (5.7 mM)	End product of protein catabolism
Creatinine (from creatine)	1 mg/dl (0.09 mM)	End product from energy metabolism
Uric acid (from nucleic acids)	5 mg/dl (0.3 mM)	End product from protein metabolism
Bilirubin (from heme)	0.2-1.2 mg/dl (0.003-0.018 mM)	End product of red blood cell destruction
Individual hormones	0.000001-0.05 mg/dl	Functions specific to target tissue

Data from Vander AJ, Sherman JH, Luciano DS: *Human physiology: the mechanisms of body function,* ed 8, New York, 2001, McGraw-Hill.

specifically bind and carry a variety of inorganic and organic molecules, including iron (transferrin), copper (ceruloplasmin), steroid hormones, and vitamins (e.g., retinol-binding protein). The plasma lipids, triglycerides, phospholipids, cholesterol, and fatty acids are carried through the blood as complexes with plasma proteins; they are known as *lipoproteins* (see Chapters 1 and 32). Regulatory proteins include a variety of enzymatic inhibitors (e.g., α_1-antitrypsin) that protect the tissues from damage, precursor molecules (e.g., kininogen) that are converted into active biologic molecules when needed, and protein hormones (e.g., cytokines) that communicate between cells.

Plasma also contains several charged inorganic ions (electrolytes) that regulate cell function, osmotic pressure, and blood pH. (Electrolytes are described in Chapters 1 and 3.)

Cellular Components of the Blood

The cellular elements of the blood are broadly classified as red blood cells (RBCs) (i.e., erythrocytes), white blood cells (WBCs) (i.e., leukocytes), and platelets (thrombocytes). The components of the blood are listed in Table 27-2.

Erythrocytes. In 1628 Robert Burton described blood as a "hot, temperate red humor whose office is to nourish the whole body, to give it strength and color being dispersed by the veins through every part of it."[1] A few years later, with the invention of the microscope, researchers learned that erythrocytes give blood its red color.

Erythrocytes (red blood cells [RBCs]) are the most abundant cells of the blood, occupying approximately 48% of the blood volume in men and about 42% in women. Erythrocytes are primarily responsible for tissue oxygenation. The erythrocyte contains hemoglobin, which carries the gases, and electrolytes, which regulate diffusion through a cell's plasma membrane. The mature erythrocyte lacks a nucleus and cytoplasmic organelles (e.g., mitochondria), so it cannot synthesize protein or carry out oxidative reactions. Because it cannot undergo mitotic division, the erythrocyte has a limited life span

TABLE 27-2 CELLULAR COMPONENTS OF THE BLOOD

CELL	STRUCTURAL CHARACTERISTICS*	NORMAL AMOUNTS OF CIRCULATING BLOOD	FUNCTION	LIFE SPAN
Erythrocyte (red blood cell)	Nonnucleated cytoplasmic disk containing hemoglobin	4.2-6.2 million/mm^3	Gas transport to and from tissue cells and lungs	80-120 days
Leukocyte (white blood cell)	Nucleated cell	5000-10,000/mm^3	Body defense mechanisms	See below
Lymphocyte	Mononuclear immunocyte	25-33% of leukocyte count (leukocyte differential)	Humoral and cell-mediated immunity (see Chapter 7)	Days or years depending on type
Monocyte and macrophage	Large kidney-shaped mononuclear phagocyte	3-7% of leukocyte differential	Phagocytosis; mononuclear phagocyte system	Months or years
Eosinophil	Segmented polymorphonuclear granulocyte with granules stainable by eosin dyes	1-4% of leukocyte differential	Phagocytosis; response to parasites, control of allergic reactions	8-12 days
Neutrophil	Segmented polymorphonuclear granulocyte with granules stainable by neutral staining	57-67% of leukocyte differential	Phagocytosis, particularly during early phase of inflammation, bacterial killing	4 days
Basophil	Lobate nuclear granulocyte with granules stainable by basic dyes	0-0.75% of leukocyte differential	Similar to mast cell, secretes inflammatory mediators (e.g., histamine, chemotactic factors for eosinophils and neutrophils), involved with allergic reactions	Few hours to days
Platelet	Irregularly shaped cytoplasmic fragment (not a cell)	140,000-340,000/mm^3	Hemostasis following vascular injury; normal coagulation and clot formation/retraction	8-11 days

*See bottom row of Figure 27-10 for illustrations of cells.

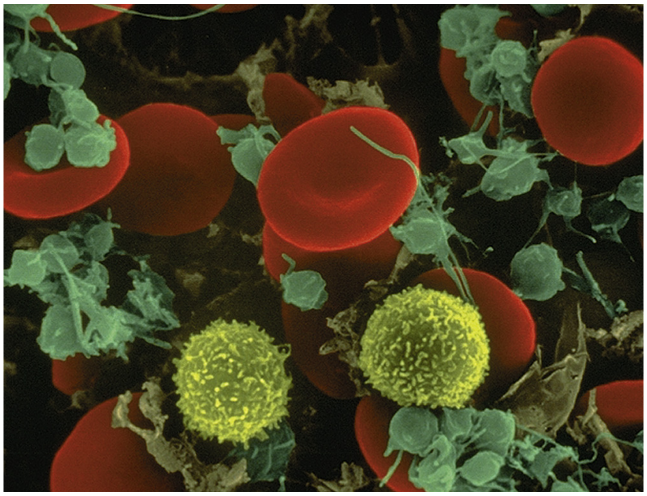

FIGURE 27-2 Blood Cells. Leukocytes are spherical and have irregular surfaces with numerous extending pili (appear as yellow). Erythrocytes are flattened spheres with a depressed center. Activated platelets are green. (Copyright Dennis Kunkel Microscopy, Inc.)

(approximately 100 to 120 days), ages, and is removed from the circulation to be replaced by new erythrocytes.

The erythrocyte's size and shape are ideally suited to its function as a gas carrier. An RBC is a small disk with two unique properties: (1) a *biconcave* shape and (2) the capacity to be *reversibly deformed* (Figure 27-2 and Figure 27-6). The flattened, biconcave shape provides a surface area/volume ratio that is optimal for gas diffusion into and out of the cell and for deformity.[2] During its life span, the erythrocyte, which is 6 to 8 μm in diameter, repeatedly circulates through sinusoids of the spleen and capillaries that are only 2 μm in diameter. Reversible deformity enables the erythrocyte to assume a more compact torpedo-like shape, squeeze through the microcirculation, and return to normal.

Leukocytes. **Leukocytes (white blood cells [WBCs])** defend the body against microorganisms that cause infection and remove debris, including dead or injured cells of all kinds (see Figure 27-2). The leukocytes act primarily in the tissues but are transported in the circulation. The average adult has approximately 5000 to 10,000 leukocytes/mm^3 of blood.

Leukocytes are classified according to structure as either **granulocytes** or **agranulocytes** and according to function as either **phagocytes** or **immunocytes.** The granulocytes, which include neutrophils, basophils, and eosinophils, are all phagocytes. (Phagocytic action is described in Chapter 7.) Of the agranulocytes, the monocytes and macrophages are phagocytes, whereas the lymphocytes are immunocytes (cells that create immunity; see Chapter 8).

Granulocytes. Granulocytes have many membrane-bound granules in their cytoplasm. These granules contain enzymes capable of killing microorganisms and catabolizing debris ingested during phagocytosis. The granules also contain powerful biochemical mediators with inflammatory and immune functions. These mediators, along with the digestive enzymes, are released from granulocytes in response to specific stimuli. The biochemical mediators have vascular and intercellular effects and the enzymes participate in the breakdown of debris from sites of infection or injury. Granulocytes are capable of amoeboid movement, by which they migrate through vessel walls (diapedesis) and then to sites where their action is needed (see Chapter 7).

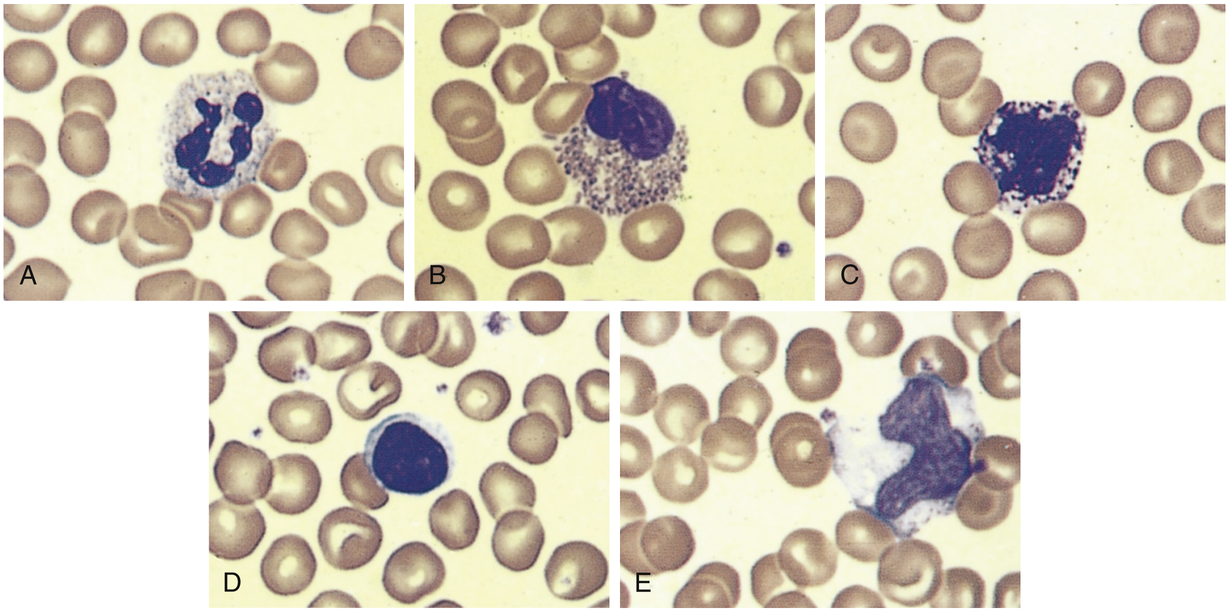

FIGURE 27-3 **Leukocytes.** An example of leukocytes in a human blood smear. **A,** Neutrophil. **B,** Eosinophil. **C,** Basophil. **D,** Lymphocyte. **E,** Monocyte. (From Erlandsen S, Magney J: *Color atlas of histology,* St Louis, 1992, Mosby.)

The **neutrophil** (**polymorphonuclear neutrophil** [**PMN**]) is the most numerous and best understood of the granulocytes (Figure 27-3, *A*). Neutrophils constitute about 55% of the total leukocyte count in adults. The cytoplasm of neutrophils contains small lysosomal granules and a central nucleus with two to five distinct lobes. Immature neutrophils are called *bands* or *stabs*. Mature neutrophils are called *segmented neutrophils* because of the characteristic appearance of their nucleus. Neutrophils reach a fully mature state in the bone marrow, and these mature neutrophils are called the *marrow neutrophil reserve.* Normally it takes about 14 days for neutrophils to develop from early precursors, but this process is accelerated by infection and treatment with colony-stimulating factors.

Neutrophils are the chief phagocytes of early inflammation. Soon after bacterial invasion or tissue injury, neutrophils migrate out of the capillaries and into the inflamed site, where they ingest and destroy microorganisms and debris and then die in 1 or 2 days. The dissolution of dead neutrophils releases digestive enzymes from their cytoplasmic granules. These enzymes dissolve cellular debris and prepare the site for healing. (This final function, called *débridement,* is described in Chapter 7).

Eosinophils have large, coarse granules and constitute only 1% to 4% of the normal leukocyte count in adults (see Figure 27-3, *B*). Like neutrophils, eosinophils are capable of amoeboid movement and phagocytosis. Using a spectrum of pattern-recognition receptors, eosinophils ingest antigen-antibody complexes and viruses and are induced by mast cell chemotactic factors to attack parasites.[3] Eosinophil secondary granules contain toxic chemicals (e.g., major basic protein, eosinophil cationic protein, eosinophil peroxidase, eosinophil-derived neurotoxin) that are highly destructive to parasites and viruses. The eosinophil granules contain a variety of enzymes (e.g., histaminase) that help to control inflammatory processes. (Their function in inflammation and defense against parasites is described in Chapters 7 and 8.) Eosinophils also release leukotrienes, prostaglandins, platelet-activating factor (PAF), and a variety of cytokines (e.g., interleukin-1 [IL-1], IL-6, tumor necrosis factor-alpha [TNF-α], granulocyte-macrophage colony-stimulating factor [GM-CSF]) and chemokines (e.g., IL-8) that augment the inflammatory response.[4] Type I hypersensitivity allergic reactions and asthma are characterized by high numbers of circulating eosinophils, which may be involved in a dual role of regulation of inflammation and may contribute to the destructive inflammatory processes observed in the lungs of persons with asthma (see Chapter 9).

Basophils, which comprise less than 1% (0.01% to 0.3%) of the leukocytes, contain cytoplasmic granules that have an abundant mixture of biochemical mediators, including histamine, chemotactic factors, proteolytic enzymes (e.g., elastase, lysophospholipase), and an anticoagulant (heparin) (see Figure 27-3, *C*). Stimulation of basophils also induces synthesis of vasoactive lipid molecules (e.g., leukotrienes) and cytokines. Basophils produce IL-6 which induces IL-10 by Th1 cells and induction of Th2 cells that favor B-cell differentiation.[5] Basophils also are a particularly rich source of the cytokine IL-4, which preferentially guides B-cell differentiation toward plasma cells that secrete IgE (see Chapter 8).

The numbers of basophils are often increased at sites of allergic inflammatory reactions and parasitic infection, particularly exoparasites (e.g., ticks). IgE receptors on the basophil would induce degranulation at sites of IgE-mediated hypersensitivity reactions and contribute to the local inflammatory response.

Mast cells are highly similar to basophils, but are generated from a different set of precursor cells in the bone marrow, from which they migrate in an immature form into tissues.[6] They reside in vascularized connective tissues just beneath body epithelial surfaces, including the submucosal tissues of the gastrointestinal and respiratory tracts and the dermal layer that lies

just below the surface of the skin. Mast cells play a central role in inflammation, and their activation and degranulation affect a great number of cells, including those involved in inflammation (e.g., vascular endothelial cells, smooth muscle cells, circulating platelets and leukocytes, nerves) and healing (e.g., fibroblasts), as well as glandular cells and cells of the immune system. Their activation contributes greatly to increased permeability of blood vessels and smooth muscle contraction (see Figure 7-11).

The **agranulocytes**—monocytes, macrophages, and lymphocytes—differ from the granulocytes in that they contain relatively fewer granules in their cytoplasm. The lymphocytes do not contain any enzyme-filled digestive vacuoles, and the digestive vacuoles of the monocytes and macrophages are larger and fewer than those of the granulocytes.

Lymphocytes constitute approximately 36% of the total leukocyte count and are the primary cells of the immune response (see Figure 27-3, *D,* and Chapter 8). Most lymphocytes transiently circulate in the blood and eventually reside in secondary lymphoid tissues as mature T cells, B cells, or plasma cells. The life span of the lymphocyte can be days, months, or years, depending on its type and subtype. (Lymphocyte function and dysfunction are described in detail in Unit III.)

Natural killer (NK) cells, which resemble large granular lymphocytes, kill some types of tumor cells (in vitro) and some virus-infected cells without being induced by previous exposure to these antigens (see Chapters 7 and 8). Hence they are named *natural killer cells* to differentiate them from T-cytotoxic cells, which are induced by antigen. NK cells also have the capacity to activate T cells and phagocytes and produce a variety of cytokines that can regulate immune responses. The predominant form of NK cells develops in the bone marrow and circulates in the blood, where it accounts for 5% to 10% of the circulating lymphoid pool, and is found mainly in the peripheral blood and spleen. NK cells develop independent of a thymus, although some NK precursors are found in the thymus and may develop into NKT cells that have markers of NK and T cells.

The monocytes and macrophages make up the **mononuclear phagocyte system (MPS),** formerly called the *reticuloendothelial system (RES).*[7] Monocytes and macrophages are active phagocytes that participate in the immune and inflammatory responses. They also ingest dead or defective host cells, particularly blood cells.

Monocytes are the largest normal blood cell and have a horseshoe-shaped nucleus (see Figure 27-3, *E*). They are formed and released by the bone marrow into the bloodstream. Monocytes migrate into a variety of tissues and fully mature into tissue **macrophages** and myeloid **dendritic cells** (Table 27-3). Other monocytes may mature into macrophages in the circulation and migrate out of the vessels in response to infection or inflammation. Macrophages are generally larger and are more active as phagocytes than monocytes. Dendritic cells frequently extend projections *(dendrites)* into the tissue and take on a "neuron-like" appearance. The origin and turnover of many of the tissue macrophages are not precisely known. It seems clear that once monocytes leave the circulation, they do not return. They can survive many months or even years.

The normal role of macrophages is to remove old and damaged cells and large-molecular substances from the blood.

TABLE 27-3 MONONUCLEAR PHAGOCYTE SYSTEM*

NAME OF CELL	LOCATION
Committed Stem Cells†	Bone marrow
Monoblasts	Bone marrow
Promonoblasts	Bone marrow
Monocytes	Bone marrow and peripheral blood
Macrophages	Tissue
Kupffer cells	Liver macrophages
Alveolar macrophages	Lung
Histiocytes	Connective tissue
Macrophages	Bone marrow
Fixed and free macrophages	Spleen and lymph nodes
Pleural and peritoneal macrophages	Serous cavities
Adipose macrophages	Adipose (fat) tissue
Microglial cells	Nervous system
Mesangial cells	Kidney
Osteoclasts	Bone
Langerhans cells	Skin
Dendritic cells	Lymphoid tissue, lining of respiratory and gastrointestinal tracts

Modified from Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 7, Philadelphia, 2005, Saunders.
*Formerly called the reticuloendothelial system.
†Development of blood cells from stem cells in the marrow is described on this page and illustrated in Figure 27-10.

Cellular targets of macrophage phagocytosis include circulating senescent or damaged erythrocytes and platelets (removed primarily in spleen), dead neutrophils (in the circulation and at sites of inflammation), and cells undergoing apoptosis. Noncellular targets include antigen-antibody complexes, cellular debris, products of coagulation, and macromolecules (such as lipids and carbohydrates synthesized by the body as the result of faulty metabolism, as in storage diseases). Macrophages remove and kill contaminating microorganisms in the blood (mostly in the liver and spleen) and at sites of infection. Macrophages and, particularly, dendritic cells are the major "antigen-processing" and "antigen-presenting" cells that initiate immune responses (see Chapter 8). Macrophages initiate wound healing and tissue remodeling and if activated by cytokines from T cells secrete a large array of biologically active chemicals that if uncontrolled result in chronic inflammation and tissue injury (see Chapter 7). Osteoclasts are multinucleated macrophage-like cells specialized for the function of lacunar bone resorptions and remodeling in addition to phagocytosis.[8]

Platelets. **Platelets (thrombocytes)** are not true cells but irregularly-shaped cytoplasmic fragments that are essential for blood coagulation and control of bleeding.[9] They are formed by fragmentation of very large (40 to 100 μm in diameter) cells known as **megakaryocytes** (Figure 27-4). They lack a nucleus and deoxyribonucleic acid (DNA), and are incapable of mitotic division. They do, however, contain cytoplasmic granules (i.e., dense granules, alpha granules) capable of releasing biochemical mediators when stimulated by injury to a blood vessel. The contents of the dense granules are generally proinflammatory (e.g., adenosine

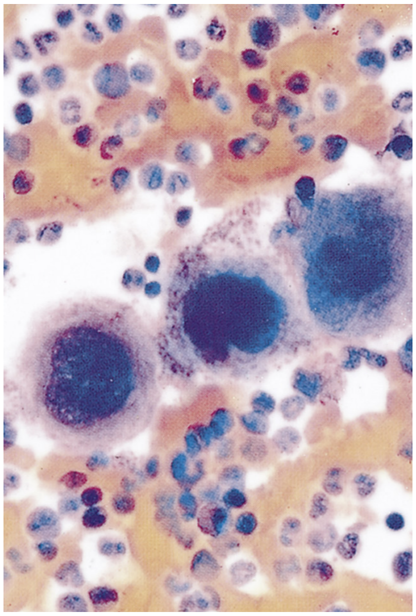

FIGURE 27-4 **Megakaryocyte and Platelets.** Note the large number of platelets *(purple)* surrounding the large megakaryocytes in the center. (From Miale JB: *Laboratory medicine: hematology,* ed 6, St Louis, 1982, Mosby.)

diphosphate [ADP], adenosine triphosphate [ATP], calcium, serotonin, and histamine).[10] The alpha granules contain a mixture of coagulation factors, growth and angiogenic factors (e.g., platelet-derived growth factor [PDGF], vascular endothelial growth factor [VEGF], and basic fibroblast growth factor), and angiogenesis inhibitors (e.g., platelet factor 4, thrombospondin, and inhibitors of metalloproteinases). Depending upon the particular stimulus, platelets may selectively release promoters or inhibitors of angiogenesis.[11] Activation also stimulates synthesis of arachidonic acid pathway products (e.g., thromboxane A_2) (see Chapter 7).

There are approximately 140,000 to 340,000 platelets/mm^3 of circulating blood. An additional one third of the body's available platelets are in a reserve pool in the spleen. A platelet circulates for approximately 10 days, ages, and is removed by macrophages of the MPS, mostly in the spleen.

Lymphoid Organs

The lymphoid system is closely integrated with the circulatory system. The lymphoid organs, some of which are merely aggregations of lymphoid tissue, are classified as primary or secondary. The primary lymphoid organs are the thymus and the bone marrow. The secondary lymphoid organs consist of the spleen, lymph nodes, tonsils, and Peyer patches of the small intestine (see Figure 8-3). All of the lymphoid organs link the hematologic and immune systems in that they are sites of residence, proliferation, differentiation, or function of lymphocytes and mononuclear phagocytes (monocytes and macrophages).[12] (The liver, which also has hematologic functions, is primarily a digestive organ and is described in Chapter 40.)

Spleen

The spleen is the largest of the secondary lymphoid organs. It is a site of fetal hematopoiesis; its mononuclear phagocytes filter and cleanse the blood; its lymphocytes mount an immune response to blood-borne microorganisms; and it serves as a blood reservoir (see Chapter 29).

The spleen is a concave, encapsulated organ that weighs approximately 150 g and is about the size of a fist. It is located in the left upper abdominal cavity, curved around a portion of the stomach (see Figure 8-3). Strands of connective tissue (trabeculae) extend from the capsule, dividing the spleen into compartments (Figure 27-5). The compartments contain masses of lymphoid tissue called *splenic pulp*. The spleen is interlaced with many blood vessels, some of which are capable of distending to store blood. Blood that circulates through the spleen comes from the splenic artery, which branches from the descending aorta and reenters the circulatory system through the splenic vein and into the portal vein.

The portion of arterial blood that enters the spleen first encounters the white splenic pulp, which consists of masses of lymphoid tissue containing macrophages and lymphocytes, primarily T lymphocytes in proximity to the arterioles (see Figure 27-5, *B* and *D*). Cellular clumps (lymphoid follicles) are formed in the white pulp around the splenic arterioles. The lymphoid follicles consist primarily of B lymphocytes. These are the chief sites of immune function within the spleen. Here blood-borne antigens encounter lymphocytes, initiating the immune response and the conversion of lymphoid follicles into germinal centers (see Chapter 8).[13]

Some of the blood that enters the terminal capillaries continues through the microcirculation and enters highly distensible storage areas called venous sinuses in the red pulp of the spleen. The venous sinuses are capable of storing more than 300 ml of blood. Passive dilation of the venous sinuses enables the spleen to increase its storage capacity as needed by the body. Sudden reductions in blood pressure cause the sympathetic nervous system to stimulate constriction of the sinuses, resulting in expulsion of as much as 200 ml of blood into the venous circulation, which helps restore blood volume and increases the hematocrit by as much as 4%.

The endothelial lining of the venous sinuses is discontinuous (having gaps between endothelial cells) and therefore extremely permeable so that blood cells are allowed to exit the circulation (Figure 27-6). The red pulp contains a system of loosely interconnected resident macrophages that provide the principal site of splenic filtration. Because of the slow circulation in the sinuses, the macrophages easily phagocytose old, damaged, or dead blood cells of all kinds (but chiefly erythrocytes), microorganisms, macromolecules, and particles of debris. Hemoglobin from phagocytosed erythrocytes is catabolized, and heme (iron) is stored in the cytoplasm of the macrophages or released back into the blood (see Figure 27-17). The macrophages also can remove particulate inclusions containing denatured hemoglobin (Heinz bodies) from erythrocytes without harming the cells themselves. Blood that filters through the red pulp also finds its way into the venous sinuses and hence into the portal circulation.

The spleen is not absolutely necessary for life or for adequate hematologic function. However, splenic absence from any cause (atrophy, traumatic injury, or removal because of disease) has several secondary effects on the body. For example, leukocytosis (high levels of circulating leukocytes) often occurs after

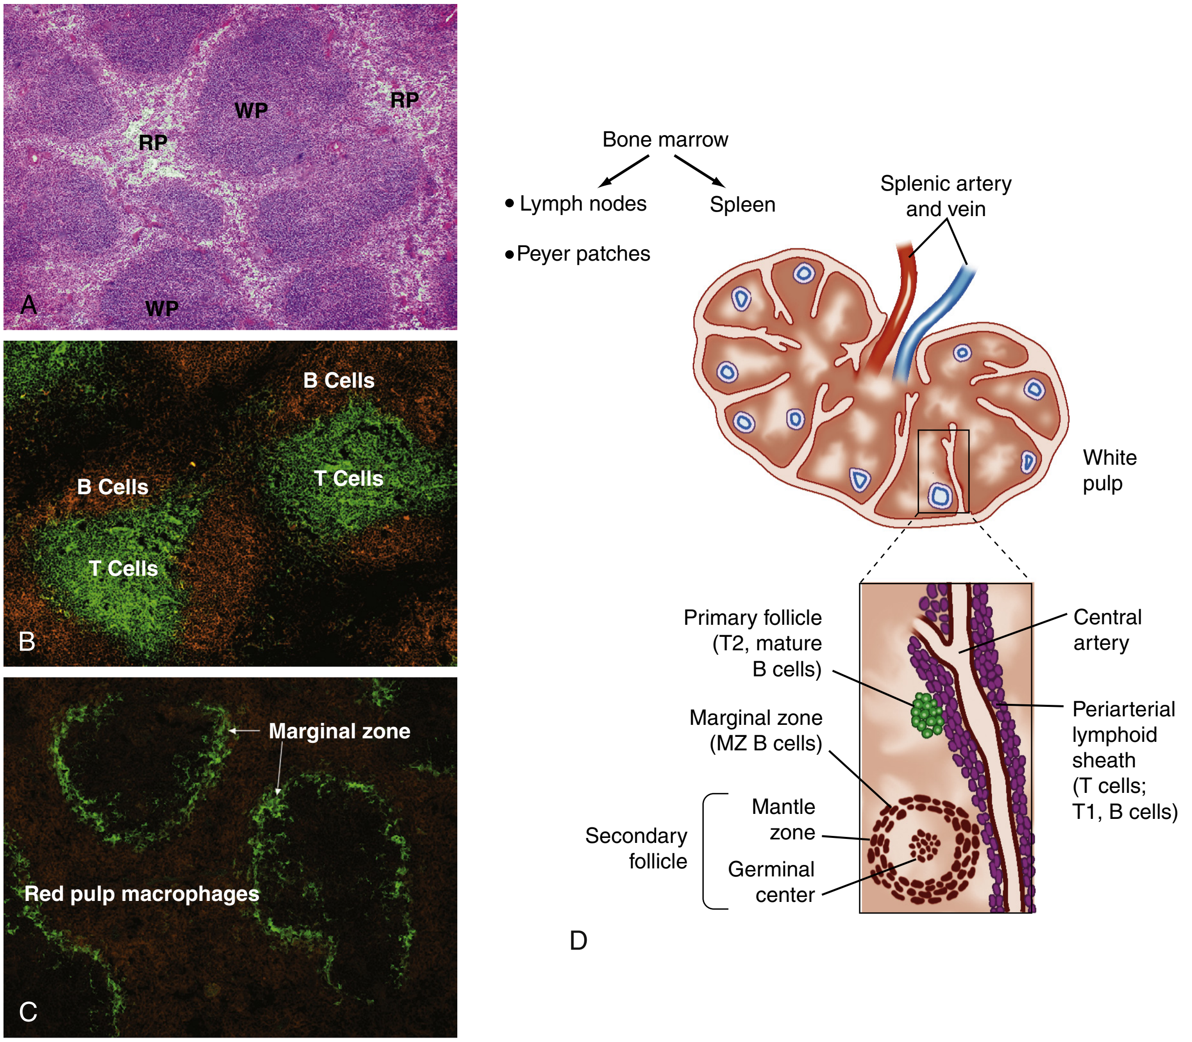

FIGURE 27-5 **Spleen Architecture. A,** Spleen section stained with hematoxylin and eosin shows areas of densely packed cells, referred to as the white pulp *(WP),* separated by areas with more dispersed cell populations, referred to as the red pulp *(RP).* **B,** Spleen section that has been stained with fluorescently labeled antibodies specific for B cells *(orange)* and T cells *(green)* shows the distinct localization of B cells and T cells within the white pulp. **C,** Staining for macrophages *(orange)* and the splenic marginal zone *(green)* shows the density of macrophages and phagocytic cells in the red pulp and marginal zone. **D,** The spleen is enclosed in a capsule with the interior pulp divided into compartments by strands of connective tissue. The splenic pulp contains regions that are rich in lymphocytes (white pulp) and those containing erythrocytes (red pulp). The central arteries are frequently surrounded by a periarterial lymphoid sheath, primarily containing T cells, B cells, and macrophages, with adjacent lymphoid follicles. The secondary lymphoid follicles contain B cells that are proliferating in response to antigen. (**A, B,** and **C** from Mandell G, Bennett J, Dolin R: *Mandell, Douglas, and Bennett's principles and practice of infectious diseases,* ed 7, Philadelphia, 2010, Churchill Livingstone; **D** from Hoffman R et al: *Hematology: basic principles and practice,* ed 6, Philadelphia, 2013, Churchill Livingstone.)

splenectomy, suggesting that the spleen exerts some control over the rate of proliferation of leukocyte stem cells in the bone marrow or their release into the bloodstream. Circulating levels of iron may also decrease, reflecting the spleen's role in the iron cycle. The immune response to encapsulated bacteria (e.g., *Streptococcus pneumoniae* [pneumococcus], *Neisseria meningitidis* [meningococcus], *Haemophilus influenzae*), which is primarily an IgM response, may be severely diminished, resulting in increased susceptibility to disseminated infections. Loss of the spleen results in an increase in morphologically defective blood cells in the circulation, confirming the spleen's role in removing old or damaged cells.

Lymph Nodes

Structurally, lymph nodes are part of the lymphatic system. Lymphatic vessels collect interstitial fluid from the tissues and transport it, as lymph, through vessels of increasing size to the thoracic duct, which drains into the superior vena cava returning the lymph to the circulation. Lymph nodes are distributed throughout the body and provide filtration of the lymph during its journey through the lymphatics. Each lymph node is enclosed in a fibrous capsule, branches of which (trabeculae) extend inward to partition the node into several compartments (Figure 27-7). Reticular fibers of connective tissue divide the compartments into a meshwork throughout the lymph node.

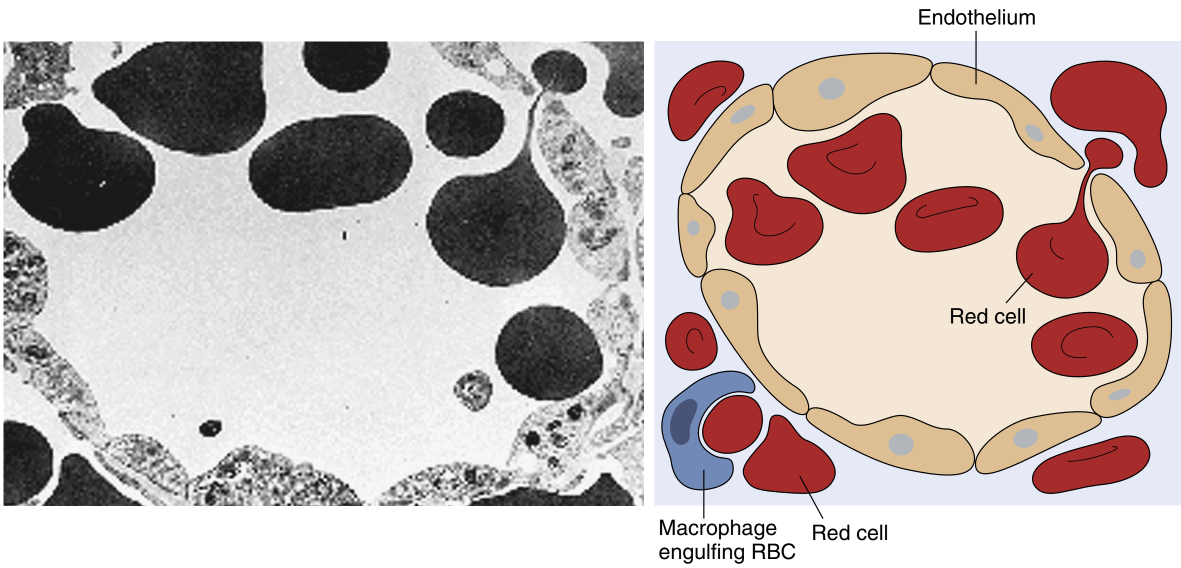

FIGURE 27-6 **Splenic Sinus.** Transmission electron micrograph and schematic of erythrocytes in the process of squeezing from the red pulp cords into the sinus lumen. Note the degree of deformability required for red cells to pass through the wall of the sinus. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby. Schematic from Kumar V, Fausto N, Abbas A: *Robbins & Cotran pathologic basis of disease,* ed 7, St Louis, 2005, Saunders.)

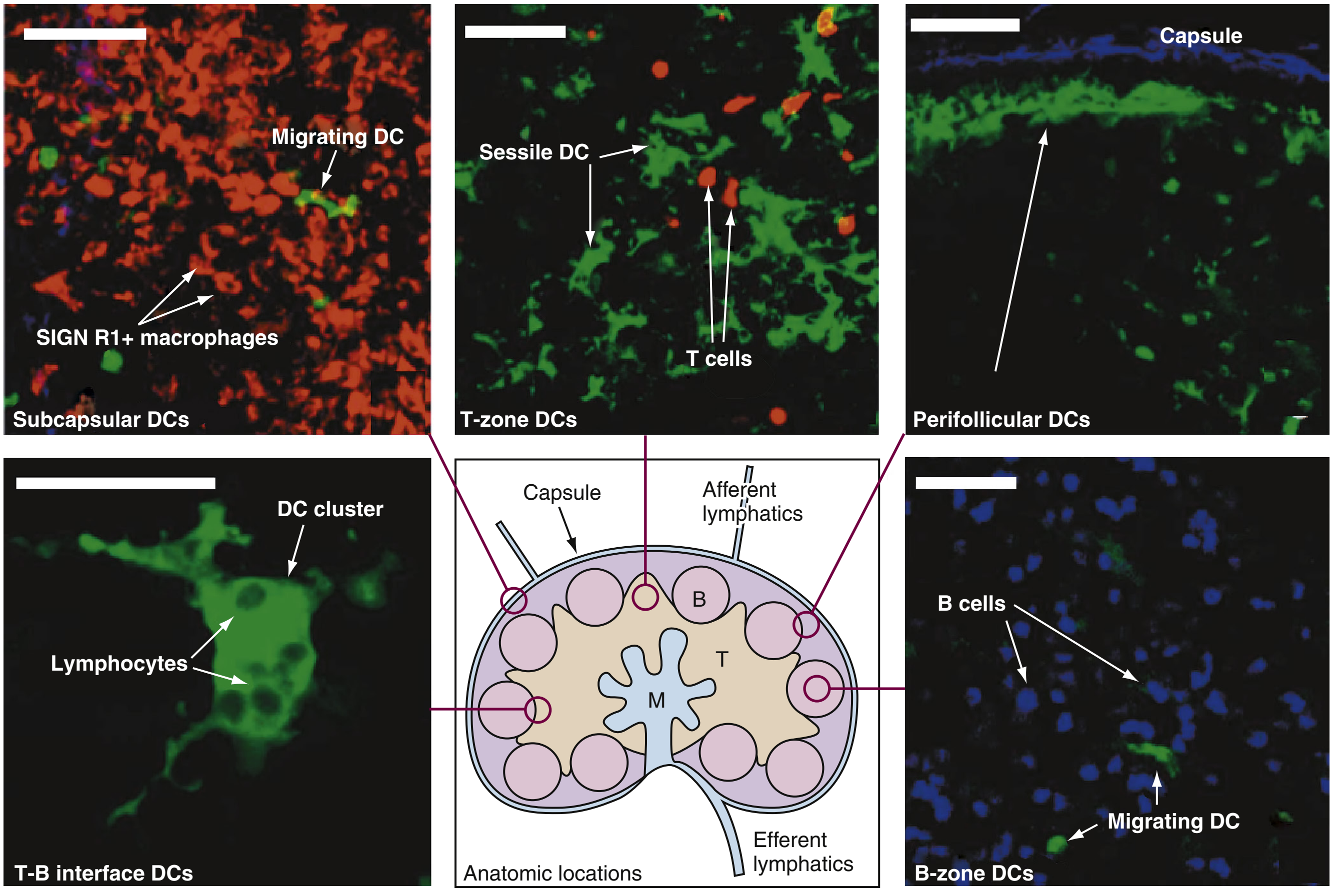

FIGURE 27-7 **Lymph Node Architecture.** *Drawing in lower center:* Lymph enters via the afferent lymphatics and exits via the efferent lymphatics. T cells enter the lymph nodes via the high endothelial venules and exit via the medulla to the efferent lymphatics. *B,* B-cell follicles; *M,* medullary cords; *T,* T-cell zone. Other structures are labeled. *Stained microscopic images:* All images are linked to the drawing of the lymph node. *DC,* Dendritic cell. (All scale bars 50 μm.) (From Lindquist RL et al: *Nat Immunol* 5:1243–1250, 2004, by permission from Macmillan Publishers Ltd.)

The node consists of outer (cortex) and inner (paracortex) cortical areas and an inner medulla. Lymph enters through multiple small afferent lymphatic vessels into the subcapsular sinus, just beneath the capsule; drains into the cortical sinuses to the medullary sinuses, from which the lymph is collected; and leaves the node by way of the efferent lymphatic vessel. Blood flows into the lymph nodes through the lymphatic artery, which ends in groups of postcapillary venules disturbed throughout the outer cortex. The blood is drained through the lymphatic vein.

Functionally, lymph nodes are part of the hematologic and immune systems and are the primary site for the first encounter between antigen and lymphocytes. Lymphocytes enter the lymph node from the blood through the postcapillary venules by means of diapedesis across the endothelial lining. B lymphocytes tend to migrate preferentially to nodes in the cortex and medulla, whereas T lymphocytes predominantly migrate to the paracortex (see Figure 27-7). Macrophages reside in the lymph node; help filter the lymph of debris, foreign substances, and microorganisms; and provide antigen-processing functions. The dendritic cells encounter and process antigens and microorganisms in other tissues, enter the lymph node through the afferent lymph vessels, and migrate throughout the nodes. The reticular network provides adhesive surfaces for trapping large numbers of phagocytes and lymphocytes and facilitating their organization into follicles or primary nodules. The presence of antigen, either removed from the lymph by macrophages or presented on the surface of dendritic cells, results in the production of secondary nodules containing germinal centers. In the germinal centers lymphocytes, particularly B cells, respond to antigenic stimulation by undergoing proliferation and further differentiation, including class-switch, into memory cells and plasma cells (see Chapter 8). Plasma cells migrate to the medullary cords. The B-lymphocyte proliferation in response to a great deal of antigen (e.g., during infection) may result in lymph node enlargement and tenderness (reactive lymph node).

DEVELOPMENT OF BLOOD CELLS

Hematopoiesis

The typical human requires about 100 billion new blood cells per day. Blood cell production, termed **hematopoiesis,** is constantly ongoing, occurring in the liver and spleen of the fetus and only in bone marrow *(medullary hematopoiesis)* after birth (see Chapter 30). This process involves the biochemical stimulation of populations of relatively undifferentiated cells to undergo mitotic division (i.e., proliferation) and maturation (i.e., differentiation) into mature hematologic cells (Table 27-4). Although proliferation and differentiation are usually sequential, certain blood cells proliferate and differentiate simultaneously. Erythrocytes and granulocytes generally differentiate fully before entering the blood, but monocytes and lymphocytes continue to mature in the blood and in secondary lymphatic organs.

Hematopoiesis continues throughout life, increasing in response to a need to replenish destroyed circulating cells (e.g., during hemorrhage, hemolytic anemia [peripheral destruction of erythrocytes], consumptive thrombocytopenia) or in response to infection. In general, long-term stimuli, such as chronic diseases, cause a greater increase in hematopoiesis than acute conditions, such as hemorrhage.

Various abnormalities in medullary hematopoiesis have been identified and are discussed in Chapter 28. Extramedullary

TABLE 27-4 HUMAN HEMATOPOIETIC GROWTH FACTORS (CYTOKINES, COLONY-STIMULATING FACTORS)

FACTOR	CELL ORIGIN	PRIMARY CELL STIMULATED
M-CSF	Macrophage, lymphocyte, fibroblast, endothelial cell, osteoblast	Monocyte progenitor to monocyte
GM-CSF	Macrophage, T cell, endothelial cell, fibroblast, mast cell	Common myeloid progenitor to granulocyte progenitor and monocyte progenitor
G-CSF	Macrophage, fibroblast, endothelial cell	Granulocyte progenitor to neutrophil
IL-2	Th cell	T-cell progenitor to T cell
IL-3	T cell, monocyte/macrophage, stromal cell	Common myeloid progenitor to progenitors for megakaryocyte, erythroid, granulocyte, and monocyte series
IL-4	Th cell	B-cell progenitor to B cell
IL-5	Th cell, mast cell	Common myeloid progenitor to eosinophil
IL-7	Stromal cell, intestinal epithelium	Hematopoietic stem cell to common lymphoid progenitor Common lymphoid progenitor to progenitor B cell, pro NK cell, and progenitor T cell Progenitor T cell to T cell and progenitor B cell to B cell
IL-11	Stromal cell	Megakaryocyte progenitor to megakaryocyte
IL-15	Monocyte/macrophage	NK progenitor to NK cell
Erythropoietin	Peritubular kidney cell and Kupffer cell	Common myeloid progenitor to erythrocyte progenitor Erythrocyte progenitor to erythrocyte
Thrombopoietin	Liver, kidney, skeletal muscle	All cells in megakaryocyte lineage from common myeloid progenitor to platelet
Stem cell factor (steel factor)	Stromal cell in bone marrow and many other cells	Hematopoietic progenitor to common myeloid progenitor Common myeloid progenitor to progenitors for megakaryocyte, erythroid, granulocyte, and monocyte series

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IL,* interleukin; *M-CSF,* macrophage colony-stimulating factor; *NK,* natural killer; *pro,* progenitor; *Th,* T helper.

hematopoiesis—blood cell production in tissues other than bone marrow—of apparently normal blood cells has been reported in the spleen, liver, and, less frequently, lymph nodes, adrenal glands, cartilage, adipose tissue, intrathoracic areas, and kidneys. In adults, however, extramedullary hematopoiesis is usually a sign of disease, occurring in pernicious anemia, sickle cell anemia, thalassemia, hemolytic disease of the newborn (erythroblastosis fetalis), hereditary spherocytosis, and certain leukemias.

Bone Marrow

Bone marrow is confined to the cavities of bone and is the primary site of residence of hematopoietic stem cells (Figure 27-8). Adults have two kinds of bone marrow: red, or active (hematopoietic), marrow (also called **myeloid tissue**) and yellow, or inactive, marrow. The large quantity of fat in inactive marrow gives its characteristic yellow color. Not all bones contain active marrow. In adults, active marrow is found primarily in the flat bones of the pelvis (34%), vertebrae (28%), cranium and mandible (13%), sternum and ribs (10%), and in the extreme proximal portions of the humerus and femur (4% to 8%). Inactive marrow predominates in cavities of other bones. (Bones are discussed further in Chapter 43.)

Hematopoietic marrow is vascularized by the primary arteries of the bones, which terminate in a capillary network forming large venous sinuses. Hematopoietic marrow and fat fill the spaces surrounding the network of venous sinuses. Newly produced blood cells traverse narrow openings between endothelial cells in the venous sinus walls and thus enter the circulation. Normally, immature cells have not developed the appropriate surface receptors to interact with the endothelium and enter the circulation.

The hematologic compartment of the bone marrow consists of a variety of cellular microenvironments, called **niches,** that control differentiation of hematopoietic progenitor cells[14] (Figure 27-9). The cellular composition of niches includes osteoclasts, osteoblasts, sinusoidal endothelial cells, fibroblasts, megakaryocytes, macrophages, and nerve cells.[15] Osteoblasts are derived from fibroblasts and are responsible for construction of

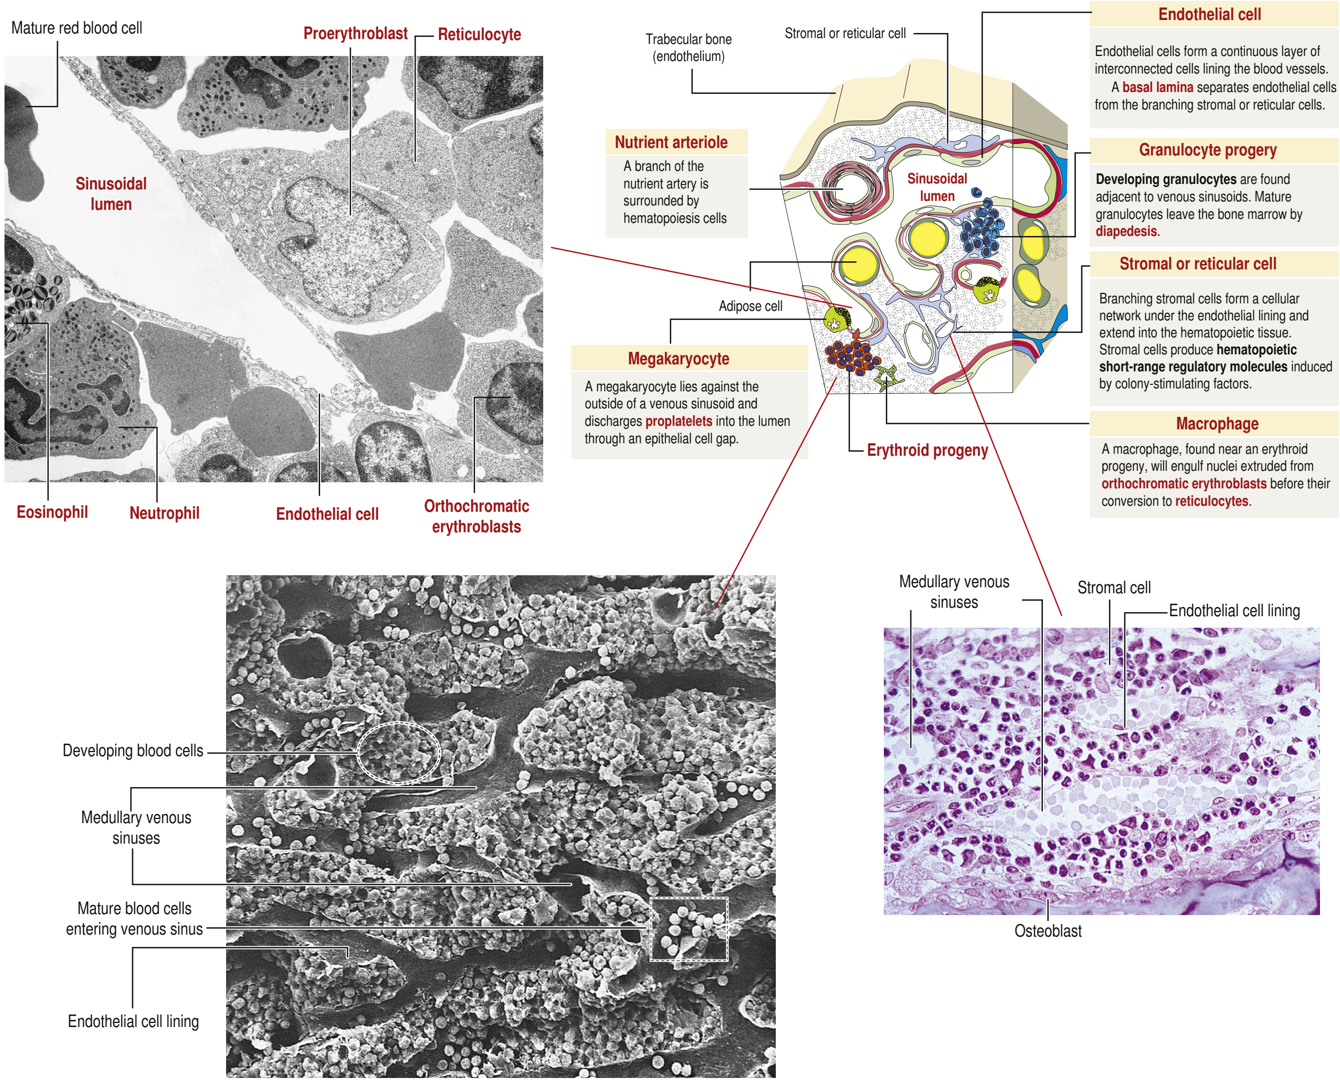

FIGURE 27-8 Bone Marrow: Structure and Vascularization. (From Kierszenbaum A, Tres L: *Histology and cell biology: an introduction to pathology,* ed 3, Philadelphia, 2012, Mosby. Scanning electron micrograph from Kessel RG, Kardon RH: *Tissues and organs,* New York, 1979, WH Freeman.)

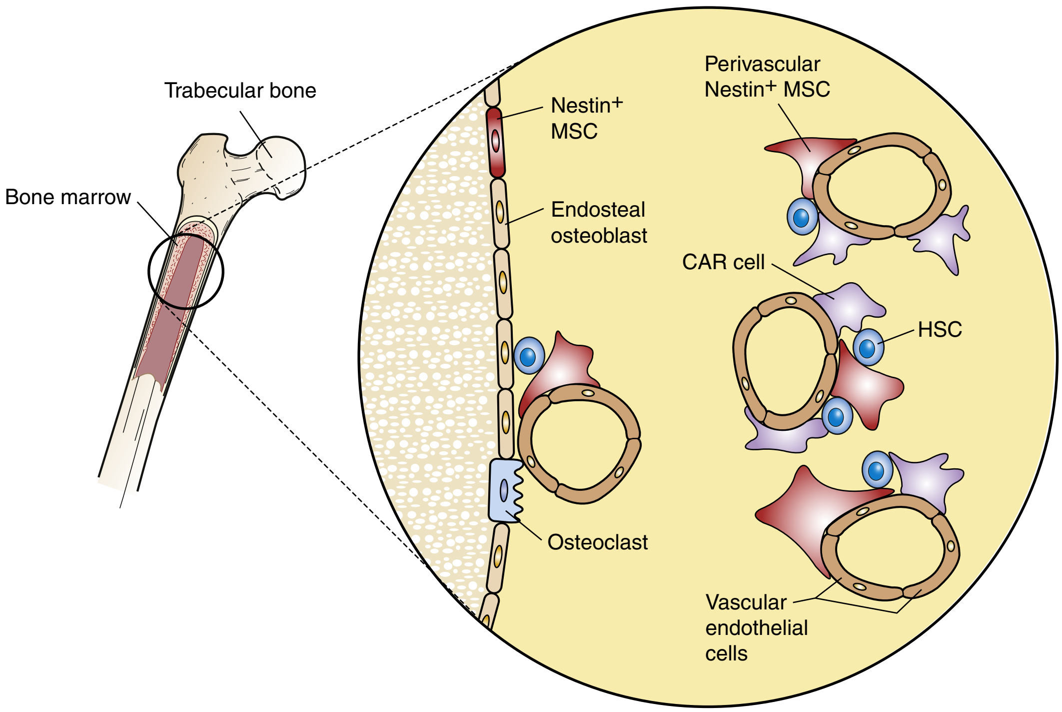

FIGURE 27-9 Bone Marrow Stem Cell Niches. Stem cell niches are microenvironments where stem cells undergo hematopoiesis into all forms of blood cells. Stem cell niches retain and maintain adult resting hematopoietic stem cells (HSCs) and are activated after cell injury to promote cell renewal or differentiation to form new tissues. The fate of individual HSCs is determined by interactions (intercellular adherence, cytokines, chemokines) with specialized cells within the niches. Within osteoblastic niches the HSC interacts primarily with the osteoblasts and specialized mesenchynal stem cells (MSCs) that include nestin-expressing (Nestin+) MSCs and CXCL12-abundant reticular (CAR) cells. Within the vascular niches, the HSC interacts with vascular endothelial cells, Nestin+ MSC, and a more abundant population of CAR cells.

bone. Osteoclasts are multinucleate cells of monocytic origin that remodel bone by resorption. Both cells can produce cytokines that affect proliferation of hematopoietic cells. Recent studies have identified macrophage and megakaryocyte populations in bone marrow niches. The area is innervated through the sympathetic nervous system. At least two populations of stem cells are found in bone marrow niches. **Mesenchymal stem cells (MSCs)** are stromal cells that can differentiate into a variety of cells, including osteoblasts, adipocytes, and chondrocytes (produce cartilage). **Hematopoietic stem cells (HSCs)** are progenitors of all hematologic cells. Both populations of stem cells also undergo self-renewal in the bone marrow so that additional MSCs and HSCs are produced to replace those undergoing differentiation.

Two distinct types of niches have been identified: the *osteoblastic* (also called endosteal) *niche* and the *vascular niche*. The **osteoblastic niche** is centralized around osteoblasts, which line the surface of bone, whereas the **vascular niche** is organized around sinusoidal endothelial cells. In both niches, HSCs are affected by direct cell-to-cell signaling and by soluble mediators produced by cells within each niche. Each niche also contains two specialized cells derived from MSCs: CXCL12-abundant reticular (CAR) cells and nestin-expressing cells.[16]

CAR cells resemble reticular cells with long cellular processes. CAR cells closely interact with HSCs and provide important intercellular signaling through several HSC regulatory molecules, including CXCL12, SCF, VCAM-1, and ANG1. Chemokine ligand 12 (CXCL12) is a chemokine that reacts with the C-X-C chemokine receptor type 4 (CXCR4) on HSCs. The cytokine stem cell factor (SCF; also known as steel factor), which is expressed as a cell surface transmembrane protein or a soluble protein, reacts with the HSC KIT receptor (named stem cell growth factor receptor, proto-oncogene c-Kit, or CD117). Vascular cell adhesion molecule 1 (VCAM-1) mediates intercellular adhesion through its receptor integrin $\alpha 4\beta 1$ (also called very late antigen 4, or VLA4). The secreted protein angiopoietin 1 (ANG1) reacts with a tyrosine kinase receptor. Nestin-expressing cells express large amounts of the intermediate filament protein nestin and, particularly, SCF and VCAM-1. Although both MSC-derived cells are present in the osteoblastic niche and vascular niche, the CAR cell is the predominant cell in the vascular niche.[17]

Each bone marrow niche affects HSCs differently. In the osteoblastic niche, HSCs are in direct contact with osteoblasts, CAR cells, and nestin-expressing cells. The effect is retention of HSCs in the bone marrow in a quiescent (dormant) state.[18] HSCs that traffic to the vascular niche directly contact endothelial cells, as well as nestin-expressing cells and larger numbers of perivascular CAR cells. The cumulative signaling events induce HSC activation, proceeding to increased cellular division and hematopoietic differentiation. Other cells in the bone marrow, including macrophages and adipocytes, contribute to regulation of hematopoiesis.

Cell Differentiation

Within the bone marrow niches, each type of blood cell originates from common hematopoietic stem cells that proliferate and differentiate under control of a variety of cytokines and growth factors (Figure 27-10 and see Table 27-4). During this

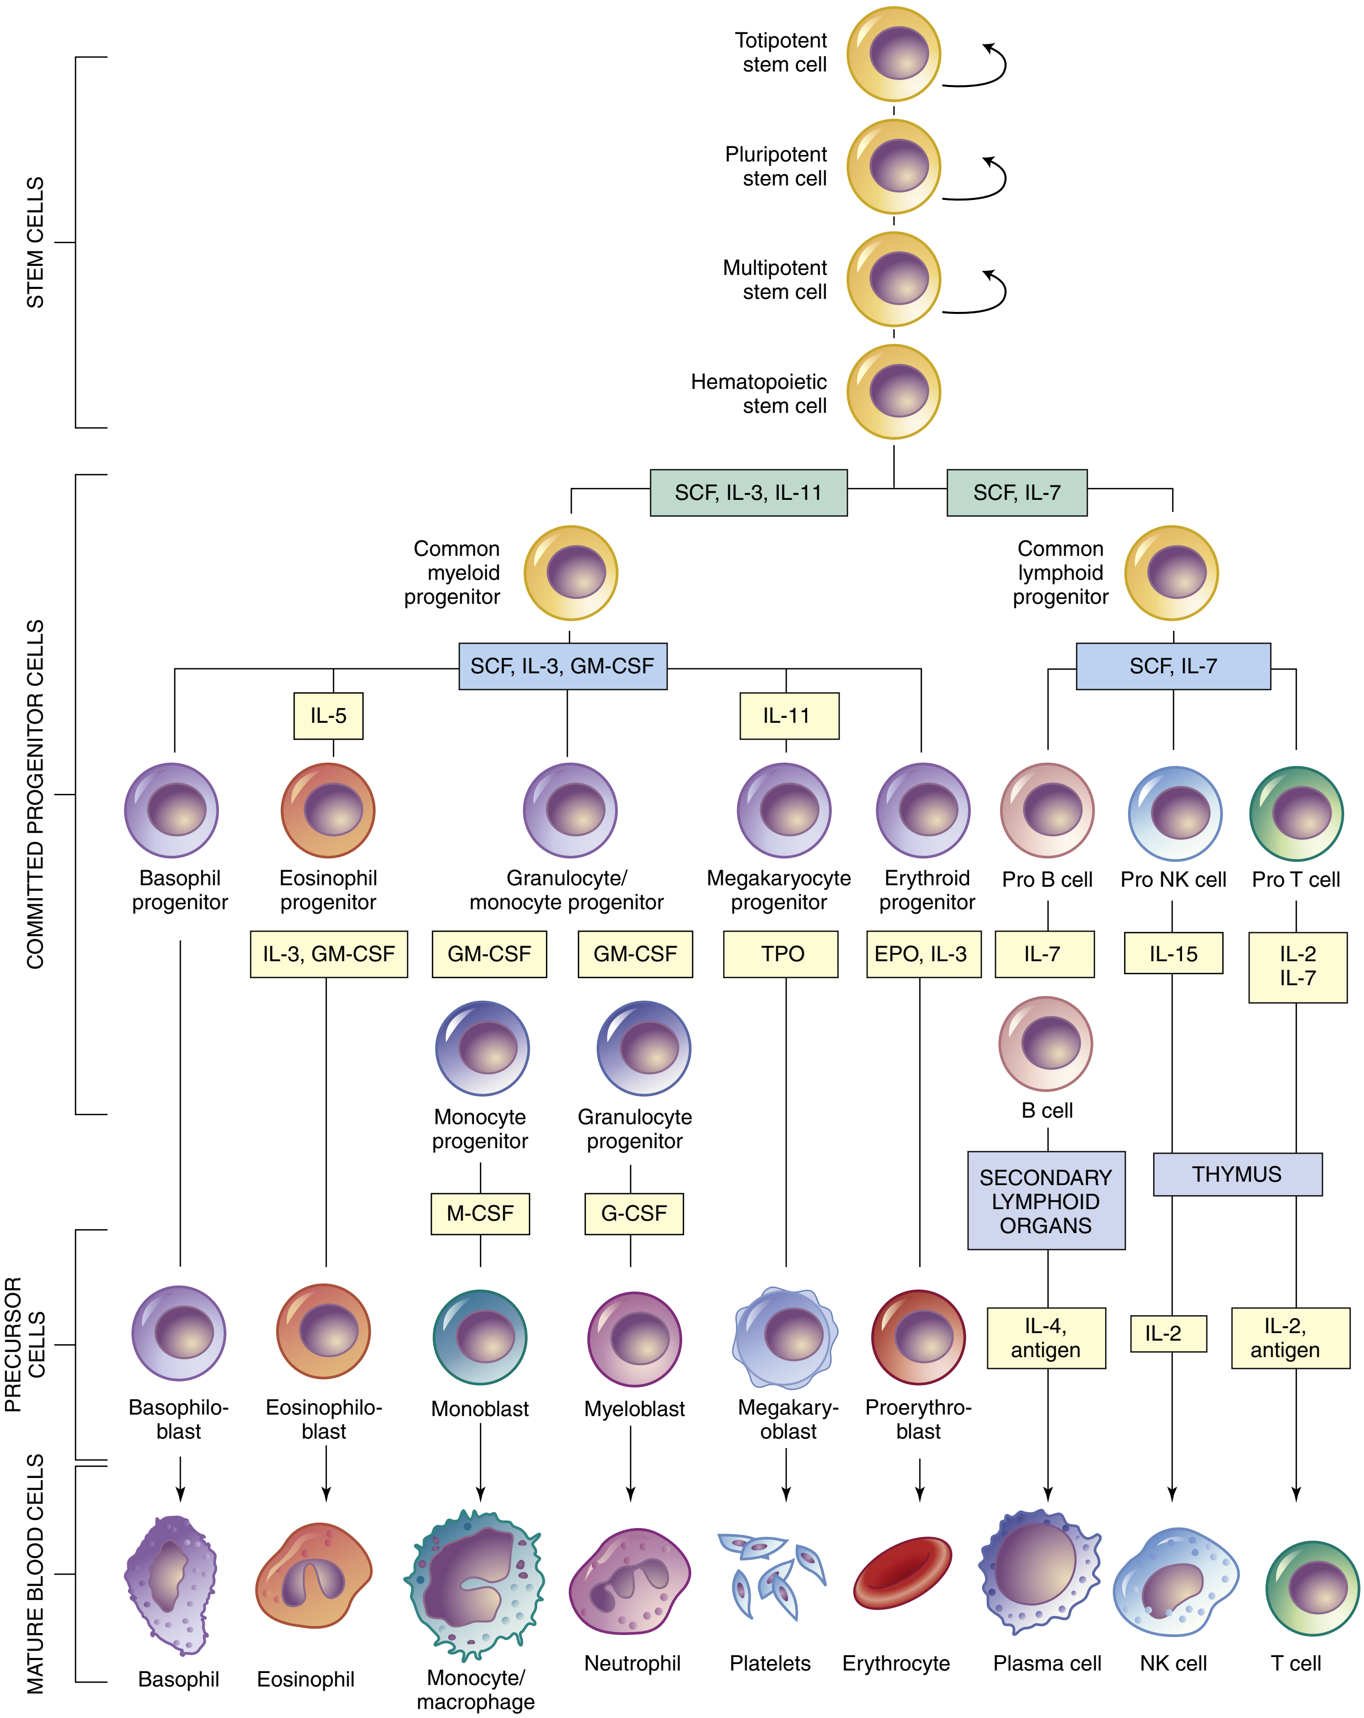

FIGURE 27-10 Differentiation of Hematopoietic Cells. Curved arrows indicate proliferation and expansion of prehematopoietic stem cell populations. *EPO,* Erythropoietin; *G-CSF,* granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IL,* interleukin; *M-CSF,* macrophage colony-stimulating factor; *NK,* natural killer; *SCF,* stem cell factor; *TPO,* thrombopoietin.

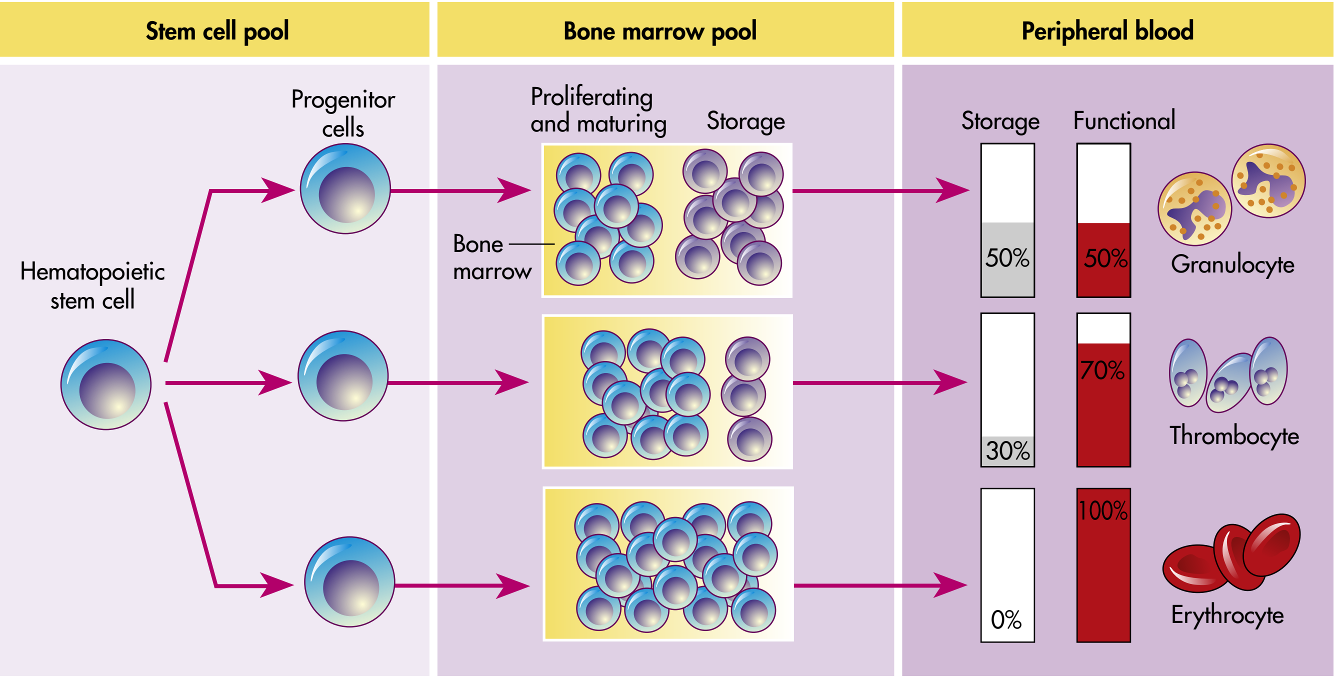

FIGURE 27-11 **Hematopoiesis.** Hematopoiesis from the stem cell pool; activity occurs mainly in the bone marrow and in the peripheral blood. (Modified from Harmening DM, editor: *Clinical hematology and fundamentals of hemostasis,* ed 3, Philadelphia, 1997, FA Davis.)

process some hematopoietic stem cells undergo alternative paths of differentiation into more differentiated stem cells that are committed to a particular line of blood cells.

Hematopoietic stem cells represent just one stage in a process of progressive cellular differentiation. All humans originate from a single cell (the fertilized egg) that has the capacity to proliferate and eventually differentiate into the huge diversity of cells of the human body. After fertilization, the egg divides over a 5-day period to form a hollow ball (blastocyst) that implants on the uterus. Until about 3 days after fertilization, each cell (blastomere) is undifferentiated and retains the capacity to differentiate into any cell type. In the 5-day blastocyst, the outer layer cells have undergone differentiation and commitment to become the placenta. Cells of the inner cell mass *(embryonic stem cells),* however, continue to have unlimited differentiation potential (currently referred to as being *pluripotent*) and can grow into different kinds of tissue—blood, nerves, heart, bone, and so forth. After implantation, cells of the inner cell mass begin differentiation into other cell types. Differentiation is a multistep process and results in intermediate groups of stem cells *(multipotent stem cells)* with more limited, but still impressive, abilities to differentiate into many different types of cells (see Figure 27-10).[19]

Hematopoietic stem cells have partially differentiated.[20] They have the capacity to differentiate easily into any of the hematologic cell populations but are very difficult to differentiate into other cell types, like nerve or muscle cells. The challenge of getting any partially committed multipotent stem cells to differentiate reliably involves coaxing them with identical chemical signals that the body uses naturally for differentiation. This is a daunting task with potentially astonishing clinical implications. For example, bone marrow might become the reservoir from which stem cells are harvested and then stimulated to produce nerve cells to help with the treatments of spinal cord injuries.

As with all stem cells, the hematopoietic stem cells are self-renewing (they have the ability to proliferate without further differentiation) so that a relatively constant population of stem cells is available. Some hematopoietic stem cells will continue differentiation into hematopoietic progenitor cells. Progenitor cells retain proliferative capacity but are committed to possible further differentiation into particular types of hematologic cells: lymphoid (lymphocytes, NK cells), granulocyte-monocyte (granulocytes, monocytes, macrophages), and megakaryocyte-erythroid (platelets, erythrocytes) progenitor cells (see Figure 27-10).

In addition to intercellular signaling events between HSCs and cells in the osteoblastic and vascular niches, several cytokines participate in hematopoiesis, particularly **colony-stimulating factors (CSFs** or **hematopoietic growth factors),** which stimulate the proliferation of progenitor cells and their progeny and initiate the maturation events necessary to produce fully mature cells (see Figure 27-10).[21] Multiple cell types in the hematopoietic organs, including endothelial cells, fibroblasts, and lymphocytes, produce the necessary CSFs.

Hematopoiesis in the bone marrow occurs in two separate pools: the stem cell pool and the bone marrow pool (Figure 27-11). The stem cell pool is the product of self-renewal that maintains the number of pluripotent stem cells and partially committed progenitor cells. The bone marrow pool contains cells that are proliferating and maturing in preparation for release into the circulation and mature cells that are stored for later release into the peripheral blood. The peripheral blood

also contains two pools of cells: those in the circulation and those stored around the walls of the blood vessels (often called the **marginating storage pool**). The marginating storage pool primarily consists of neutrophils that adhere to the endothelium in vessels where the blood flow is relatively slow. These cells can rapidly move into tissues and mucous membranes when needed in an inflammatory response.

Under certain conditions of rapid depletion of the circulating pool, the circulating hematologic cells need to be rapidly replenished. Medullary hematopoiesis can be accelerated by any or all of three mechanisms: (1) conversion of yellow bone marrow, which does not produce blood cells, to hematopoietic red marrow by the actions of **erythropoietin** (a hormone that stimulates erythrocyte production); (2) faster differentiation of progenitor cells; and (3) faster proliferation of stem cells into progenitor cells (see Table 27-4).

Clinical Uses of Colony-Stimulating Factors

Neutrophils are normally present in the blood in the range of 4000 to 6000 cells/μL, and in response to a bacterial infection, numbers usually increase to 10,000 to 20,000 cells/μL. Susceptibility to infection develops when levels drop below 1000 cells/μL, such as during congenital neutropenia or as a consequence of cytotoxic therapy for cancer. Similarly normal levels of other hematologic cells may be suppressed (e.g., congenital or acquired immune deficiencies and anemia; see Chapters 9 and 28).

The numbers of circulating hematologic cells are under the control of CSFs (see Table 27-4). Administration of CSFs can raise white cell numbers to extremely high levels in healthy individuals. These excessive levels of white blood cells may result in production of toxic products and tissue damage. Therapy with CSFs has been tested in individuals with subnormal levels of circulating blood cells, such as acquired immunodeficiency syndrome (AIDS), aplastic anemia, or congenital neutropenia or as a consequence of cytotoxic therapy lymphoma or leukemia (Figure 27-12). The results of CSF use in individuals with cancer have been disappointing. An analysis of 19 trials in which CSFs were administered postchemotherapy to those with acute myelogenous leukemia detected no effect on overall survival or infections.[22] Results of using CSF prophylactically to avoid neutropenia in individuals undergoing chemotherapy for metastatic solid tumors have been controversial.[23] An analysis of randomized trials of prophylactic use of granulocyte-macrophage CSF (GM-CSF) and granulocyte CSF (G-CSF) in individuals undergoing chemotherapy for metastatic breast cancer indicated a significant effect on prevention of febrile neutropenia and a decrease of general mortality and need for hospital care.[24] However, no effect was observed on the incidence of severe neutropenia, infections, or infection-related mortality. CSF therapy can stimulate increases in circulating granulocyte-monocyte populations, but the degree of response depends on the available numbers of stem and progenitor cells that have survived chemotherapy or the effects of disease. CSF treatment has corrected some cases of congenital neutropenia and resulted in reconstitution of hematopoiesis after bone marrow transplantation.[25]

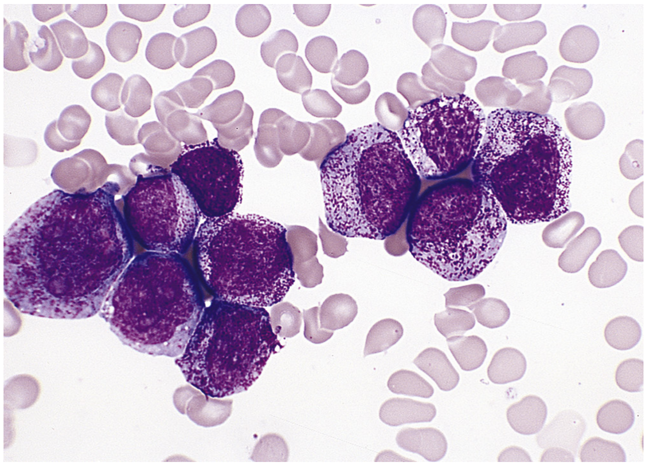

FIGURE 27-12 **Colony-Stimulating Factor (CSF) Effects.** Morphologic effects of growth factor. Marrow aspirate from a patient receiving granulocyte colony-stimulating factor (G-CSF) showing an early neutrophil response. There is a marked shift toward immaturity in the neutrophils with the majority at the promyelocyte and early myelocyte stages of maturation (Wright-Giemsa stain). (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

CSF treatment can result in shorter periods of intensive nursing and hospitalization. Recombinant CSFs (e.g., granulocyte colony-stimulating factor [G-CSF], GM-CSF, erythropoietin) are being mass-produced for therapeutic use.

Development of Erythrocytes

For almost 100 years it was believed that erythrocytes developed from lymphocytes that were transformed in the spleen. It was not until the 1850s that the bone marrow was identified as the site of **erythropoiesis,** or development of red blood cells.

Erythropoiesis

In the confines of the bone marrow erythroid progenitor cells proliferate and differentiate into large, nucleated **proerythroblasts,** which are committed into producing cells of the erythroid series (Figure 27-13). Erythroid development from the proerythroblast onward is contained in a compartment referred to as the *erythron*.[26] The proerythroblast, which has ribosomes and can produce protein, differentiates through several intermediate forms of **erythroblast** while synthesizing hemoglobin and progressively eliminating most intracellular structures, including the nucleus. Thus the maturing erythroblast becomes more compact and progressively assumes the shape and characteristics of an erythrocyte. Hemoglobin is readily apparent and increases in quantity as nuclear size shrinks throughout the basophilic and polychromatophilic stages. The orthochromatic erythroblast (**normoblast**) is the smallest of the nucleated erythrocyte precursors.

The last immature form of erythroblast is the **reticulocyte,** which is anucleate and contains a meshlike (reticular) network of ribosomal ribonucleic acid (rRNA) that is visible microscopically after staining with certain dyes. The reticulocyte contains polyribosomes (for globin synthesis) and mitochondria (for oxidative metabolism and heme synthesis). The

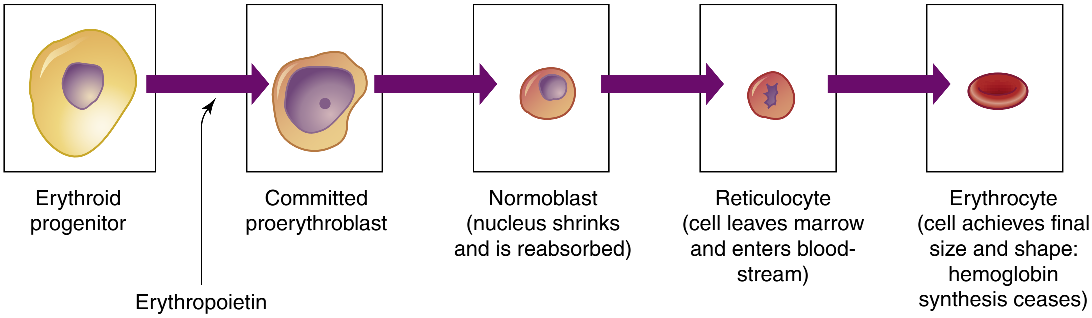

FIGURE 27-13 **Erythrocyte Differentiation.** Erythrocyte differentiation from large nucleated progenitor cells to small nonnucleated erythrocytes.

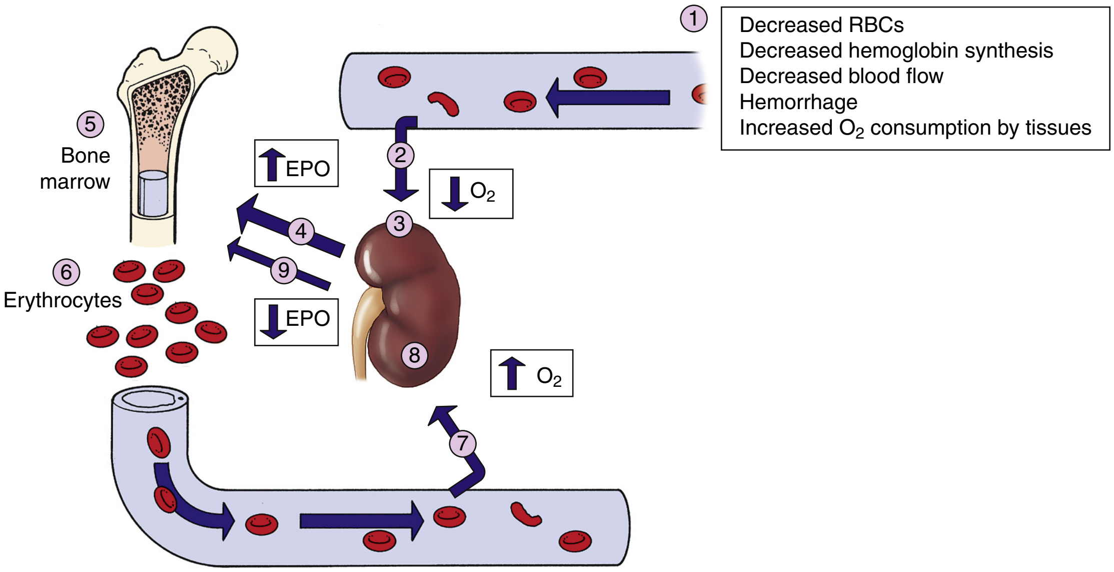

FIGURE 27-14 **Role of Erythropoietin in Regulation of Erythropoiesis. (1)** Decreased arterial oxygen levels result in **(2)** decreased tissue oxygen (hypoxia) that **(3)** stimulates the kidney to increase **(4)** production of erythropoietin. Erythropoietin is carried to the bone marrow **(5)** and binds to erythropoietin receptors on proerythroblasts, resulting in increased red cell production and maturation and expansion of the erythron **(6).** The increased release of red cells into the circulation frequently corrects the hypoxia in the tissues **(7). (8)** Perception of normal oxygen levels by the kidney causes **(9)** diminished production of erythropoietin (negative feedback) and return to normal levels of erythrocyte production. *EPO,* Erythropoietin; *O_2,* oxygen in the blood and tissue; *RBCs,* red blood cells.

reticulocyte matures into an erythrocyte within 24 to 48 hours. During this period, mitochondria and ribosomes disappear and the cell becomes smaller and more disk-like. With these final changes, the erythrocyte loses its capacity for hemoglobin synthesis and oxidative metabolism. Reticulocytes remain in the marrow approximately 1 day and are released into the venous sinuses. They continue to mature in the bloodstream and may travel to the spleen for several days of additional maturation. The normal reticulocyte count is 1% of the total red blood cell count. Approximately 1% of the body's circulating erythrocyte mass normally is generated every 24 hours. Therefore, the reticulocyte count is a useful clinical index of erythropoietic activity and indicates whether new red cells are being produced.

Regulation of Erythropoiesis

In healthy individuals, the total volume of circulating erythrocytes remains surprisingly constant. Most steps of erythropoiesis are primarily under the control of a feedback loop involving the glycoprotein erythropoietin (see Table 27-4). In conditions of tissue hypoxia, erythropoietin is secreted by the liver and, primarily, by the peritubular cells of the kidney (Figure 27-14).[27] Rising levels of circulating erythropoietin cause a compensatory increase in proliferation and differentiation of proerythroblasts in the bone marrow. The density of cellular erythropoietin receptor decreases progressively during erythroid maturation to almost undetectable levels on reticulocytes. The normal steady-state rate of production of approximately 2.5 million erythrocytes per second can increase to 17 million per second during anemia or under conditions of low oxygen concentration, such as high-altitude environments or pulmonary disease. Thus the body responds to reduced oxygenation of blood in two ways: (1) stimulation of chemoreceptors of the carotid body and aortic arch that signal the brain to increase respiration, and (2) stimulation of receptors on the kidney peritubular cells to increase erythropoietin synthesis and release.

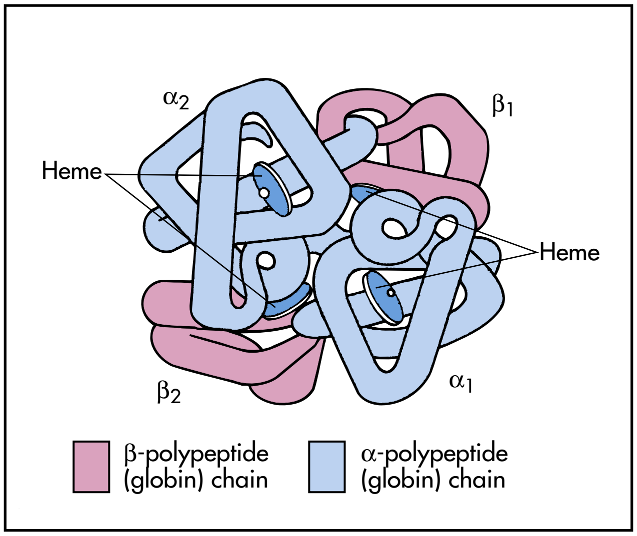

FIGURE 27-15 Molecular Structure of Hemoglobin. Molecule is a spherical tetramer weighing approximately 64,500 daltons. It contains a pair of α-polypeptide and a pair of β-polypeptide chains and several heme groups.

TABLE 27-5 STRUCTURE OF NORMAL HEMOGLOBIN MOLECULES

TYPE OF HEMOGLOBIN (Hb)	IDENTITY OF POLYPEPTIDE CHAIN	SIGNIFICANCE
HbA	$\alpha_2\beta_2$	92% of adult Hb
HbA_{1c}	α_2 (β-*NH*-glucose)	5% of adult Hb; increased in diabetes (see Chapter 22)
HbA_2	$\alpha_2\delta_2$	2% of adult Hb; increased in beta-thalassemia (see Chapter 30)
HbF	$\alpha_2\gamma_2$	Major fetal Hb from the third through ninth month of gestation; promotes oxygen transfer across platelets; increased in beta-thalassemia
Hb Gower I	ε_4 or $\zeta_2\beta_2$	Present in early embryo; function unknown
Hb Gower II	$\alpha_2\varepsilon_2$	Present in early embryo; function unknown
Hb Portland	$\zeta_2\gamma_2$	Present in early embryo; function unknown

NH, Amine.

One of the most significant advances in the study of hematopoietic growth factors has been the development of erythropoietin for use in individuals with chronic renal failure. In 1986 large amounts of recombinant human erythropoietin (r-HuEPO) became widely available for clinical research. Erythropoietin is administered intravenously or subcutaneously for the treatment of anemia caused by decreased production of erythropoietin. An immediate effect of increased endogenous or exogenous erythropoietin is an increase in the blood reticulocyte count, followed by increasing levels of erythrocytes. The most significant side effect associated with r-HuEPO is increased blood pressure.

Hemoglobin Synthesis

Hemoglobin (Hb), the oxygen-carrying protein of the erythrocyte, constitutes approximately 90% of the cell's dry weight. Hemoglobin-packed blood cells take up oxygen in the lungs and exchange it for carbon dioxide in the tissues. A single erythrocyte can contain as many as 300 hemoglobin molecules. Hemoglobin increases the oxygen-carrying capacity of blood by 100-fold. Each hemoglobin molecule is composed of two pairs of polypeptide chains (the **globins**) and four colorful complexes of iron plus protoporphyrin (the hemes) (Figure 27-15).[28] Hemoglobin is responsible for blood's ruby-red color.

Several variants of hemoglobin exist, but they differ only slightly in primary structure based on the use of different polypeptide chains; alpha, beta, gamma, delta, epsilon, or zeta (α, β, γ, δ, ε, or ζ) (Table 27-5). Each polypeptide chain contains approximately 150 amino acids and is arranged in the knotted-sausage configuration shown in Figure 27-15. The chains assemble to form a tetrahedron containing two pairs of identical chains. Hemoglobin A, the most common type in adults, is composed of two α- and two β-polypeptide chains ($\alpha 2\beta_2$). A normal variant, fetal hemoglobin (hemoglobin F), is a complex of two α- and two γ-polypeptide chains ($\alpha 2\gamma_2$) that binds oxygen with a much greater affinity than that found in adult hemoglobin.

Heme is a large, flat, iron-protoporphyrin disk that is synthesized in the mitochondria and can carry one molecule of oxygen (O_2). Thus an individual hemoglobin molecule with its four hemes can carry four oxygen molecules. If all four oxygen-binding sites are occupied by oxygen, the molecule is said to be saturated. Through a series of complex biochemical reactions, **protoporphyrin,** a complex four-ringed molecule, is produced and bound with ferrous iron. It is crucial that the iron be correctly charged; reduced ferrous iron (Fe^{2+}) can bind oxygen in the lungs and release it in the tissues, where oxygen concentration is less, whereas ferric iron (Fe^{3+}) cannot. Binding of oxygen to ferrous iron (**oxyhemoglobin**) temporally oxidizes Fe^{2+} to Fe^{3+}, but after the release of oxygen the body reduces the iron to Fe^{2+} (**deoxyhemoglobin** [reduced hemoglobin]) and reactivates the hemoglobin's capacity to bind oxygen. Without reactivation by methemoglobin reductase, the Fe^{3+}-containing hemoglobin (**methemoglobin**) cannot bind oxygen.

Several other molecules can competitively bind to deoxyhemoglobin. Carbon monoxide (CO) directly competes with oxygen for binding to ferrous ion with an affinity that is about 200-fold greater than that of oxygen. Thus even a small amount of CO can dramatically decrease the ability of hemoglobin to bind and transport oxygen. Hemoglobin also binds carbon dioxide (CO_2), but at a binding site separate from where oxygen binds. In the lungs, CO_2 is released, allowing hemoglobin to bind oxygen.

Erythrocytes may play a role in the maintenance of vascular relaxation. Nitric oxide (NO) produced by blood vessels is a major mediator of relaxation and dilation of the vessel walls. In the lungs, hemoglobin can concurrently bind oxygen to the ferrous ion and NO to cysteine residues in the globins. As

TABLE 27-6 NUTRITIONAL REQUIREMENTS FOR ERYTHROPOIESIS

NUTRIENT	ROLE IN ERYTHROPOIESIS	CONSEQUENCE OF DEFICIENCY
Protein (amino acids)	Structural component of plasma membrane	Decreased strength, elasticity, and flexibility of membrane; hemolytic anemia
	Synthesis of hemoglobin	Decreased erythropoiesis and life span of erythrocytes
Cobalamin (vitamin B_{12})	Synthesis of DNA, maturation of erythrocytes, facilitator of folate metabolism	Macrocytic (megaloblastic) anemia
Folate (folic acid)	Synthesis of DNA and RNA, maturation of erythrocytes	Macrocytic (megaloblastic) anemia
Vitamin B_6 (pyridoxine)	Heme synthesis	Microcytic-hypochromic anemia
Vitamin B_2 (riboflavin)	Oxidative reactions	Normocytic-normochromic anemia
Vitamin C (ascorbic acid)	Iron metabolism; acts as a reducing agent to maintain iron in its ferrous (Fe^{2+}) form	Normocytic-normochromic anemia
Pantothenic acid	Heme synthesis	Unknown in humans*
Niacin	None, but needed for respiration in mature erythrocytes	Unknown in humans
Vitamin E	Heme synthesis (?); protection against oxidative damage in mature erythrocytes	Hemolytic anemia with increased cell membrane fragility; shortens life span of erythrocytes in individuals with cystic fibrosis
Iron	Hemoglobin synthesis	Iron deficiency anemia
Copper	Required for optimal mobilization of iron from tissues to plasma	Microcytic-hypochromic anemia

Data from Ames BN, Atamna H, Killilea DW: Mineral and vitamin deficiencies can accelerate the mitochondrial decay of aging, *Mol Aspects of Med* 26(4-5), 367–378, 2005; Strine-Martin EA, Lotspeich-Steininger CA, Koepke JA: *Clinical hematology: principles, procedures, correlations,* ed 2, Philadelphia, 1998, Lippincott.

*Although pantothenic acid is important for optimal synthesis of heme, experimentally induced deficiency *failed* to produce anemia or other hematopoietic disturbances.

DNA, Deoxyribonucleic acid; *RNA,* ribonucleic acid.

hemoglobin transfers its oxygen to tissue, it may also shed small amounts of nitric oxide, contributing to dilation of the blood vessels and helping the oxygen gain access to tissues.

Nutritional Requirements for Erythropoiesis

Normal development of erythrocytes and synthesis of hemoglobin depends on an optimal biochemical milieu and adequate supplies of the necessary building blocks, including protein, vitamins, and minerals (Table 27-6). If these components are lacking for a prolonged time, erythrocyte production slows and anemia (insufficient numbers of functional erythrocytes) may result (see Chapter 28).

Erythropoiesis cannot proceed in the absence of vitamins, especially B_{12}, folate (folic acid), B_6, riboflavin, pantothenic acid, niacin, ascorbic acid, and vitamin E. Dietary vitamin B_{12} is a large molecule that requires a protein secreted by parietal cells into the stomach (intrinsic factor [IF]) for transport across the ileum. Once absorbed, vitamin B_{12} is stored in the liver and used as needed in erythropoiesis. Defects in IF production lead to decreased B_{12} absorption and pernicious anemia.

Folate is the second most important vitamin for erythrocyte production and maturation. Folate is necessary for DNA synthesis, being a component of three of the four DNA bases (thymine, adenine, and guanine), and RNA synthesis. Folate absorption occurs principally in the upper small intestine and is stored in the liver. Folate deficiency is more common than vitamin B_{12} deficiency and occurs more rapidly. Folate stores can be depleted within a few months, whereas vitamin B_{12} depletion can take years. Folate supplements are prescribed for pregnant women because pregnancy increases the demand for folate and may cause anemia.

Normal Destruction of Senescent Erythrocytes

After about 100 to 120 days in the circulation, old erythrocytes are removed by tissue macrophages, primarily in the spleen. Although mature erythrocytes lack nuclei, mitochondria, and endoplasmic reticulum, they do have cytoplasmic enzymes capable of glycolysis (anaerobic glucose metabolism) and production of small quantities of ATP, which provides the energy needed to maintain cell function and membrane pliability. Metabolic processes diminish as the erythrocyte ages, so less ATP is available to maintain plasma membrane function. Disruption of the anchorage between the cytoskeleton and the plasma membrane results in the senescent red cell becoming increasingly fragile and losing its reversible deformability, and thus becoming susceptible to rupture while passing through narrowed regions of the microcirculation.

Additionally, the plasma membrane of senescent red cells undergoes phospholipid rearrangement (movement of the phospholipid phosphatidylserine from the cytoplasmic surface of the membrane to the external surface) that is recognized by receptors for phosphatidylserine on macrophages (primarily in the spleen) that selectively remove and sequester the red cells.[29] If the spleen is dysfunctional or absent, macrophages in the liver (Kupffer cells) take over.

The erythrocytes are digested by proteolytic and lipolytic enzymes in the phagolysosomes (digestive vacuoles) of the macrophage. The heme and globin of methemoglobin dissociate easily, and the globin is broken down into its component amino acids. The iron in hemoglobin is oxidized, forming Fe^{3+} (methemoglobin), and recycled (see following section).

Porphyrin is reduced to bilirubin, which is transported to the liver, conjugated, and finally excreted in the bile as glucuronide (Figure 27-16). Approximately 6 g of hemoglobin is

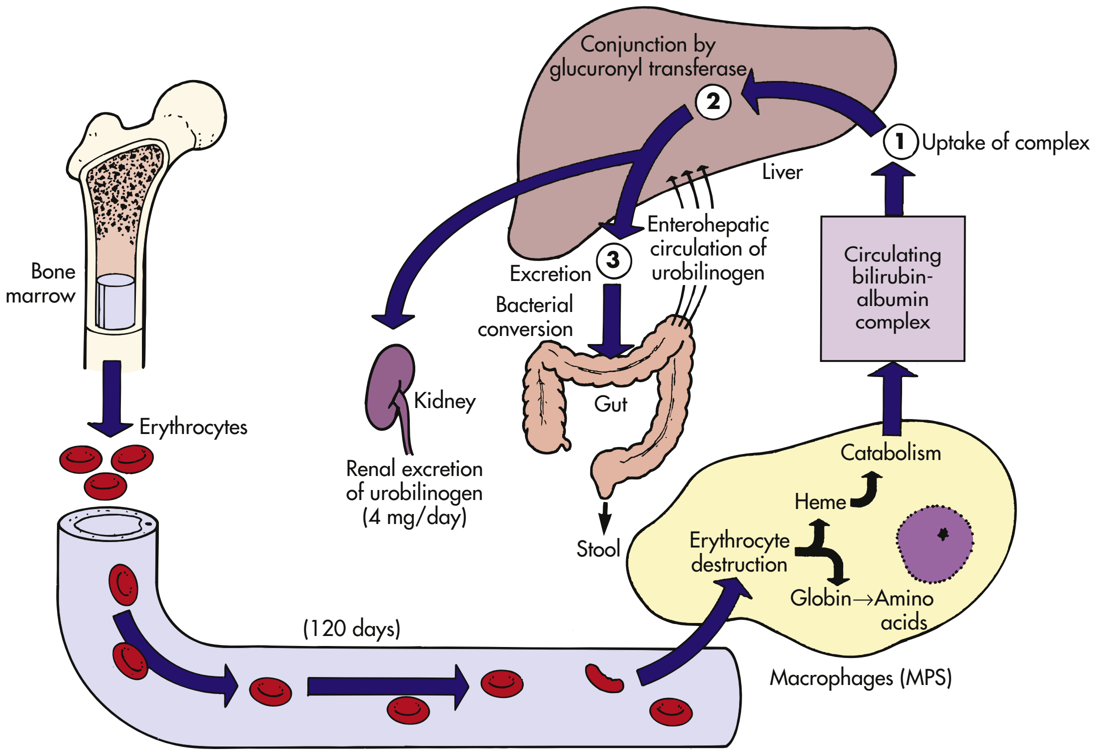

FIGURE 27-16 Metabolism of Bilirubin Released by Heme Breakdown.

catabolized daily, producing 200 mg of bilirubin. Bacteria in the intestinal lumen transform conjugated bilirubin into urobilinogen. Although a small portion is reabsorbed for further metabolism by the liver or excreted by the kidney into the urine, most urobilinogen is excreted in feces. Conditions causing accelerated erythrocyte destruction increase the load of bilirubin for hepatic clearance, leading to increased serum levels of unconjugated bilirubin and increased urinary excretion of urobilinogen. Gallstones (cholelithiasis) can result from a chronically elevated rate of bilirubin excretion.

Iron Cycle

Approximately 67% of total body iron is bound to heme in erythrocytes (hemoglobin) and muscle cells (**myoglobin),** and approximately 30% is stored in mononuclear phagocytes (i.e., macrophages) and hepatic parenchymal cells as either ferritin or hemosiderin. The remaining 3% (less than 1 mg) is lost daily in urine, sweat, bile, sloughing of epithelial cells from the skin and intestinal mucosa, and minor bleeding. Approximately 25 mg of iron is required daily for erythropoiesis; only 1 to 2 mg of iron is dietary and the remainder is obtained from iron recycling of erythrocytes.

Iron is continually recycled.[30] The methemoglobin released from the breakdown of senescent or damaged erythrocytes (see preceding section) is dissociated by the enzyme heme oxygenase, and the iron is released into the bloodstream, where it is free to bind again to transferrin or be stored in the macrophage's cytoplasm as ferritin or hemosiderin (Figure 27-17). A minute amount of iron is stored in muscle cells by the heme-containing protein myoglobin. Unavailable stores of iron are present in cytochromes, catalases, and peroxidase enzymes.

The protein ferritin is the major intracellular iron storage protein. **Apoferritin,** which is ferritin without attached iron, can store thousands of atoms of iron. Several apoferritin complexes combine to form the micelle ferritin. Large aggregates of micelles (if a large amount of iron is present) produce numerous ferritin micelles, known as **hemosiderin.** Hemosiderin is visible as an iron-based pigment under a light microscope as cell inclusions. The iron within deposits of hemosiderin is poorly available to supply iron when needed. The most common cause of hemosiderin deposition is simple bruising. Hemosiderin in small amounts within iron-rich tissues (i.e., spleen, liver, bone marrow) is considered normal. Large aggregates or its presence in tissue such as the lungs or subcutaneous tissue suggest a pathologic condition.

Iron from either dietary sources, release of iron stores, or erythrocyte catabolism is transported in the blood bound to **apotransferrin,** thus becoming **transferrin;** under normal conditions, only one third of the iron-binding sites on transferrin molecules are occupied.[31] Apotransferrin is a glycoprotein synthesized primarily by hepatocytes in the liver but also produced in small quantities by tissue macrophages, submaxillary and mammary glands, and ovaries or testes. Iron for hemoglobin production is carried by transferrin to the bone marrow, where it binds to transferrin receptors on erythroblasts. Transferrin receptors are on the plasma membrane of all nucleated cells, although at particularly high levels on erythroid precursors and rapidly proliferating cells (e.g., lymphocytes), and are thought to be the only route of cellular entry for transferrin-attached iron. Transferrin is recycled (transferrin cycle) in the following manner:

1. The transferrin-iron complex binds to a transferrin receptor on the erythroblast's plasma membrane.

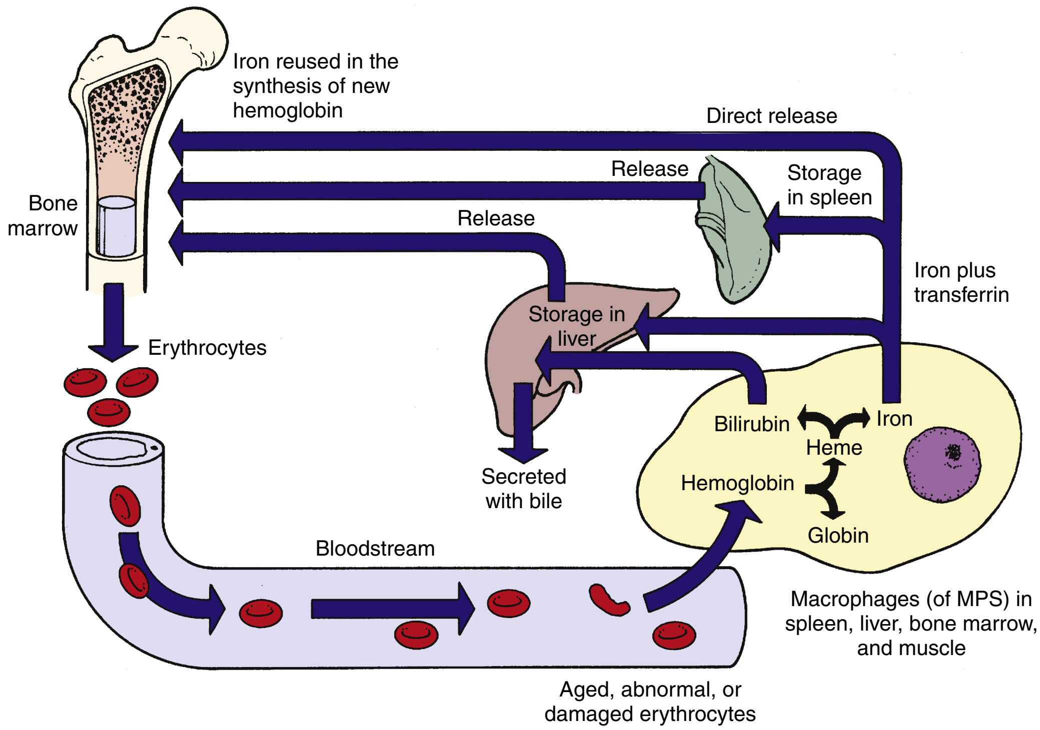

FIGURE 27-17 **Iron Cycle.** Iron (Fe) released from gastrointestinal epithelial cells circulates in the bloodstream associated with its plasma carrier, transferrin. It is delivered to erythroblasts in bone marrow, where most of it is incorporated into hemoglobin. Mature erythrocytes circulate for approximately 100 to 120 days, after which they become senescent and are removed by the mononuclear phagocyte system *(MPS)*. Tissue macrophages (mostly in spleen) break down ingested erythrocytes and return iron to the bloodstream directly or after storing it as a ferritin or hemosiderin.

2. The complex moves into the cell by receptor-mediated endocytosis.
3. Iron is released (dissociated) from transferrin.
4. The dissociated transferrin is returned to the bloodstream for reuse.

The iron is transported to the erythroblast's mitochondria (the site of hemoglobin production), where the enzyme heme synthetase inserts ferrous iron into protoporphyrin to form heme. Heme then is bound to globin to form hemoglobin. Iron not used in erythropoiesis is stored temporarily as ferritin or hemosiderin and later excreted.

The body's iron homeostasis is primarily controlled by the hormone hepcidin.[32] Hepcidin is synthesized in the liver and released as a 25 amino acid peptide, most of which is bound in the plasma with high affinity to α_2-macroglobulin and relatively lower affinity to albumin. Hepatocellular hepcidin production is regulated physiologically by the body's dietary absorption of iron, rate of erythropoiesis, and level of oxygen saturation.[33] Hepatocytes sense levels of circulating iron by means of receptors for transferrin, the major transporter of iron in the plasma. Excess iron is stored in hepatocytes and macrophages. Hepatocytes sense these levels by means of receptors for bone morphogenetic protein (BMP), most likely BMP-6, which is a growth factor produced to a large extent by bone marrow sinusoid endothelial cells. Hepcidin production also can be induced by inflammation by means of IL-6.

Hepcidin regulates iron levels through its binding capacity to ferroportin, which is a transmembrane iron exporter found in the plasma membrane of cells that transport or store iron, including macrophages, hepatocytes, and enterocytes. The body's total iron balance is maintained through controlled absorption rather than excretion.[34] Dietary iron (primarily as Fe^{2+}) is transported directly across the membranes of epithelial cells (enterocytes) in the duodenum and proximal jejunum.[35] (Transport mechanisms are described in Chapter 1.) Hepcidin induces internalization and degradation of ferroportin, thus leading to increased intracellular iron stores, decreased dietary iron absorption, and decreased levels of circulating iron.[36] Decreased production of hepcidin leads to release of stored iron and increased dietary absorption. Thus, if the body's iron stores are low or the demand for erythropoiesis increases, dietary iron is transported rapidly through the epithelial cell and into the plasma. If body stores are high and erythropoiesis is not increased, iron transport is stopped, although iron can cross the epithelial cells' plasma membrane passively and be stored as ferritin.

Development of Leukocytes

Leukocytes consist of lymphocytes, granulocytes, and monocytes. Most of the leukocytes arise from stem cells in the bone marrow (their pathways of differentiation are shown in Figure 27-10). Hematopoietic stem cells differentiate into two populations of progenitor cells: common lymphoid progenitors and common myeloid progenitors. Lymphoid progenitors that remain in the bone marrow undergo differentiation into the B-cell lineage, after which they are released into the

circulation and undergo further maturation in the peripheral lymphoid organs (described in Chapter 8 [see Figure 8-3]). The common myeloid progenitors further differentiate into progenitors for basophils, mast cells, eosinophils, and megakaryocytes, and granulocyte/monocyte progenitors. The granulocyte/monocyte progenitors further differentiate into monocyte progenitors and granulocyte progenitors, which develop into monocytes/macrophages and neutrophils, respectively. Development from hematopoietic stem cells to common granulocyte-monocyte progenitors primarily is under the control of stem cell factor, IL-3, and GM-CSF, whereas further differentiation into granulocytic and monocytic progenitors is controlled by G-CSF and M-CSF, respectively (see Table 27-4).

Monocytic progenitors undergo development into monocytes within 24 hours and are released into the circulation. Monocytes mature into various forms of macrophages, a process that is usually completed within 1 or 2 days after their release (see Tables 27-3 and 27-4).[37]

Progenitor cells for granulocytes normally fully mature in the bone marrow into neutrophils, eosinophils, and basophils. The ultimate phenotype is determined by relative local bone marrow concentrations of early- and late-acting cytokines, including GM-CSF, G-CSF, IL-3, IL-5, stem cell factor, and others (see Table 27-4). Granulocytes are released into the blood within 14 days of development. The bone marrow selectively retains immature granulocytes as a reserve pool that can be rapidly mobilized in response to the body's needs.

Most leukocytes exist in the body from days to years, depending on type. Maintenance of optimal levels of granulocytes and monocytes in the blood depends on the availability of pluripotent stem cells in the marrow, induction of these into committed stem cells, timely release of new cells from the marrow, and mobilization of the granulocyte reserve pool. Leukocyte production increases in response to infection, to the presence of steroids, and to reduction or depletion of reserves in the marrow. It is also associated with strenuous exercise, convulsive seizures, heat, intense radiation, paroxysmal tachycardias, pain, nausea and vomiting, and anxiety.

Development of Platelets

Platelets (thrombocytes) are derived from stem cells and progenitor cells that differentiate into megakaryocytes.[38] During thrombopoiesis, the megakaryocyte progenitor is programmed to undergo an endomitotic cell cycle (**endomitosis**) during which DNA replication occurs, but anaphase and cytokinesis are blocked (see Chapter 1). Thus the megakaryocyte nucleus enlarges and becomes extremely polyploidy (up to 100-fold or more of the normal amount of DNA) without cellular division. Concurrently, the numbers of cytoplasmic organelles (e.g., internal membranes, granules) increase, and the cell develops cell surface proplatelet elongations into the sinusoidal blood vessels.[39] These branches progressively fragment into platelets. A single large (30 to 100 μm) megakaryocyte may produce thousands of smaller platelets (2 to 3 μm).[40] Like erythrocytes, platelets released from the bone marrow lack nuclei.

About two thirds of platelets enter the circulation; the remainder reside in the splenic pool. Platelets circulate in the bloodstream for about 8 to 10 days before losing their ability to carry out thrombogenic activity. Senescent platelets are sequestered and destroyed in the spleen by mononuclear cell phagocytosis.

An adequate level of committed platelet precursors (megakaryoblasts) in the bone marrow and differentiation into circulating platelets are controlled by specific interactions between megakaryocyte progenitors and stromal cells in the bone marrow as well as thrombopoietin (TPO, a hormonal growth factor primarily produced by the liver) and various cytokines and colony-stimulating factors and interleukins (see Table 27-4). Platelets express high-affinity receptors for TPO, and when circulating platelet levels are normal, TPO is adsorbed onto the platelet surface and prevented from accessing the bone marrow and initiating further platelet production.[41] TPO stimulates committed cells at further stages of differentiation to differentiate faster so that rates of megakaryocyte development, endomitosis, and platelet release are increased. During inflammation IL-6 induces increased production of TPO, which increases production of newly formed platelets, which are more thrombogenic.

MECHANISMS OF HEMOSTASIS

Hemostasis is defined as arrest of bleeding (Figure 27-18). As a result of hemostasis, damaged blood vessels maintain a relatively steady-state of blood volume, pressure, and flow. The importance of hemostasis clearly varies with vessel size. Damage to large vessels cannot easily be controlled by hemostasis but requires vascular contraction and dramatically decreased blood flow into the damaged vessels.

Three equally important components of hemostasis are the vasculature (endothelial cells and subendothelial matrix), platelets, and blood proteins (clotting factors). The following describes the general sequence of events in hemostasis: (1) vascular injury leads to a transient arteriolar vasoconstriction to limit blood flow to the affected site; (2) damage to the endothelial cell lining of the vessel exposes prothrombogenic subendothelial connective tissue matrix, leading to platelet adherence and activation and formation of a *hemostatic plug* to prevent further bleeding (primary hemostasis); (3) tissue factor, produced by the endothelium, collaborates with secreted platelet factors and activated platelets to activate the clotting (coagulation) system to form fibrin clots and further prevent bleeding (secondary hemostasis); and (4) the fibrin/platelet clot contracts to form a more permanent plug, and regulatory pathways are activated (fibrinolysis) to limit the size of the plug and begin the healing process.

Function of Blood Vessels

The vessel walls consist of a layer of endothelial cells that adhere to an underlying matrix of connective tissue. The matrix contains a variety of proteins, including collagen, fibronectin, and laminins. Endothelial cells adhere to the matrix and to each other through receptors (e.g., vascular endothelial cell–specific

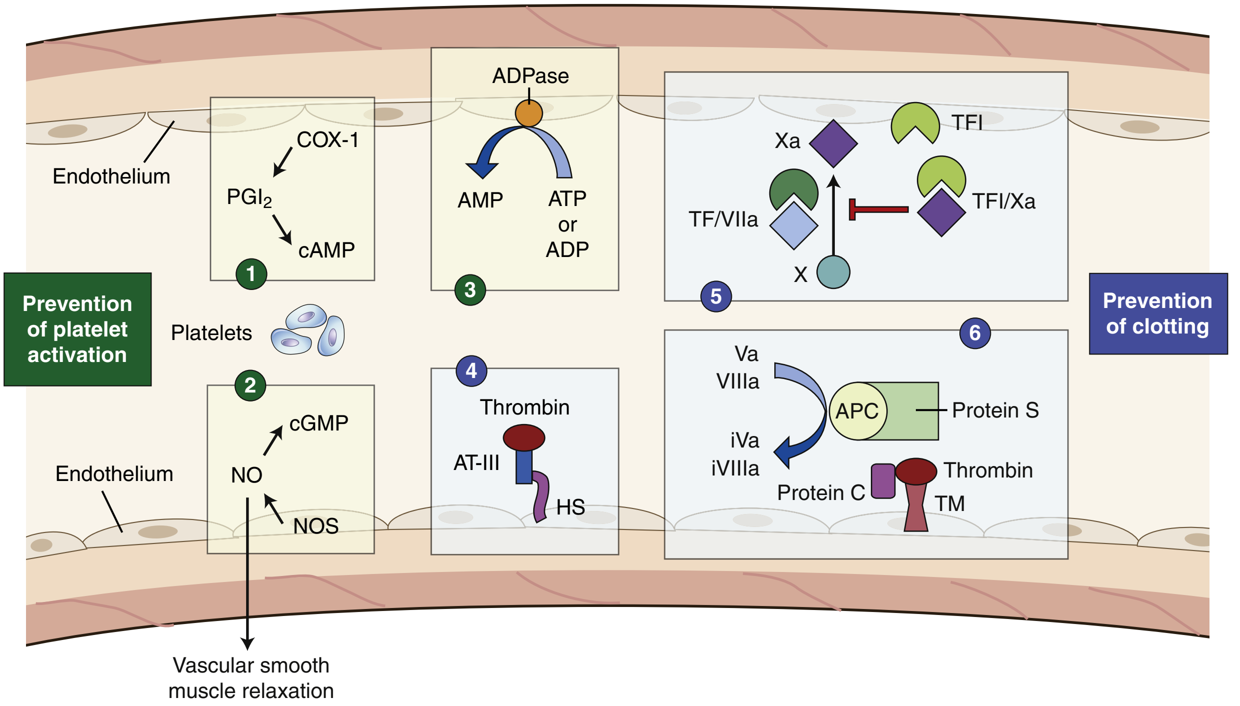

FIGURE 27-18 **Hemostasis.** Endothelium controls hemostasis by preventing platelet activation **(1-3)** and preventing activation of the clotting system **(4-6). (1)** *Prostacyclin production:* Injury activates inflammation (*COX-1,* arachidonic acid). Enzymes convert arachidonic acid into prostacylin I_2 *(PGI_2)* in endothelial cells. PGI_2 eventually increases intracellular cyclic adenosine monophosphate *(cAMP);* cAMP inhibits platelet aggregation and induces vasodilation. Nitric oxide *(NO)* formation is induced by NO synthases *(NOS)* and NO causes increased cyclic guanosine monophosphate *(cGMP).* **(2)** *Nitric oxide system:* Endothelial cell NOS produces nitric oxide, which controls platelet activation through cGMP-mediated signaling. **(3)** *ADPase:* Endothelial cells express a surface bound ADPase (CD39) that converts circulating ADP and ATP to AMP. **(4)** *Antithrombin III–heparan sulfate system:* Antithrombin III *(AT-III)* inhibits thrombin slowly when heparan sulfate *(HS)* is absent. When HS is present, it quickly activates thrombin because it binds to a specific site on AT-III that causes an instant conformational change in AT-III, allowing it to quickly activate thrombin. **(5)** *Tissue factor inhibitor (TFI) system:* Expression of TFI on the endothelial cells and secreted into the circulation complexes with factor IXa to form a competitive inhibitor of the tissue factor/factor VIIa complex *(TF/VIIa)* and prevent further activation of factor X to Xa. **(6)** *Protein C/protein S pathway (thrombomodulin):* Thrombin in the circulation binds to thrombomodulin on the endothelial cell, creating a complex that can bind and activate protein C to activated protein C *(APC)* that complexes in the blood or on the surface of active platelets with protein S. This complex degrades circulating clotting factors Va and VIIIa to inactive forms *(iVa, iVIIIa)* to prevent further activation of clotting.

cadherin [VE-cadherin], platelet-endothelial cell adhesion molecule 1 [PECAM-1], integrins [especially α2β1 and α5β1]) that are expressed only on the intercellular and basal surfaces.

Under normal conditions the endothelium actively regulates blood flow and prevents spontaneous activation of platelets and the clotting system (see Figure 27-18). Endothelial cells produce **nitric oxide (NO)** from L-arginine and synthesize **prostacyclin (PGI_2)** from arachidonic acid. Both NO, via cGMP, and PGI_2 are vasodilators that work in concert with endothelin (a vasoconstrictor) to maintain blood flow and pressure.[42] NO and PGI_2 also inhibit platelet adhesion and aggregation. Synergism between PGI_2 and NO is significant. PGI_2 production varies a great deal in response to stimuli, whereas NO is released continually to regulate vascular tone. NO has other biologic functions including cell signaling, free radical production, and possibly others. Endothelium also produces adenosine diphosphatase, which degrades ADP (a potent activator of platelets).

The endothelial cell surface contains antithrombotic molecules, such as glycosaminoglycans (e.g., heparan sulfate), thrombomodulin, and plasminogen activators. These limit platelet activation and fibrin deposition. Although thrombomodulin and plasminogen activators help control hemostasis in normal vessels, their effects are magnified during vascular damage and clot formation; therefore, further information is provided on these molecules in the following section on control of hemostatic mechanisms.

As a result of damage to the vessels, the endothelial cell barrier is frequently compromised, the remaining endothelial cells are activated by products of tissue damage, and the underlying matrix is exposed. Endothelial cells contain intracellular structures (Weibel-Palade bodies) that contain von Willebrand factor (vWF) that is released during damage. The matrix, in addition to collagen and other connective tissue, contains vWF and can bind additional vWF released by the endothelium.[43] The matrix itself and vWF are potent activators of platelets.

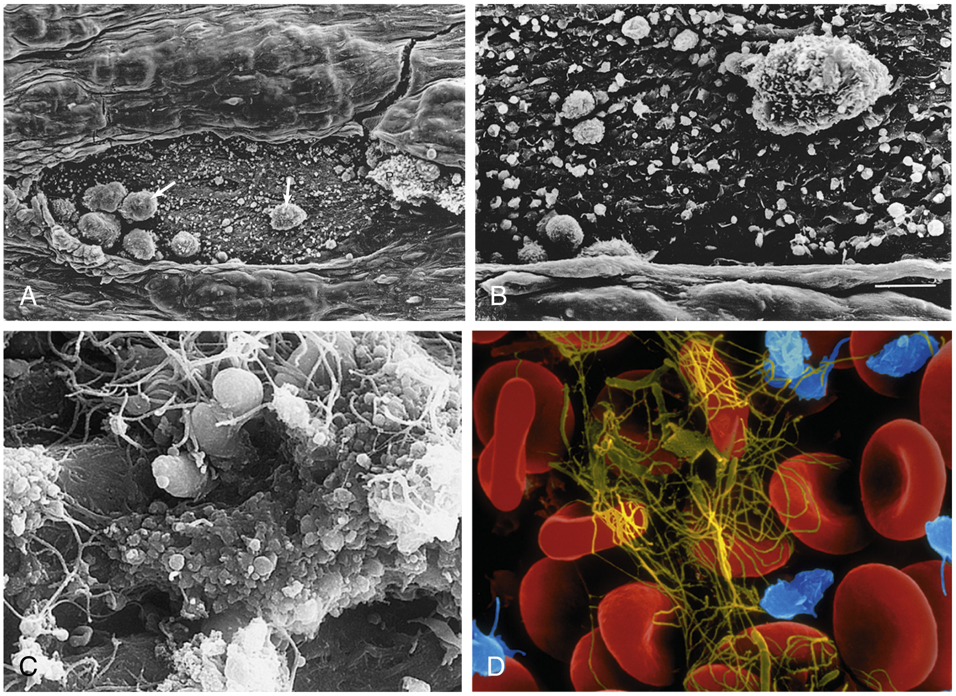

FIGURE 27-19 Platelet Activation. **A,** After endothelial denudation, platelets and leukocytes adhere to the subendothelium in a monolayer fashion. **B,** Higher-power view showing leukocytes and platelets adherent to the subendothelium. **C,** High magnification of a thrombus showing a mixture of red cells and platelets incorporated into the fibrin meshwork. **D,** An electron micrograph showing entrapped RBCs in a fibrin clot. Function of Platelets

Platelets normally circulate freely, suspended in plasma, in an unactivated state. The role of platelets is to (1) contribute to regulation of blood flow into a damaged site by induction of vasoconstriction (vasospasm), (2) initiate platelet-platelet interactions resulting in formation of a platelet plug to stop further bleeding, (3) activate the coagulation (or clotting) cascade to stabilize the platelet plug, and (4) initiate repair processes including clot retraction and clot dissolution **(fibrinolysis).** The normal platelet count ranges from 140,000 to 340,000/mm^3. If platelet counts drop below 100,000/mm^3 an individual is usually considered thrombocytopenic (abnormally low numbers of platelets) and may experience prolongation of normal clotting but is usually not at risk for spontaneous major bleeding episodes unless the platelet count falls below 20,000/mm^3. If platelet numbers are elevated (thrombocytosis) the risk for spontaneous blood clots (thrombosis), stroke, or heart attack is increased.

The state of platelet activation is primarily under the control of endothelial cells lining the vessels. Damage to the vessel initiates a process of platelet activation: (1) increased platelet *adhesion* to the damaged vascular wall; (2) *activation* leading to secretion of chemicals from platelet granules, which stimulate changes in platelet shape and biochemistry; and (3) *aggregation* as platelet–vascular wall and platelet-platelet adherence increases.[44] This process leads to activation of the clotting system and development of an immobilizing meshwork of platelets and fibrin (Figure 27-19).

Adhesion

Normally, platelets are generally observed "rolling" along the margins of vessels. At sites of vessel injury, however, platelets become adherent to the site of endothelial damage, where the subendothelial matrix is exposed and endothelial cells have released vWF and decreased their antithrombotic activities (Figure 27-20). **Platelet adhesion** is mostly mediated by the binding of platelet surface receptor glycoprotein-Ib (GPIb) (in a complex with clotting factors IX and V) to **von Willebrand factor (vWF).**[45] The vWF protein is found in the subendothelial matrix and is released by endothelial cells and platelets. Deficiencies in GPIb (Bernard-Soulier syndrome) or vWF (von Willebrand disease) lead to highly defective hemostasis and congenital bleeding disorders.[46] Platelet adhesion narrows the diameter of the blood vessel, resulting in increasing shear forces that could strip platelets off the vessel surface. However, those same forces induce conformational changes in the vWF molecule that result in increased affinity with GPIb, thus stabilizing the adherent platelet.[47]

Platelet adhesion is also facilitated by other interactions between platelet receptors and exposed molecules of the subendothelial matrix. For instance, adhesion is increased through binding of the platelet collagen receptors GPVI and integrin $\alpha 2\beta 1$ to exposed collagen in the matrix.

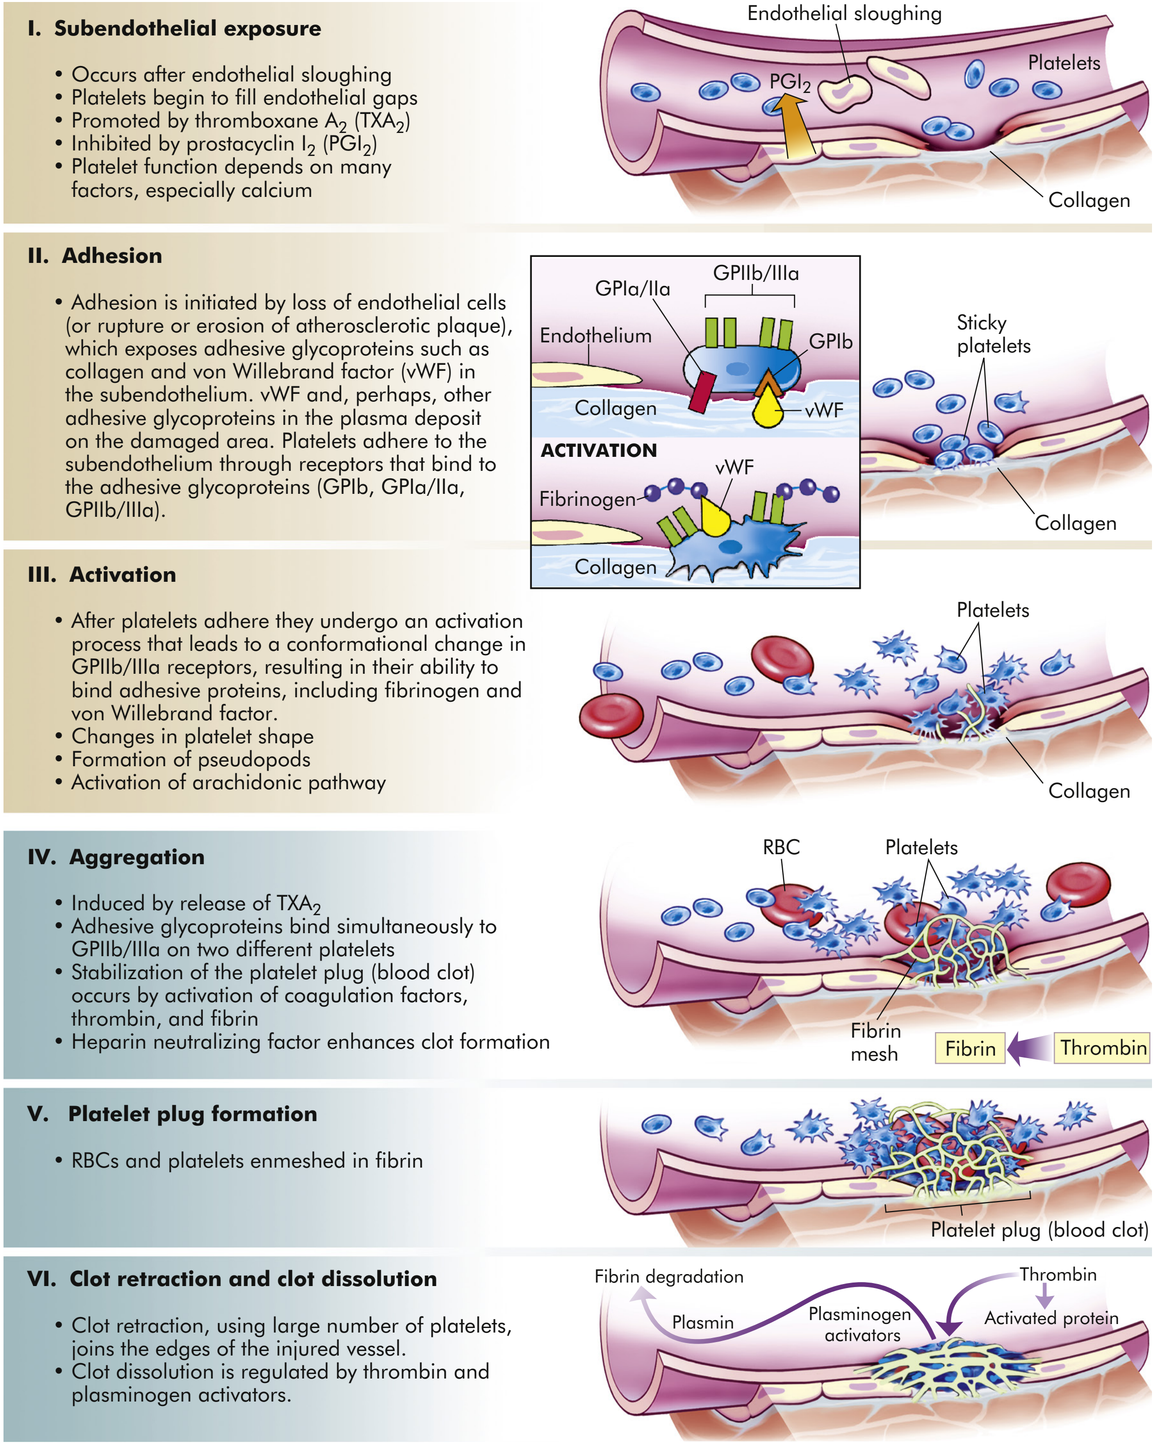

FIGURE 27-20 Blood Vessel Damage, Blood Clot, and Clot Dissolution.

Activation

As a result of interactions with the endothelium or the subendothelial matrix, as well as exposure to inflammatory mediators produced by the endothelium and other cells, the platelets are activated. Activation results in reorganization of the platelet cytoskeleton, leading to dynamic changes in platelet shape from smooth spheres to those with spiny projections and degranulation (also called the **platelet-release reaction**) and resulting in the release of various potent biochemicals (Figure 27-21).[48]

Platelets contain three types of granules: lysosomes, dense bodies, and alpha granules.[49] The contents of the dense bodies and alpha granules are particularly important in hemostasis. The dense bodies contain ADP, serotonin, and calcium. ADP recruits and activates other platelets through specific receptors. During activation the platelet plasma membrane undergoes several important changes, including becoming ruffled and sticky, undergoing cellular spreading to make tight contacts between neighboring platelets that cause the platelet plug to

FIGURE 27-21 Micrograph of an Active and Moderately Active Platelet. (Copyright Dennis Kunkel Microscopy, Inc.)

seal the injured endothelium, and externalizing the phospholipid phosphatidylserine, which provides a matrix for activation of clotting factors (see Figure 27-20). Serotonin is a vasoactive amine that functions like histamine and increases vasodilation and vascular permeability. Calcium is necessary for many of the adhesive interactions as well as intracellular signaling mechanisms that control platelet activation.

Alpha granules contain a large number of clotting factors (e.g., fibrinogen, factor V), growth factors (e.g., PDGF), and heparin-binding proteins (e.g., platelet factor 4). Many of these mediators either promote or inhibit platelet activity and the eventual process of clot formation. PDGF stimulates smooth muscle cells and promotes tissue repair. Heparin-binding proteins enhance clot formation at the site of injury.

Platelets also initiate production of the prostaglandin derivative **thromboxane A_2 (TXA_2),** which counters the effects of PGI_2 that is produced by endothelial cells (see Figure 27-20). TXA_2 promotes the degranulation of platelets, increases expression of platelet fibrinogen receptors, and stimulates platelet aggregation. The balance between TXA_2 and PGI_2 affects platelet aggregation, which is favored by TXA_2 excess and inhibited by PGI_2 excess. An isoform of **cyclooxygenase (COX-1)** converts arachidonic acid to TXA_2 in platelets. Aspirin at low doses specifically and irreversibly inactivates COX-1, decreasing production of TXA_2 and decreasing platelet activation.[50] A few days of low doses of aspirin lead to more than 95% inhibition of TXA_2.

Other stimuli of platelet activation include epinephrine, thrombin, and collagen. Thrombin and collagen are particularly strong stimuli. Thrombin cleaves the extracellular domain of G-protein–coupled protease-activated receptors (PARs), thereby initiating transmembrane signaling.

Aggregation

Platelet aggregation is stimulated primarily by TXA_2 and ADP, which induce functional fibrinogen receptors on the platelet. The **GPIIb/IIIa complex** (also called integrin αIIbβ3) undergoes a conformational change during activation to become a calcium-dependent receptor for fibrinogen (see Figure 27-20). It is a member of the integrin receptor family and binds other matrix proteins (e.g., fibronectin, fibrinogen, thrombospondin). Defects in expression of the GPIIb/IIIa complex (Glanzmann thrombasthenia) result in a failure to aggregate and diminished clotting times.[51] Although the GPIIb/IIIa complex is the most abundant aggregation receptor on the platelet, receptors for vWF (GPIb) and collagen (GPVI) also contribute to the process. Interplatelet aggregation and clot retraction that form the *primary hemostatic plug* are facilitated by fibrinogen bridges between receptors on the platelets. The GPIIb-IIIa–fibrinogen pathway is essential for the formation of a thrombus and as such is an important therapeutic target for blockage by antiplatelet drugs. In addition, fibrin strands within the clot shorten and become denser and stronger, helping the clot to approximate the edges of the injured vessel wall and sealing the site of injury. Contraction of myosin and actin filaments in the platelet cytoskeleton mediates *platelet contraction* and fusion of the platelet mass into a *secondary hemostatic plug*. Contraction expels serum from the fibrin meshwork, resulting in greater packing and increased strength. This process usually begins within a few minutes after a clot has formed, and most of the serum is expelled within 20 to 60 minutes.[52]

If blood vessel injury is minor, primary hemostasis is achieved by formation of the platelet plug within 3 to 5 minutes of injury. Platelet plugs seal the many minute ruptures that occur daily in the microcirculation, particularly in capillaries. With too few platelets, numerous small hemorrhagic areas called *purpuras* develop under the skin and throughout the tissues (see Chapter 29). If primary hemostasis is inadequate to prevent further bleeding, the process proceeds through secondary hemostasis to create a larger complex of more tightly interactive platelets within a matrix created by activation of the clotting system.

Function of Clotting Factors

A **blood clot** is a meshwork of protein strands that stabilizes the platelet plug and traps other cells, such as erythrocytes, phagocytes, and microorganisms. The strands are made of fibrin, which is produced by the **clotting (coagulation) system.** The clotting system was described in Chapter 7 and consists of a family of proteins that circulate in the blood in inactive forms (proenzymes). Initiation of the system results in sequential enzymatic activation (cascade) of multiple members of the system until a fibrin clot is created (Table 27-7).

The clotting system is usually presented as two pathways of initiation (intrinsic and extrinsic pathways) that join in a common pathway (Figure 27-22). The intrinsic pathway is activated when Hageman factor (factor XII) in plasma contacts negatively charged subendothelial substances exposed by vascular injury. Activated factor XII (XIIa) is an active enzyme with factor XI as a substrate. The extrinsic pathway is activated when **tissue factor (TF)** (also called **tissue thromboplastin**) reacts with a high affinity with circulating activated factor VII (TF/VIIa); approximately 1% of circulating factor VII has been spontaneously activated to VII.[53] TF is a transmembrane protein that exists in an inactive form on the endothelial membrane, but is activated into an active enzyme with factors IX and X as substrates.[54]

TABLE 27-7 COAGULATION FACTORS AND SYNONYMS

FACTOR	SYNONYM	PRIMARY FUNCTION
I	Fibrinogen	Source of fibrin to form clot
II	Prothrombin	Source of thrombin that activates fibrinogen, V, VII, VIII, XI, XIII, protein C, platelets
Tissue factor	Previously called factor III	Cofactor for factor VIIa
Calcium	Previously called factor IV	Cofactor for clotting factor binding to phosphatidylserine
V	Labile factor	Va is cofactor in the prothrombinase complex
VII	Stable factor, proconvertin	VIIa forms a complex with tissue factor and activates factors IX and X
VIII	Antihemophilic factor	VIIIa is a component of tenase complex
IX	Christmas factor	IXa is a component of tenase complex, activates factor X
X	Stuart-Prower factor	Xa is component of prothrombinase complex, activates prothrombin
XI	Plasma thromboplastin antecedent	XIa activates factor IX
XII	Hageman (contact) factor	XIIa activates factor XI
XIII	Fibrin-stabilizing factor	XIIIa cross-links fibrin

Activated platelets are important participants in clotting. The phosphatidylserine-rich surface produced during activation provides a matrix on which several important complexes of clotting factors are formed. These include the intrinsic pathway's *tenase complex* (factor X and activated factors VIII and IX) that activates factor X and the *prothrombinase complex* (prothrombin and activated factors X and V) that activates prothrombin into thrombin (see Figure 27-22). Thrombin then converts fibrinogen into fibrin, which polymerizes into a fibrin clot. Thrombin has broad reactivity in the inflammatory response.[55] In addition to producing fibrin, thrombin is an activator of other coagulation proteins (e.g., factors V, VIII, XI, XIII), platelets (e.g., aggregation, degranulation), endothelial cells (e.g., up-regulation of adhesion molecules for leukocytes, increased NO, PGI_2, PDGF), and monocytes (e.g., cytokine secretion, increased receptors for endothelial cells).

The extrinsic pathway is clearly predominant; individuals with deficiencies in intrinsic pathway components (i.e., factor XI, factor XII) do not have prolonged bleeding.[56] As with the complement cascade, the clotting system is complex with a large number of alternative activators and inhibitors, and the relative importance of particular factors may differ between in vivo hemostasis and in vitro testing of clotting or may depend on the particular mechanism by which the pathway is activated.[57] Also there is interaction between components of the intrinsic and extrinsic pathways so that an activated member of one pathway may activate a member of the other pathway (e.g., factor VIIa of the extrinsic pathway can directly activate factor IX of the intrinsic pathway).

Another similarity with the complement system is that some complexes may have biologic activities outside the predominantly described pathway. For instance, in vitro studies have showed that the TF/VIIa complex activates protease-activated receptors (PARs); thus TF may contribute to other biologic processes by facilitating signaling in vascular cells (Figure 27-23). Abnormal TF expression in the vessel wall and/or low circulating cells initiates life-threatening thrombosis in various diseases. TF also contributes to inflammation, tumor angiogenesis and metastasis, and cell migration (Figure 27-24).

Control of Hemostatic Mechanisms

The endothelium is the major site of hemostasis. Despite the continual presence of clotting factors and platelets in the circulation, blood normally remains fluid. Thus the major regulatory factors that control hemostasis reside where the greatest probability of clotting would occur: on the endothelial cell surface (see Figure 27-18). The primary anticoagulant mechanisms include thrombin inhibitors (e.g., antithrombin III), tissue factor inhibitors (e.g., tissue factor pathway inhibitor), and mechanisms for degrading activated clotting factors (e.g., protein C).[58] Antithrombotic mechanisms are listed in Table 27-8.

Antithrombin III (AT-III) is a circulating plasma serine protease inhibitor produced by the liver. Specifically, it inhibits thrombin and several activated clotting factors (e.g., VIIa, IXa, Xa, XIa, XIIa). Clinically administered heparin or heparan sulfate (on the surface of endothelial cells) binds to AT-III and induces a conformational change that greatly enhances its activity. Under normal conditions the presence of endothelial cell heparan sulfate and available AT-III in the circulation cooperate to protect the vessels from the effects of spontaneously activated thrombin (see Figure 27-18).

Acquired AT-III deficiencies can result from infection with bacteria that produce AT-III inhibitors, sepsis, liver disease, and nephrotic syndrome and lead to venous thrombosis and pulmonary embolism.

Tissue factor pathway inhibitor (TFPI) is produced by endothelial cells and platelets and complexes to, and reversibly inhibits, factor Xa.[59] The resultant TFPI/Xa complex inhibits TF/VIIa, which mediates feedback inhibition of tissue factor as well as factor VIIa (see Figure 27-18). Although the majority of TFPI remains associated with endothelial or platelet surfaces, about 20% circulates in plasma with lipoproteins. Heparin increases plasma levels of TFPI, which may contribute to heparin's antithrombotic effects.

Thrombomodulin is a membrane thrombin-binding protein on the surface of endothelial cells. **Protein C** in the circulation binds to thrombomodulin in a thrombin-dependent manner and is converted to activated protein C (see Figure 27-18).[60] Activated protein C, in association with a cofactor **(protein S),** degrades factors Va and VIIIa. Deficiencies of AT-III, protein C, or protein S are important causes of hypercoagulation (increased clotting).[61] Expression of thrombomodulin and the endothelial cell protein C receptor is down-regulated by cytokines and other products of inflammation (e.g., IL-1α, tumor necrosis factor-alpha [TNF-α], endotoxin). Decreased

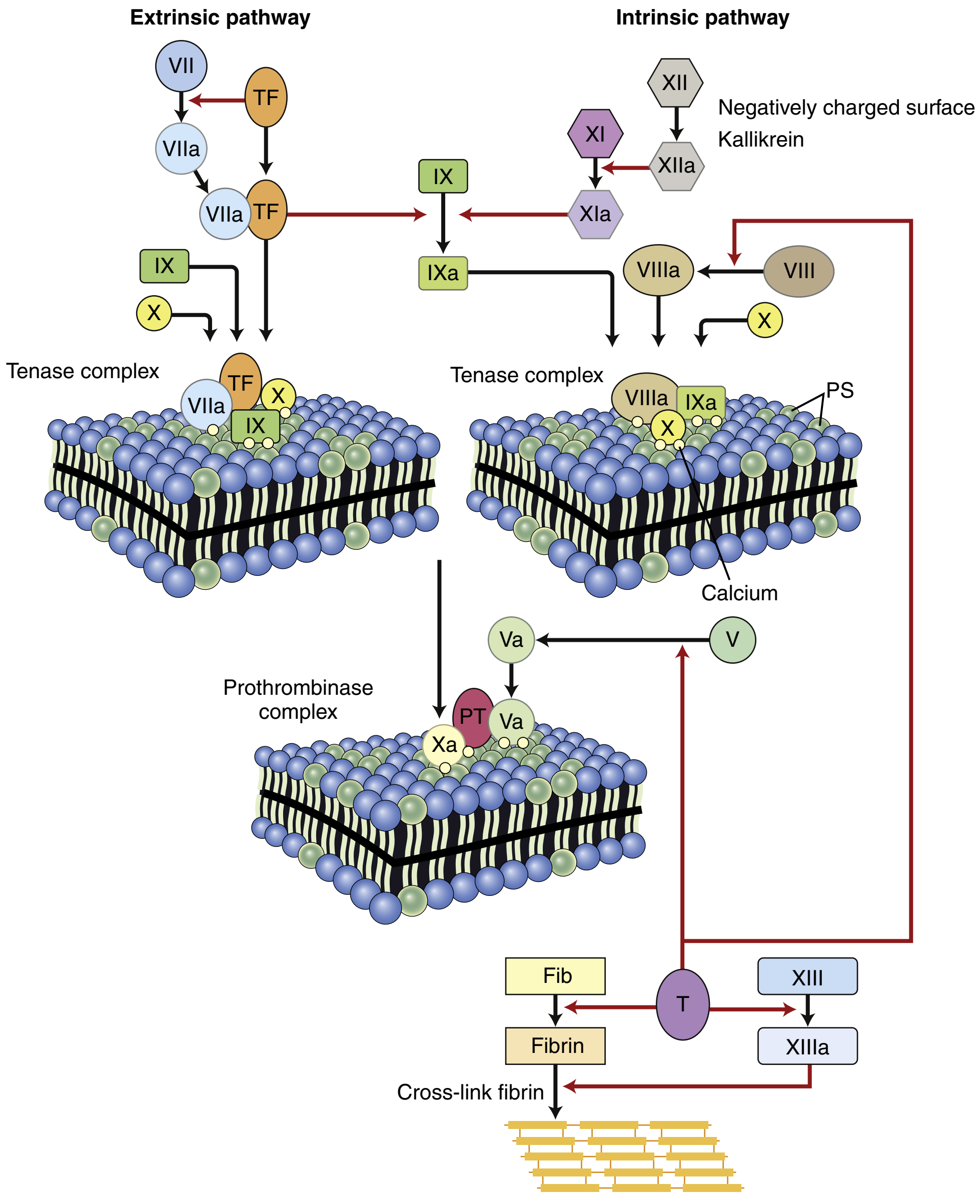

FIGURE 27-22 **The Clotting System.** The clotting system is frequently presented with two routes of initiation: the intrinsic and extrinsic pathways. The intrinsic pathway is initiated by activation of factor XII to XIIa by negatively charged molecules or surfaces or by the action of kallikrein, a member of the kinin system. Factor XIIa induces enzymatic activation of factor XI to XIa, which activates IX to IXa. A complex of factors IXa/VIIIa/X and calcium aggregate on the surface of activated platelets that have externalized the plasma membrane phospholipid phosphatidylserine *(PS).* The IXa/VIIIa complex is an active enzyme ("tenase") that can activate factor X to Xa. The extrinsic pathway is the primary physiologic route of activation and is activated by exposure of tissue factor *(TF)* on endothelial cells or in the circulation. TF activates factor VII in the blood to factor VIIa. The TF/VIIa complex associates with circulating factors IX and X and calcium on the PS-rich surface of activated platelets. The TF/VIIa/IX complex is a tenase that produces Xa. The VIIa/TF complex also can activate factor IX to IXa and facilitate the formation of the VIIIa/IXa tenase. Factor Xa associates with activated factor V *(Va)* and prothrombin *(PT)* in a PS and calcium-dependent complex that is a "prothrombinase," which converts PT to thrombin *(T).* Thrombin is an active enzyme that converts fibrinogen *(Fib)* to fibrin. Thrombin also activates factor XIII to XIIIa, which cross-links fibrin into a matrix that seals clots. Thrombin amplifies the clotting process by activating factor VIII to VIIIa and facilitating formation of the VIIIa/IXa tenase and by activating factor V to Va to create further prothrombinase complexes.

expression prevents protein C activation, thereby enhancing clot formation. Activated protein C inhibits the adhesion of neutrophils to the endothelium, but during inflammation the neutrophil enzyme elastase enzymatically removes thrombomodulin from the endothelial cell surface.[62]

Lysis of Blood Clots

Concurrent with activation of coagulation is the activation of pathways that limit the size of the clot and remove the clot after bleeding has ceased and repair has begun. The primary mechanism for lysis (breakdown) of blood clots is the

fibrinolytic system (plasminogen-plasmin system) that produces plasmin. **Plasmin** (also called *fibrinase* or *fibrinolysin*) is a serine protease that degrades fibrin polymers in clots.[63]

The inactive precursor of plasmin is **plasminogen,** which is produced in the liver (Figure 27-25). Plasminogen activation may occur by several means, although the most physiologically important is by the action of **tissue plasminogen activator (t-PA).**[64] Endothelial cells at a site of vascular injury express t-PA, which is also a serine protease that reaches maximal enzymatic activity after binding to fibrin and proteolytically activates plasminogen to plasmin. Another activator of plasminogen is **urokinase-like plasminogen activator (u-PA).** The u-PA is a serine protease that can bind to a specific cellular u-PA receptor (u-PAR), causing activation of plasminogen and resulting in plasmin generation. This urokinase is the major activator of fibrinolysis in the *extravascular* or tissue compartment, whereas t-PA is largely involved in *intravascular* fibrinolysis. Several cancers appear to use membrane-bound u-PA to digest intercellular matrix and greatly facilitate tumor invasion and metastasis. Both t-PA and u-PA have been used clinically to treat diseases associated with a blood clot (e.g., pulmonary embolism, myocardial infarction, stroke).

As with most components of inflammation, plasmin interacts greatly with other factors. In addition to activation by t-PA and u-PA, plasminogen is activated to plasmin by thrombin, fibrin, factor XIIa, factor XIa, and kallikrein. Plasmin is proteolytic to several substrates, including activation of collagenases, complement components C1 and C3, and factor XII, and cleaves fibronectin, fibrin, thrombospondin, laminin, and vWF. Plasmin activity is usually controlled directly by the serine protease inhibitor α_2-antiplasmin or by inhibiting plasminogen activation by specific plasminogen activator inhibitors (PAIs).

Congenital defects in the fibrinolytic system are very rare and variable in effects. Congenital plasminogen deficiency is associated with venous thrombosis if the plasminogen level is decreased by more than 50%. Apparent defects in plasminogen may result from dysfunctional plasminogen or an absence of fibrinogen. Congenital deficiencies of plasminogen activator or abnormal increases in plasminogen activator inhibitor also may increase the chance for spontaneous thrombosis. Alternative routes of fibrin degradation may mitigate the severity of symptoms in these deficiencies. Other enzymes released during inflammation (e.g., leukocyte elastase, cathepsin G, metalloproteinases [MMPs]) are fibrinolytic.

Cross-linked fibrin is deposited in tissues around wounds, inflammatory sites, and tumors. Fibrin removal is an

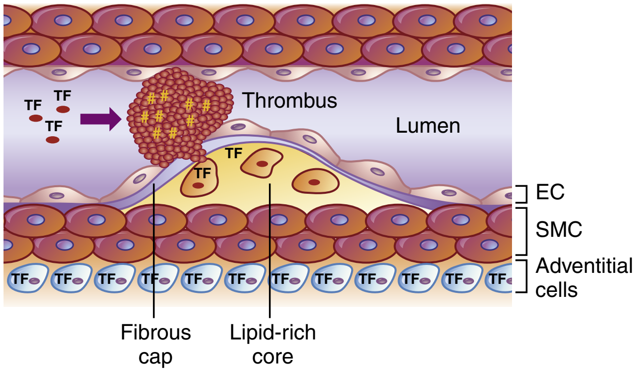

FIGURE 27-23 Tissue Factor (TF) in Thrombus Formation after Rupture of an Atherosclerotic Plaque. In atherosclerosis TF is expressed by macrophage-derived foam cells and within atherosclerotic plaque. High levels of TF exposed on rupture trigger thrombosis and myocardial infarction. In addition, blood-borne TF may contribute to thrombus propagation. TF is also expressed by adventitial cells *(blue). EC,* Endothelial cells; *SMC,* smooth muscle cells. FIGURE 27-25 The Fibrinolytic System. Fibrinolysis is initiated by the binding of plasminogen to fibrin. Although tissue plasminogen activator *(t-PA)* initiates intravascular fibrinolysis, urokinase plasminogen activator *(u-PA)* is the major activator of fibrinolysis in tissue (extravascular). Inhibitors (indicated by red lines) of fibrinolysis include α_2-antiplasmin *(α_2-AP)* that inhibits plasmin and plasminogen activator inhibitor 1 *(PAI-1)* that inhibits t-PA. Plasmin digests the fibrin into smaller soluble pieces (fibrin degradation products). *u-PAR,* Urokinase-like plasminogen activator receptor.

important biologic process, for intravascular and extravascular spaces, with various controlling mechanisms that can lead to abnormalities of fibrin accumulation and thrombotic events and can be a structural barrier to tumor invasion (see Chapter 13).

Products of fibrinolysis include **fibrin degradation products (FDPs)** (see Figure 27-25). A major FDP is D-dimer. **D-dimer** is two D domains from adjacent fibrin monomers that are cross-linked by factor XIIIa and released as a result of enzymatic cleavage by plasmin. Measurement of levels of circulating D-dimer has been used for diagnosis of deep venous thrombosis (DVT) or pulmonary embolism (PE). Despite extensive literature, the diagnostic role of D-dimer is unclear because of the use of multiple D-dimer assays with different sensitivities and variabilities.[65]

CLINICAL EVALUATION OF THE HEMATOLOGIC SYSTEM

Tests of Bone Marrow Function

The bone marrow is the soft spongy tissue found within bones, especially the sternum, pelvis, and femur. Several abnormal conditions in the numbers or morphology of circulating blood cells or suspected infection of the marrow may justify further investigation of the bone marrow.

Usually bone marrow is aspirated from the sternum or pelvis using a needle. In children a bone marrow aspirate can be obtained from the vertebrae or the femur. The aspirate is examined microscopically and may be cultured if infection (e.g., fungi, mycobacteria, brucellosis, typhoid fever) is suspected. Microscopic evaluation may also include flow cytometry, chromosome analysis, or polymerase chain reaction (PCR) related to the presence of atypical cells, the presence of atypical numbers of normal cells, and the absence of particular cell types. A normal bone marrow aspirate contains stromal cells (fibroblasts, macrophages, osteoblasts, adipocytes), stem cells (hematopoietic, mesenchymal, and endothelial), and immature and mature forms of blood cells (erythrocytes, leukocytes, platelets) (Figure 27-26). The differential cell count of a bone marrow aspirate involves examining approximately 400 nucleated cells under oil-immersion magnification and counting populations of cells differentiated based on morphology. The relative number of each type of stem cell is expressed as a fraction of 400 (Table 27-9).

Bone marrow iron stores, primarily in macrophages, can be examined using special stains (e.g., Prussian blue) for iron-containing granules. A direct measure of iron stores also can be obtained only from liver biopsy specimens, although bone marrow is preferred as a safer procedure and because the bone marrow is the immediate source of iron destined for erythrocyte production.

Bone marrow aspiration is an important diagnostic test for severe central defects in hematopoiesis (e.g., aplastic anemia, metabolic anemias arising from insufficient iron or inadequate erythropoietin, thrombocytopenia, neutropenia; see Chapters 28 and 29). Examination of the bone marrow is also useful to diagnose B-lymphocyte immune deficiencies (see Chapter 9), nonmalignant myeloproliferative disorders (e.g., polycythemia vera), and lymphoid/monocytic malignancies (e.g., leukemias, myelomas, lymphomas; see Chapters 29 and 30). This test can also be used to monitor the effects of chemotherapy on malignancies that have invaded the bone marrow (see Figure 27-26). A marrow aspirate that is richly cellular implies normal or increased hematopoiesis but does not indicate whether marrow activity is effective.

Results from bone marrow aspiration are sometimes limited because this technique disturbs the architecture of the marrow and only provides an analysis of the general cellularity (numbers of constituent cells) of the marrow. On occasion, analysis of an aspirate may only suggest the presence of a malignancy or a central defect in hematopoiesis without being clearly confirmatory, or the sample may be inadequate for diagnosis of bone marrow fibrosis. In these cases the need for a bone marrow biopsy may be indicated.

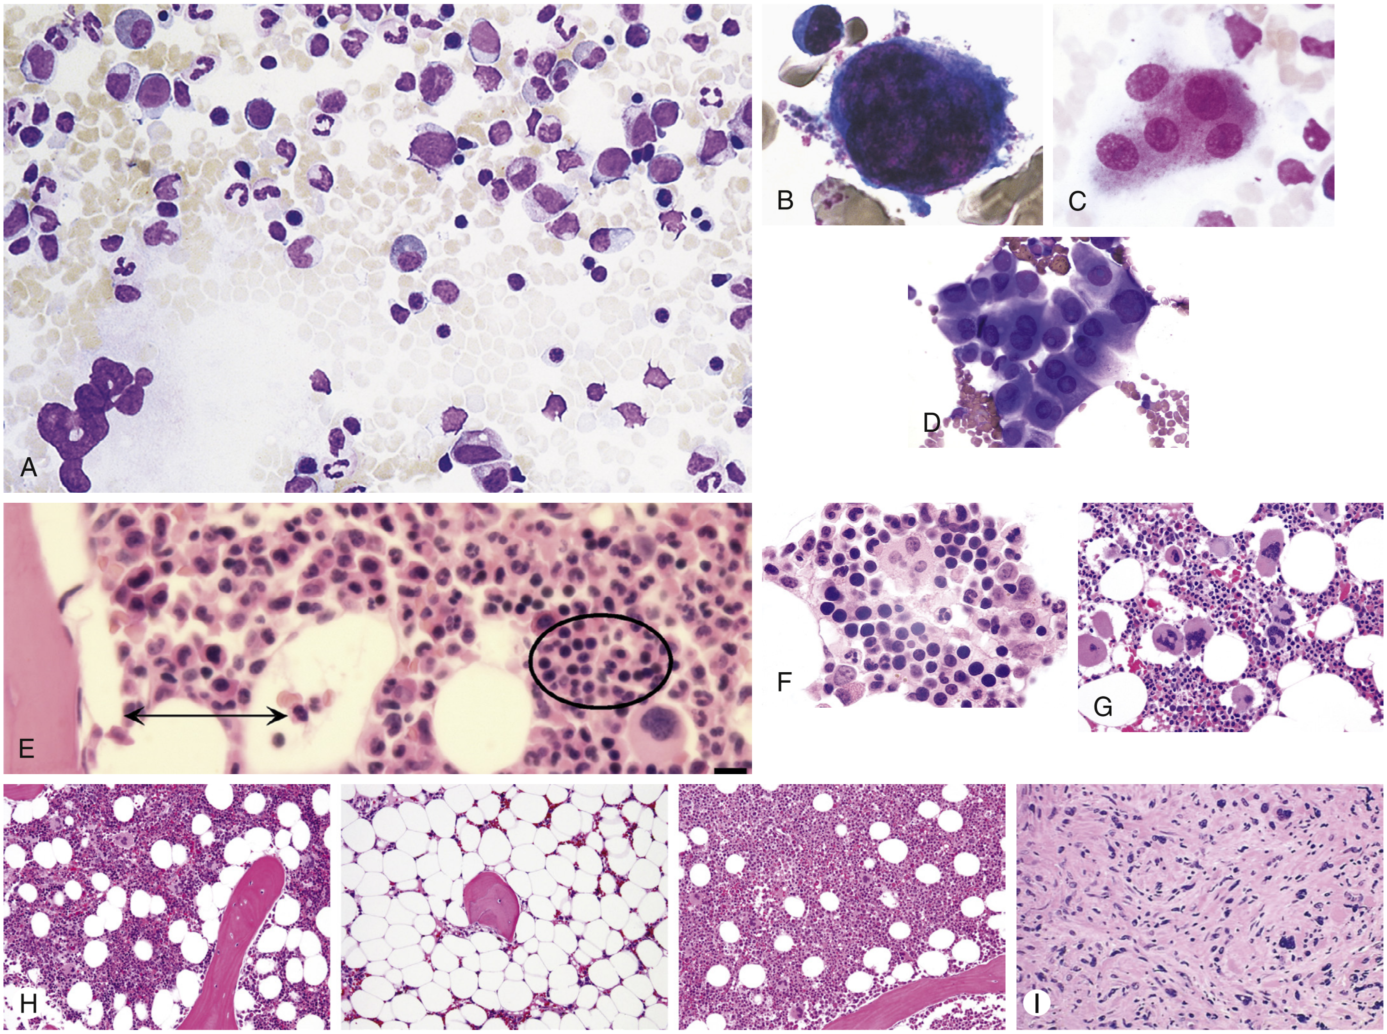

FIGURE 27-26 **Bone marrow samples.** Images **A** through **D** contain bone marrow aspirates; images **E** through **I** contain bone marrow biospy specimens. **A,** Normal bone marrow aspirate stained by the May-Grünwald/Giemsa technique. **B,** A normal megakaryocyte with budding platelets at the plasma membrane (Wright stain). **C,** Osteoclasts containing multiple nuclei that are separated by cytoplasm. These cells may be confused with megakaryocytes. **D,** Metastatic adenocarcinoma of the breast. **E,** Normal bone marrow biospy with paratrabecular space with immature myeloid cells (two-headed arrow) and circled erythron (site of erythrocyte production). **F,** A normal erythroid island in which several erythroid precursor clusters. **G,** Essential thrombocytopenia with normal cellularity, but increased numbers of large megakaryocytes. **H,** Bone marrow biopsies representing conditions of normal cellularity *(left),* hypocellularity *(middle)* as would be seen in conditions of bone marrow depletion such as aplastic anemia, and hypercellularity *(right)* as seen in malignant conditions. **I,** Advanced chronic idiopathic myelofibrosis marked by extensive replacement of the normal marrow stroma by fibrous tissue (stained pink; hematoxylin-eosin stain). (Sources for photographs: **A, C** from Hoffbrand V et al: *Color atlas of clinical hematology,* ed 4, Philadelphia, Mosby, 2013; **B** from Rodak BF et al: *Hematology,* ed 4, Philadelphia, Saunders, 2012; **D, F, G, H** from Jaffe E: *Hematology,* Philadelphia, Saunders, 2010; **E** from Young: *Clinical hematology,* ed 1, Mosby, 2005; **I** from Cleveland Clinic: *Current clinical medicine,* ed 2, Philadelphia, Saunders, 2010.)

TABLE 27-9 DIFFERENTIAL CELL COUNTS IN BONE MARROW WITH AGE

DEVELOPING CELLS IN MARROW	BIRTH	1 MONTH-1 YEAR	1-4 YEARS	4-12 YEARS	ADULT
Erythrocytic series	14	8	19	21	20
Lymphocytic series	14	47	22	18	17
Eosinophilic series	3	3	6	3	3
Neutrophilic series	60	33	50	52	57
Myeloid/erythroid ratio	4:3	4:0	1:3	2:5	1:3

NOTE: Values are percentages of cell types counted during examination of a marrow specimen containing approximately 400 nucleated cells.

During a biopsy, a special needle is used to obtain a "core" or cylindrical sample of bone and marrow in which the three-dimensional structure of the marrow is preserved. The biopsy specimens provide the most reliable and complete information about marrow cellularity (see Figure 27-26). Obtaining a bone marrow biopsy is, however, usually more painful and expensive than aspiration. Therefore, biopsy is not performed unless insufficient information is obtained from aspiration.

Blood Tests

Blood tests provide information about the absolute and relative numbers of blood cells in a specimen of blood, as well as various structural and functional characteristics of the cells, and usually provide the initial justification for performing a bone marrow aspiration. Deviations from the normal differential distribution and the presence of abnormal or immature cells can reflect disease, physiologic states (e.g., pregnancy, infancy, old age), injury, or dysfunction in almost any part of the body. Blood tests that reflect chiefly hematologic disorders are listed in Table 27-10.

PEDIATRICS AND THE HEMATOLOGIC SYSTEM

Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood. Table 27-11 lists normal ranges during infancy and childhood. The immediate rise in values is the result of accelerated hematopoiesis during fetal life, increased numbers of cells that result from the trauma of birth, and cutting of the umbilical cord.

Average blood volume in the full-term neonate is 85 ml/kg of body weight. The premature infant has a slightly larger blood volume of 90 ml/kg of body weight, with the mean increasing to 150 mg/kg during the first few days after birth. In both full-term and premature infants, blood volume decreases during the first few months. Thereafter the average blood volume is 75 to 77 ml/kg, which is similar to that of older children and adults.

The hypoxic intrauterine environment stimulates erythropoietin production in the fetus and accelerates fetal erythropoiesis, producing polycythemia (excessive proliferation of erythrocyte precursors) of the newborn. After birth the oxygen from the lungs saturates arterial blood, and more oxygen is delivered to the tissues. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of erythropoietin and the rate of blood cell formation decrease.

The very active rate of fetal erythropoiesis results in a large number of immature erythrocytes (reticulocytes) in the peripheral blood of full-term neonates. After birth the number of reticulocytes decreases about 50% every 12 hours so that it is rare to find an elevated reticulocyte count after the first week of life. During this period of rapid growth, the rate of erythrocyte destruction is greater than that in later childhood and adulthood. In full-term infants, normal erythrocyte life span is 60 to 80 days; in premature infants, it may be as short as 20 to 30 days; and in children and adolescents, it is the same as that in adults—120 days.

The postnatal decrease in hemoglobin and hematocrit values is more marked in premature infants than in the full-term infant. In the preschool and school-age child, hemoglobin, hematocrit, and red blood cell counts gradually rise. Metabolic processes within the erythrocytes of neonates differ significantly from those of erythrocytes in the normal adult. Among other differences, the relatively young population of erythrocytes in the newborn consumes greater quantities of glucose than do erythrocytes in adults.

Children have quantitative and qualitative differences in clotting factors that result in decreased risk for thrombotic diseases and complications.[66] Levels of some clotting-related proteins are reduced in newborns (e.g., antithrombin III). Several clotting factors are initially produced in fetal forms (e.g., fibrinogen, antithrombin III) that are less active in thrombosis than adult forms.

At birth, the lymphocyte count is high and continues to rise during the first year of life, and then steadily declines until lower adult values are reached. The lymphocytes of children also tend to have more cytoplasm and less compact nuclear chromatin than do the lymphocytes of adults. A possible explanation is that children tend to have more frequent viral infections, some of which are subclinical, and are receiving vaccinations, both of which are associated with atypical lymphocytes.

The neutrophil count, like the lymphocyte count, is high at birth and rises during the first days of life. After 2 weeks the neutrophil count falls to within or below the normal adult range. By approximately 4 years of age, the neutrophil count is the same as that of an adult. The eosinophil count is high in the first year of life and higher in children than in teenagers or adults. Monocyte counts also are high in the first year of life but then decrease to adult levels. Platelet counts in full-term neonates are comparable with platelet counts in adults and remain so throughout infancy and childhood.

AGING AND THE HEMATOLOGIC SYSTEM

Blood composition changes little with age. Erythrocyte life span in older adults is normal, although erythrocytes are replenished more slowly after bleeding, probably because of iron depletion. Total serum iron, total iron-binding capacity, and intestinal iron absorption are all decreased in older adults. Iron deficiency is often responsible for the low hemoglobin levels noted in older adults. The plasma membranes of erythrocytes become increasingly fragile, presumably because of physical trauma inflicted during circulation.

Lymphocyte function decreases with age (see Chapters 8 and 9), causing changes in cellular immunity with some decline in T-cell function. The humoral immune system is less able to respond to antigenic challenge. No changes in platelet numbers or structure have been observed in elderly persons, yet platelet adhesiveness probably increases. Although fibrinogen levels and levels of factors V, VII, and IX tend to be increased in older adults, evidence concerning hypercoagulability is inconclusive.

TABLE 27-10 **BLOOD TESTS FOR HEMATOLOGIC DISORDERS**

CELL TYPE AND TEST	PROPERTY EVALUATED BY TEST	POSSIBLE HEMATOLOGIC CAUSE OF ABNORMAL FINDINGS
Erythrocyte		
Red cell count	Number (in millions) of erythrocytes/μL of blood	Altered erythropoiesis, anemias, hemorrhage, Hodgkin disease, leukemia
Mean corpuscular volume	Size of erythrocytes	Anemias, thalassemias
Mean corpuscular hemoglobin (MCH)	Amount of hemoglobin in each erythrocyte (by weight)	Anemias, hemoglobinopathy
Mean corpuscular hemoglobin concentration (MCHC)	Concentration of hemoglobin in each erythrocyte (percentage of erythrocyte occupied by hemoglobin)	Anemias, hereditary spherocytosis
Hemoglobin determination	Amount of hemoglobin (by weight)/dl of blood	Anemias
Hematocrit determination	Percentage of a given volume of blood that is occupied by erythrocytes	Hemorrhage, polycythemia, erythrocytosis, anemias, leukemia
Reticulocyte count	Number of reticulocytes/μL of blood (also expressed as percentage of reticulocytes in total red cell count)	Hyperactive or hypoactive bone marrow function
Erythrocyte osmotic fragility test	Cellular shape (biconcavity), structure of plasma membrane	Anemias, hemolytic disease caused by ABO or Rh incompatibility, Hodgkin disease, polycythemia vera, thalassemia major
Hemoglobin electrophoresis	Relative percentage of different types of hemoglobin in erythrocytes	Sickle cell disease, sickle cell trait, hemoglobin C disease, hemoglobin C trait, thalassemias
Sickle cell test	Presence of hemoglobin S in erythrocytes	Sickle cell trait, sickle cell anemia
Glucose-6-phospahte dehydrogenase (G6PD) deficiency test	Deficiency of G6PD in erythrocytes	Hemolytic anemia
Hemoglobin Metabolism		
Serum ferritin determination	Depletion of body iron (potential deficiency of heme synthesis)	Iron deficiency anemias
Total iron-binding capacity (TIBC)	Amount of iron in serum plus amount of transferrin available in serum (mcg/dl)	Hemorrhage, iron deficiency anemia, hemochromatosis, hemosiderosis, iron overload, anemias, thalassemias
Transferrin saturation	Percentage of transferrin that is saturated with iron	Acute hemorrhage, hemochromatosis, hemosiderosis, sideroblastic anemia, iron deficiency anemia, iron overload, thalassemias
Porphyrin analysis (protoporphyrin analysis)	Concentration of protoporphyrin in erythrocytes (mcg/dl); an indicator of iron-deficient erythropoiesis	Megaloblastic anemia, congenital erythropoietic porphyria
Direct antiglobulin test (DAT)	Antibody binding to erythrocytes	Hemolytic disease of the newborn, autoimmune hemolytic anemia, drug-induced hemolytic anemia, transfusion reaction
Antibody screen (indirect Coombs test)	Detection of antibodies to erythrocyte antigens (other than the ABO antigens)	Same as for DAT
Leukocytes		
Differential white cell count (absolute number of a type of leukocyte/μL of blood)	See below	See below
Neutrophil count	Neutrophils/μL	Myeloproliferative disorders, hematopoietic disorders, hemolysis, infection, immune deficiency
Lymphocyte count	Lymphocytes/μL	Infectious lymphocytosis, infectious mononucleosis, hematopoietic disorders, anemias, leukemia, lymphosarcoma, Hodgkin disease, primary immune deficiency
Plasma cell count	Plasma cells/μL	Infectious mononucleosis, lymphocytosis, plasma cell leukemia, primary immune deficiency
Monocyte count	Monocytes/μL	Hodgkin disease, infectious mononucleosis, monocytic leukemia, non-Hodgkin lymphoma, polycythemia vera, primary immune deficiency
Eosinophil count	Eosinophils/μL	Hematopoietic disorders
Basophil count	Basophils/μL	Chronic myelogenous leukemia, hemolytic anemias, Hodgkin disease, polycythemia vera

TABLE 27-10 BLOOD TESTS FOR HEMATOLOGIC DISORDERS—cont'd

CELL TYPE AND TEST	PROPERTY EVALUATED BY TEST	POSSIBLE HEMATOLOGIC CAUSE OF ABNORMAL FINDINGS
Platelets and Clotting Factors*		
Platelet count	Number of circulating platelets (in thousands)/µL of blood	Anemias, multiple myeloma, myelofibrosis, polycythemia vera, leukemia, disseminated intravascular coagulation (DIC), hemolytic disease of the newborn, idiopathic thrombocytopenic purpura, transfusion reaction, lymphoproliferative disorders
Bleeding time	Duration of bleeding following a standardized superficial puncture wound of the skin, integrity of the platelet plug, measured in minutes following puncture	Leukemia, anemias, DIC, fibrinolytic activity, purpuras, hemorrhagic disease of the newborn, infectious mononucleosis, multiple myeloma, clotting factor deficiencies, thrombasthenia, thrombocytopenia, von Willebrand disease
Clot retraction test	Platelet number and function, fibrinogen quantity and use, measured in hours required for expression of serum from a clot incubated in a test tube	Acute leukemia, aplastic anemia, factor XIII deficiency, increased fibrinolytic activity, Hodgkin disease, hyperfibrinogenemia or hypofibrinogenemia, idiopathic thrombocytopenic purpura, multiple myeloma, polycythemia vera, secondary thrombocytopenia, thrombasthenia
Platelet adhesion studies	Ability of platelets to adhere to foreign surfaces	Anemia, macroglobulinemia, Bernard-Soulier syndrome, multiple myeloma, myeloid metaplasia, plasma cell dyscrasias, thrombasthenia, thrombocytopathy, von Willebrand disease
Platelet aggregation tests	Ability of platelets to adhere to one another	Afibrinogenemia, Bernard-Soulier syndrome, thrombasthenia, hemorrhagic thrombocythemia, myeloid metaplasia, plasma cell dyscrasias, platelet release defects, polycythemia vera, preleukemia, sideroblastic anemia, von Willebrand disease, Waldenström macroglobulinemia, hypercoagulability
Whole blood clotting time (Lee-White coagulation time)	Overall ability of blood to clot, as measured in minutes in a test tube	Afibrinogenemia, clotting factor deficiencies, excessive fibrinolysis, hemorrhagic disease of the newborn, hypofibrinogenemia, hypoprothrombinemia, leukemia
Circulating anticoagulants (immunoglobulin G [IgG] or M [IgM] antibodies that inhibit coagulation)	Presence of antibodies that neutralize clotting factors and inhibit coagulation, as indicated by prolonged clotting time, prothrombin time, or partial thromboplastin time	Afibrinogenemia, presence of fibrin-fibrinogen degradation products, macroglobulinemia, multiple myeloma, DIC, plasma cell dyscrasias
Partial thromboplastin time (PTT)	Effectiveness of clotting factors (except factors VII and VIII), effectiveness of intrinsic pathway of coagulation cascade, as measured by a test tube (in seconds)	Presence of circulating anticoagulants, DIC, clotting factor deficiencies, excessive fibrinolysis, hemorrhagic disease of the newborn, hypofibrinogenemia and afibrinogenemia, prothrombin deficiency, von Willebrand disease, acute hemorrhage
Prothrombin time (PT)	Effectiveness of activity of prothrombin, fibrinogen, and factors V, VII, and X; effectiveness of vitamin K–dependent coagulation factors of the extrinsic and common pathways of the coagulation cascade as measured in a test tube (in seconds)	Hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia; presence of circulating anticoagulants; DIC; deficiency of factors V, VII, or X; presence of fibrin degradation products, increased fibrinolytic activity, hemolytic jaundice, hemorrhagic disease of the newborn; acute leukemia, polycythemia vera, prothrombin deficiency, multiple myeloma
Thrombin time	Quantity and activity of fibrinogen as measured in a test tube (in seconds)	Hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia; presence of circulating anticoagulants; hemorrhagic disease of the newborn, polycythemia vera; increase in fibrin-fibrinogen degradation products; increased fibrinolytic activity
Fibrinogen assay	Amount of fibrinogen available for fibrin formation	Acute leukemia, congenital hypofibrinogenemia or afibrinogenemia, DIC, increased fibrinolytic activity, severe hemorrhage
Fibrin-fibrinogen degradation products (fibrin-fibrinogen split products)	Fibrinogenic activity as measured by levels of fibrin-fibrinogen degradation products (in mcg/ml of blood)	Transfusion reactions, DIC, internal hemorrhage in the newborn, deep vein thrombosis, pulmonary embolism

WBC, White blood cell.

SUMMARY REVIEW

Components of the Hematologic System

1. Blood consists of cells suspended in a solution of about 90% water and 10% solutes. In adults the total blood volume is approximately 5.5 L.
2. Plasma, the liquid portion of the blood, contains two major groups of proteins: albumins and globulins.
3. The cellular elements of blood are the erythrocytes (red blood cells), leukocytes (white blood cells), and platelets (thrombocytes).
4. Erythrocytes are the most abundant cells of the blood, occupying approximately 48% of the blood volume in men and approximately 42% in women. Erythrocytes are responsible for tissue oxygenation.
5. Leukocytes are fewer in number than erythrocytes and constitute approximately 5000 to 10,000 cells/mm^3 of blood. Leukocytes defend the body against infection and remove dead or injured host cells.
6. Leukocytes are classified as either granulocytes (neutrophils, basophils, eosinophils) or agranulocytes (monocytes, macrophages, lymphocytes).
7. The neutrophil is the most abundant leukocyte (approximately 55% of the leukocytes) and is the primary granulocyte that defends against infections.
8. Lymphocytes are the primary cells of the immune response.
9. Platelets are not cells—they are disk-shaped cytoplasmic fragments. Platelets are essential for blood coagulation and control of bleeding.
10. The lymphoid organs are classified as primary (thymus and bone marrow) or secondary (spleen, lymph nodes, tonsils, and Peyer patches of the small intestine).
11. The lymphoid organs are sites of residence, proliferation, differentiation, and function of lymphocytes and mononuclear phagocytes.
12. The spleen is the largest of the secondary lymphoid organs and functions as the site of hematopoiesis in the fetus, filters and cleanses the blood, and is a reservoir for lymphocytes and other blood cells.
13. The lymph nodes are the site of development or activity of large numbers of lymphocytes, monocytes, and macrophages.
14. The MPS is composed of macrophages in tissue and lymphoid organs.
15. The MPS is the main line of defense against bacteria in the bloodstream and cleanses the blood by removing old, injured, or dead blood cells; antigen-antibody complexes; and macromolecules.

Development of Blood Cells

1. Hematopoiesis, or blood cell production, occurs in the liver and spleen of the fetus and in the bone marrow after birth.
2. Hematopoiesis involves two stages: (a) proliferation, and (b) maturation.
3. Hematopoiesis continues throughout life to replace blood cells that grow old and die, are killed by disease, or are lost through bleeding.
4. Bone marrow consists of red (hematopoietic) marrow (blood vessels, mononuclear phagocytes, stem cells, blood cells in various stages of differentiation, stromal cells) and yellow marrow (fatty tissue).
5. The bone marrow contains multiple populations of *stem cells;* mesenchymal stem cells develop into fibroblasts, osteoclasts, and adipocytes; and hematopoietic stem cells develop into blood cells.
6. Regulation of hematopoiesis occurs in specialized microenvironments (niches) in the bone marrow (an osteoblastic niche and a vascular niche) in which hematopoietic stem cells are signaled to undergo differentiation through the effects of multiple cytokines and chemokines and through direct contact with osteoblasts (osteoblastic niche) or vascular endothelial cells (vascular niche), as well as several other specialized cells, including CAR cells and nestin-expressing cells.
7. Specific hematopoietic growth factors (e.g., colony-stimulating factors) are necessary for the adequate production of myeloid, erythroid, lymphoid, and megakaryocytic lineages.
8. Erythropoiesis (production of erythrocytes) is regulated by erythropoietin. Erythropoietin is secreted by the kidneys in response to tissue hypoxia and causes a compensatory increase in erythrocyte production if the oxygen content of the blood decreases because of anemia, high altitude, or pulmonary disease.
9. Hemoglobin, the oxygen-carrying protein of the erythrocyte, enables the blood to transport 100 times more oxygen than could be transported dissolved in plasma alone.
10. The iron cycle reutilizes iron released from old or damaged erythrocytes. Iron binds to transferrin in the blood, is transported to macrophages of the MPS, and is stored in the cytoplasm as ferritin.
11. Iron homeostasis is controlled by hepcidin, a small hormone produced by hepatocytes, which regulates ferroportin, the principal transporter of iron from stores in hepatocytes and macrophages and from intestinal cells that take up dietary iron.
12. Granulocytes and monocytes in the blood develop from common myeloid progenitor cells in the bone marrow under the direction of several growth factors, including stem cell factor, IL-3, and GM-CSF.
13. Platelets develop from megakaryocytes by a process called *endomitosis,* which is controlled by thrombopoietin. During endomitosis the megakaryocytes undergo mitosis but not cell division and the cytoplasm and plasma membrane fragment into platelets.

Mechanisms of Hemostasis

1. Hemostasis, or arrest of bleeding in damaged vessels, involves: (a) vasoconstriction, (b) damage to the endothelium and exposure of connective tissue resulting in formation of a platelet plug, (c) activation of the clotting cascade, (d) formation of a blood clot, and (e) activation of fibrinolysis for clot retraction and clot dissolution.

SUMMARY REVIEW—cont'd

2. Platelet activation involves three linked processes: (a) adhesion, (b) activation, and (c) aggregation.
3. A blood clot is a meshwork of protein strands that stabilizes the platelet plug. The strands are made of fibrin. Fibrin is the end product of the coagulation cascade.
4. The coagulation cascade is composed of intrinsic and extrinsic pathways, with the extrinsic pathway being dominant. The intrinsic pathway is initiated by TF that forms a complex with the TF/VIIa complex.
5. The endothelium prevents the formation of spontaneous clots in normal vessels by several anticoagulant mechanisms, including by production of NO and PGI_2, thrombin inhibitors (antithrombin III), and tissue factor inhibitors (tissue factor pathway inhibitors) and by degradation of activated clotting factors (thrombomodulin–protein C).
6. Fibrinolysis (breakdown of blood clots) is the function of the plasminogen-plasmin system. Plasmin is a degrading enzyme of fibrin clots. It is produced from plasminogen by activation of plasminogen activators (t-PA, u-PA), thrombin, fibrin, factor XIIa, factor XIa, and kallikrein.
7. Products of fibrinolysis include fibrin degradation products, such as D-dimer.

Clinical Evaluation of the Hematologic System

1. Tests of bone marrow function include bone marrow aspiration and bone marrow biopsy.
2. Cells contained in the marrow specimen are assessed with respect to: (a) relative numbers of stem cells and their developing daughter cells, and (b) morphologic structure.

Pediatrics and the Hematologic System

1. Blood cell counts rise above adult levels at birth and then gradually decline throughout childhood.
2. The average blood volume of an infant is 75 to 77 ml/kg, which is similar to that of older children and adults.
3. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of erythropoietin and the rate of blood cell formation decrease.
4. The normal erythrocyte life span is 60 to 80 days in full-term infants, 20 to 30 days in premature infants, and 120 days in children, adolescents, and adults.
5. The lymphocyte count is high at birth, rises further during the first year of life, and steadily declines until lower adult volumes are reached.
6. The neutrophil count is very high at birth, falls to adult ranges after 2 weeks, and is the same as that for adults by 4 years of age.
7. The eosinophil count is high in the first year of life and is higher in children than in adolescents and adults. Monocyte counts are high in the first year of life and decrease to adult levels.
8. Platelet counts in full-term infants are comparable with those in adults and remain so throughout childhood.

Aging and the Hematologic System

1. Blood composition changes little with age. A delay in erythrocyte replenishment may occur after bleeding, presumably because of iron deficiency.
2. Lymphocyte function appears to decrease with age. Particularly affected is a decrease in cellular immunity.
3. Platelet adhesiveness probably increases with age.

KEY TERMS

Agranulocyte, 948, 950
Albumin, 946
Antithrombin III (AT-III), 970
Apoferritin, 963
Apotransferrin, 963

CHAPTER OUTLINE

Alterations of erythrocyte function involve either insufficient or excessive numbers of erythrocytes in the circulation or normal numbers of cells with abnormal components. Anemias are conditions in which there are too few erythrocytes or an insufficient volume of erythrocytes in the blood. Polycythemias are conditions in which erythrocyte numbers or volume is excessive. Each of these conditions has many causes and is a pathophysiologic manifestation of a variety of disease states.

ANEMIA

Strictly speaking, **anemia** is a reduction in the total number of erythrocytes in the circulating blood or a decrease in the quality or quantity of hemoglobin. Anemias commonly result from (1) impaired erythrocyte production, (2) blood loss (acute or chronic), (3) increased erythrocyte destruction, or (4) a combination of these three factors.

Classification

Anemias are classified by their causes (e.g., anemia of chronic disease) or by changes that affect the size, shape, or hemoglobin content of the erythrocyte (Box 28-1). The most common classification is based on changes that affect the erythrocyte's size or hemoglobin content (Table 28-1). The terminology reflects these characteristics; terms that end in "-cytic" refer to cell size, whereas "-chromic" refers to hemoglobin content (Table 28-2). Additional descriptors of erythrocytes associated with some anemias include **anisocytosis** (assuming various sizes) or **poikilocytosis** (assuming various shapes) (Figure 28-1).

CLINICAL MANIFESTATIONS. The fundamental physiologic manifestation of anemia is a reduced oxygen-carrying capacity of the blood resulting in tissue hypoxia. Symptoms of anemia vary, depending on the body's ability to compensate for reduced oxygen-carrying capacity (Figure 28-2). Anemia that is mild and develops gradually is usually easier to compensate and may cause problems for the individual only during physical exertion. As the reduction in red blood cells (RBCs) continues, symptoms become more pronounced and alterations of specific organs and compensatory effects become more apparent. Compensation generally involves the cardiovascular, respiratory, and hematologic systems.

BOX 28-1 ETIOLOGIC (PATHOPHYSIOLOGIC) CLASSIFICATION OF ANEMIAS

Decreased or Defective Production of Erythrocytes

Altered hemoglobin synthesis
- Iron deficiency
- Thalassemia
- Anemia of chronic inflammation

Altered deoxyribonucleic acid (DNA) synthesis resulting from deficient nutrients

Pernicious anemia (decreased B_{12}, folate)

Stem cell dysfunction
- Aplastic anemia
- Myeloproliferative leukemia

Bone marrow infiltration
- Carcinoma
- Lymphoma

Pure red cell aplasia

Increased Erythrocyte Destruction

Blood loss
- Acute—hemorrhage, trauma
- Chronic—gastrointestinal bleeding, menorrhagia

Hemolysis (intracorpuscular defect)
- Membrane—hereditary spherocytosis
- Hemoglobin—sickle cell trait or disease
- Glycolysis—pyruvate kinase
- Oxidation—glucose-6-phosphate dehydrogenase (G6PD) deficiency

Hemolysis (extracorpuscular defect)
- Immune mechanisms—warm antibody/cold antibody
- Infection—clostridial, malarial
- Trauma to erythrocyte—hemolytic uremic syndrome
- Splenic sequestration—hypersplenism

TABLE 28-1 MORPHOLOGIC CLASSIFICATION OF ANEMIAS

MORPHOLOGY OF REMAINING ERYTHROCYTES	NAME AND MECHANISM OF ANEMIA	PRIMARY CAUSE
Macrocytic-normochromic anemia: large, abnormally shaped erythrocytes but normal hemoglobin concentrations	Pernicious anemia: lack of vitamin B_{12} (cobalamin) for erythropoiesis; abnormal deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) synthesis in the erythroblast; premature cell death	Congenital or acquired deficiency of intrinsic factor (IF); genetic disorder of DNA synthesis
	Folate deficiency anemia: lack of folate for erythropoiesis; premature cell death	Dietary folate deficiency
Microcytic-hypochromic anemia: small, abnormally shaped erythrocytes and reduced hemoglobin concentration	Iron deficiency anemia: lack of iron for hemoglobin production; insufficient hemoglobin	Chronic blood loss; dietary iron deficiency; disruption of iron metabolism or iron cycle (see Chapter 27)
	Sideroblastic anemia: dysfunctional iron uptake by erythroblasts and defective porphyrin and heme synthesis	Congenital dysfunction of iron metabolism in erythroblasts; acquired dysfunction of iron metabolism as a result of drugs or toxins
	Thalassemia: impaired synthesis of α- or β-chain of hemoglobin A; phagocytosis of abnormal erythroblasts in the marrow	Congenital genetic defect of globin synthesis
Normocytic-normochromic anemia: normal size, normal hemoglobin concentration	Aplastic anemia: insufficient erythropoiesis	Depressed stem cell proliferation resulting in bone marrow aplasia
	Posthemorrhagic anemia: blood loss	Acute or chronic hemorrhage that stimulates increased erythropoiesis, which eventually depletes body iron
	Hemolytic anemia: premature destruction (lysis) of mature erythrocytes in the circulation	Increased fragility of erythrocytes
	Sickle cell anemia: abnormal hemoglobin synthesis, abnormal cell shape with susceptibility to damage, lysis, and phagocytosis	Congenital dysfunction of hemoglobin synthesis
	Anemia of chronic disease: abnormally increased demand for new erythrocytes	Chronic infection or inflammation; malignancy

TABLE 28-2 TERMS USED IN ASSESSMENT OF ERYTHROCYTES

	ERYTHROCYTE VOLUME	HEMOGLOBIN CONTENT
Normal	Normocytic	Normochromic
Increased	Macrocytic (higher mean corpuscular volume [MCV])	Hyperchromic (higher mean corpuscular hemoglobin concentration [MCHC])
Decreased	Microcytic (lower MCV)	Hypochromic (lower MCHC)

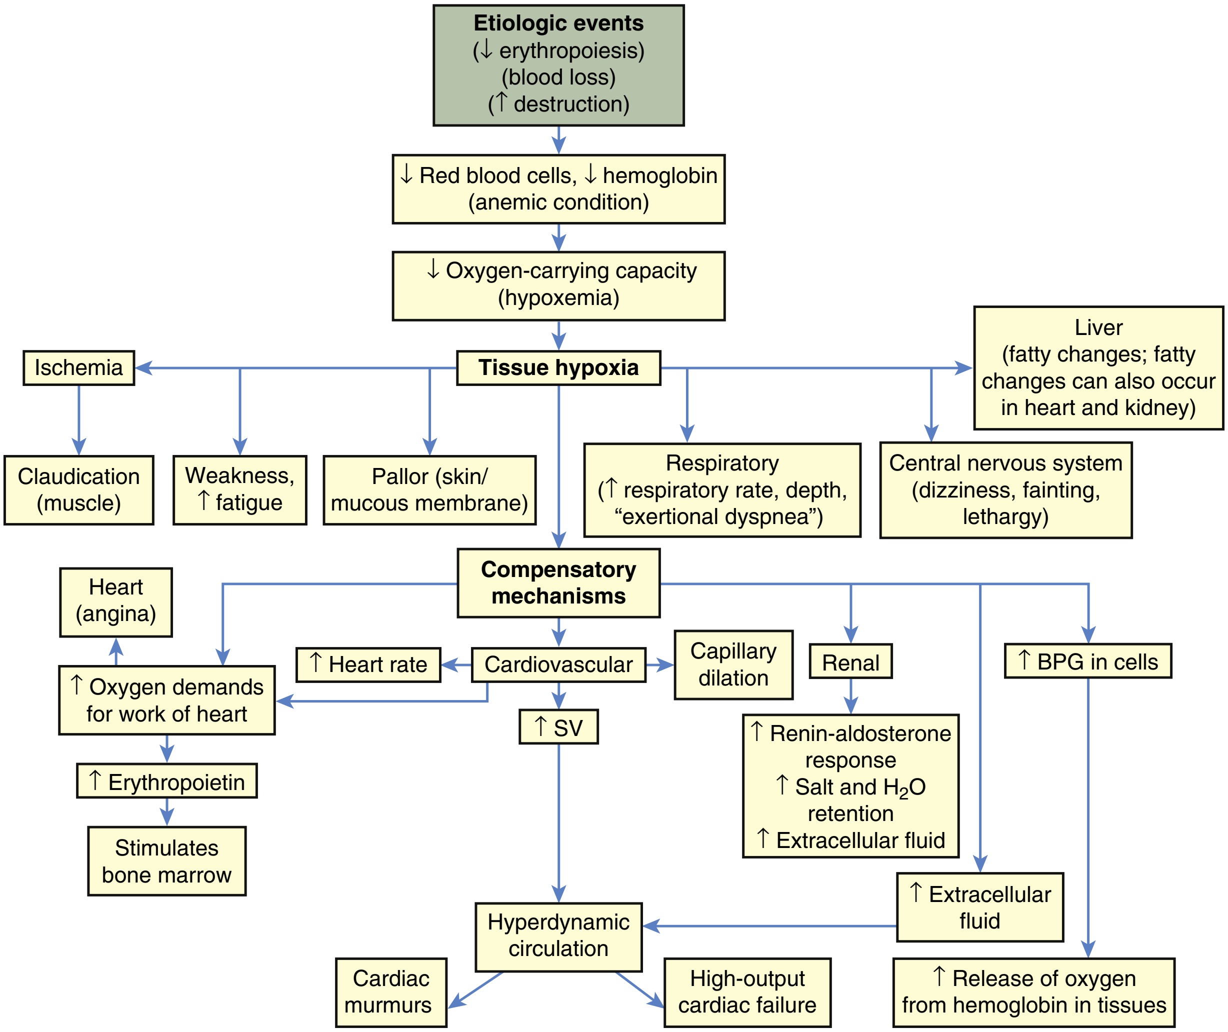

FIGURE 28-2 Progression and Manifestations of Anemia. *BPG,* Biphosphoglycerate; *SV,* stroke volume.

(Hematologic findings associated with various anemias are listed in Table 28-3 and progression and manifestations of anemias are shown in Figure 28-2.)

A reduction in the number of blood cells in the blood causes a reduction in the consistency and volume of blood. Compensation for a reduced blood volume causes interstitial fluid to move into the intravascular space, expanding plasma volume. This movement maintains adequate blood volume, but the viscosity (thickness) of the blood decreases. The diluted blood flows faster and more turbulently than normal blood, causing a hyperdynamic circulatory state. This hyperdynamic state creates cardiovascular changes—increased stroke volume and heart rate. These changes may lead to cardiac dilation and heart valve insufficiency if the underlying anemic condition is not corrected.

Hypoxemia, reduced oxygen levels in the blood, further contributes to cardiovascular dysfunction by causing dilation of arterioles, capillaries, and venules, thus leading to decreased vascular resistance and increased flow. Increased peripheral blood flow and venous return further contribute to an increase in heart rate and stroke volume in a continuing effort to meet normal oxygen demand and prevent cardiopulmonary congestion. These compensatory mechanisms may lead to heart failure.

Tissue hypoxia creates additional demands and compensatory actions on the pulmonary and hematologic systems. The rate and depth of breathing increase in an attempt to increase the availability of oxygen. These demands are accompanied by an increase in the release of oxygen from hemoglobin. (Mechanisms of oxygen transport and release by hemoglobin are described in Chapter 27.) All of these compensatory mechanisms may cause individuals to experience shortness of breath (dyspnea); a rapid, pounding heartbeat (palpitations); dizziness; and fatigue. In mild, chronic conditions, these symptoms might be present only when demand for oxygen is increased (e.g., during physical exertion), but in severe conditions they may be experienced at rest.

Manifestations of anemia may be observed in other parts of the body. The skin, mucous membranes, lips, nail beds, and

TABLE 28-3 LABORATORY FINDINGS FOR VARIOUS ANEMIAS

TEST	PERNICIOUS ANEMIA	FOLATE DEFICIENCY ANEMIA	IRON DEFICIENCY ANEMIA	SIDEROBLASTIC ANEMIA	APLASTIC ANEMIA	POSTHEMORRHAGIC ANEMIA	HEMOLYTIC ANEMIA	ANEMIA OF CHRONIC DISEASE
Hemoglobin	Low	Low	Low	Low	Low or normal	Normal or low	Low	Low
Hematocrit	Low	Low	Low	Low	Low or normal	Normal or low	Low	Low
Reticulocyte count	Low	Low	Normal or slightly high or low	Normal or slightly high	Low	Increased	High	Normal

Transferrin	Slightly high	Slightly high	Low	High	Normal	Normal	Normal	Slightly low

conjunctivae become pale as a result of reduced hemoglobin concentration. If anemia is caused by RBC destruction (hemolysis), the skin may become yellowish because of accumulation of the products of hemolysis. Tissue hypoxia of the skin results in impaired healing and loss of elasticity, as well as thinning and early graying of the hair. Nervous system manifestations can occur if the anemia is caused by a vitamin B_{12} deficiency. Myelin degeneration may occur, causing a loss of nerve fibers in the spinal cord and producing paresthesias (numbness), gait disturbances, extreme weakness, spasticity, and reflex abnormalities. Decreased oxygen supply to the gastrointestinal (GI) tract often produces abdominal pain, nausea, vomiting, and anorexia. A low-grade fever of less than 38.5° C (less than about 101° F) occurs in some anemic individuals and may result from the release of leukocyte pyrogens from ischemic tissues.

When the anemia is severe or acute in onset (e.g., hemorrhage), the initial compensatory mechanism is peripheral blood vessel constriction, diverting blood flow to vital organs. Decreased blood flow detected by the kidneys activates the renal renin-angiotensin response, causing salt and water retention in an attempt to increase blood volume. These situations are emergencies and require immediate intervention to correct the underlying problem that caused the acute loss of blood; therefore, long-term compensatory mechanisms do not develop.

Therapeutic interventions for slowly developing anemic conditions require treatment of the underlying disorder and palliation of associated symptoms. Therapies include transfusions, dietary correction, and administration of supplemental vitamins or iron.

Macrocytic-Normochromic Anemias

The **macrocytic (megaloblastic) anemias** are characterized by unusually large stem cells (megaloblasts) in the marrow that mature into erythrocytes that are unusually large in size (macrocytes), thickness, and volume.[1] The hemoglobin content is normal (normochromic). These anemias are the result of defective erythrocyte DNA synthesis, commonly caused by deficiencies of vitamin B_{12} (cobalamin) or folate (folic acid), coenzymes that are required for nuclear maturation and DNA synthesis. These defective erythrocytes die prematurely, which decreases their numbers in the circulation, causing anemia.

Premature death of damaged erythrocytes, **eryptosis,** is a common mechanism of cellular loss in individuals with anemias secondary to deficiencies of iron, infections (e.g., malaria, mycoplasma), chronic diseases (e.g., diabetes, renal disease), genetic diseases (e.g., beta-thalassemia, glucose-6-phosphate dehydrogenase [G6PD] deficiency, sickle-cell trait), and myelodysplastic syndrome.[2] The process is similar to the removal of old or senescent erythrocytes (see Chapter 27), but is triggered by erythrocyte damage before the cell's normal life span. Damaged erythrocytes undergo cell shrinkage, membrane changes (blebbing), and rearrangement of plasma membrane phospholipid distribution with efflux of phosphatidylserine (PS). Macrophages have receptors that recognize surface PS and remove the damaged erythrocytes from the circulation. The erythrocyte's life span may be decreased by as much as 50%.[3]

Defective DNA synthesis in megaloblastic anemias causes red cell growth and development to proceed at unequal rates. DNA synthesis and cell division are blocked or delayed. However, ribonucleic acid (RNA) replication and protein (hemoglobin) synthesis proceed normally. Asynchronous development leads to an overproduction of hemoglobin during prolonged cellular division, creating a larger-than-normal erythrocyte with a disproportionately small nucleus. With each cell division, the disproportion between RNA and DNA becomes more apparent.

Immature precursors of the megaloblastic erythrocytes have a greater chance of dying during maturation than do normoblastic precursors. Additionally, there is an increase in the amounts of lactic dehydrogenase, reflecting cellular destruction, and indirect bilirubin, from the breakdown of heme. Both of these substances may be measured in the blood, providing biochemical evidence of ineffective erythropoiesis.

Defective DNA synthesis also may result in significant enlargement of neutrophil precursors creating giant metamyelocytes with a tendency to have more nuclear lobes than normal. Other cells throughout the body also may demonstrate enlargement and nuclear abnormalities. Cells lining epithelium and those with high turnover rates are most affected.

Pernicious Anemia

Pernicious anemia (PA), the most common type of megaloblastic anemia, is caused by vitamin B_{12} deficiency, which is often associated with the end stage of type A chronic atrophic (congenital or autoimmune) gastritis (see Figure 28-1, *C;* Figure 28-3).[4] *Pernicious* means highly injurious or destructive and reflects the fact that this condition was once fatal. It most commonly affects individuals older than the age of 30 (60 being the median age of diagnosis) who are of Northern European descent, primarily those of Scandinavian, English, and Irish descent, and PA is less common in individuals of Greek or

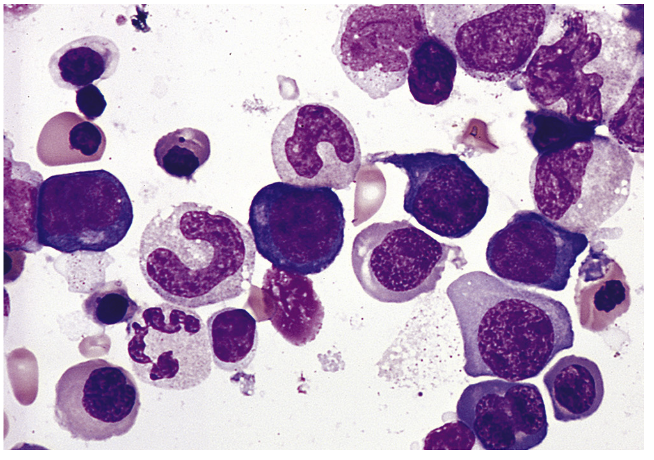

FIGURE 28-3 Bone Marrow Aspirate from Individual with Pernicious Anemia. Bone marrow aspirate smear from an individual with megaloblastic red blood cell precursors and giant metamyelocytes. The chromatin in the red blood cell nuclei is more dispersed than that in normal red blood cell precursors at comparable stages of maturation; the giant metamyelocytes have dispersed nuclear chromatin in contrast to a normal metamyelocyte, which has condensed chromatin (Wright-Giemsa stain). (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

Italian origin, Recently, PA has also been reported in blacks and Hispanics. Females are more prone to develop PA, with black females having an earlier onset.

PATHOPHYSIOLOGY. The principal disorder in PA is an absence of **intrinsic factor (IF),** a transporter required for absorption of dietary vitamin B_{12}, which is essential for nuclear maturation and DNA synthesis in erythrocytes. IF is secreted by gastric parietal cells and complexes with dietary vitamin B_{12} in the small intestine. The B_{12}-IF complex binds to cell surface receptors in the ileum and is transported across the intestinal mucosa.

Deficiency in IF secretion may be congenital or, more often, an autoimmune process directed against gastric parietal cells. Congenital IF deficiency is a genetic disorder that demonstrates an autosomal recessive inheritance pattern.[5] The autoimmune form of the disease also has a genetic component, as do most autoimmune diseases (see Chapter 9). Family clusters have been identified; 20% to 30% of individuals related to persons with PA also have PA. These relatives, particularly first-degree female relatives, also demonstrate a higher frequency of the presence of gastric autoantibodies. PA is also frequently a component of autoimmune polyendocrinopathy, which is a cluster of autoimmune diseases of endocrine organs (e.g., chronic autoimmune thyroiditis [Hashimoto thyroiditis], type 1 diabetes mellitus, Addison disease, primary hypoparathyroidism, Graves disease, and myasthenia gravis) that frequently present as comorbidities. Autoimmune thyroiditis and type 1 diabetes mellitus, in particular, are associated with PA.

Most cases of PA result from an autoimmune gastritis (type A chronic gastritis) in which gastric atrophy results from destruction of parietal and zymogenic cells. Individuals with PA commonly have autoantibodies against the gastric H^+-K^+ ATPase, which is the major protein constituent of parietal cell membranes. Early in the disease process the gastric submucosa becomes infiltrated with inflammatory cells, including CD4 lymphocytes, eventually extending into the lamina propria and causing degeneration of the parietal and zymogenic cells. The parietal and zymogenic cells are destroyed and replaced by mucous-containing cells (intestinal metaplasia). Gastric mucosal atrophy, in which gastric parietal cells are destroyed, results in a deficiency of all secretions of the stomach—hydrochloric acid, pepsin, and IF. A direct correlation exists between the severity of the gastric lesion and the degree of malabsorption of vitamin B_{12}.[6] Additionally, autoantibodies against IF prevent the formation of the B_{12}-IF complex. Thus, PA is secondary to autoimmune destruction of parietal cells, thus diminishing the production of IF, and the presence of autoantibodies that neutralize the capacity of remaining IF to transport vitamin B_{12}.

Initiation of the autoimmune process may be secondary to a past infection with *Helicobacter pylori*.[7] Although active infection with *H. pylori* is rare in individuals with PA, more than half of these individuals possess circulating antibodies against this microorganism, suggesting a history of infection. The current opinion is that in genetically prone individuals, antigens expressed by *H. pylori* mimic the parietal cell H^+-K^+ ATPase, resulting in production of an antibody that binds and damages the parietal cell (see Chapter 9 for a discussion of antigenic mimicry and autoimmune disease).

Environmental conditions also may contribute to chronic gastritis. These include excessive alcohol or hot tea ingestion and smoking. Complete or partial removal of the stomach (gastrectomy) causes IF deficiency. Drugs known as proton pump inhibitors (PPIs) are used to decrease gastric acidity, but also may decrease cobalamin absorption, although it is not thought that they actually cause PA. Although PA is a benign disorder, individuals with type A chronic gastritis also are at risk for developing gastric adenocarcinoma and gastric carcinoid type I. The incidence of carcinoma in these individuals is 2% to 3%.

CLINICAL MANIFESTATIONS. PA develops slowly (possibly over 20 to 30 years); 60 years of age is the median age at time of diagnosis. Because of the slow onset of symptoms, PA is usually severe by the time treatment is sought. Early symptoms are often ignored because they are nonspecific and vague and include infections, mood swings, and gastrointestinal, cardiac, or kidney ailments. When the hemoglobin level has decreased significantly (7 to 8 g/dl), the individual experiences the classic symptoms of anemia—weakness, fatigue, paresthesias of the feet and fingers, difficulty in walking, loss of appetite, abdominal pains, weight loss, and a sore tongue that is smooth and beefy red secondary to atrophic glossitis. The skin may become "lemon yellow" (sallow) as a result of a combination of pallor and icterus. Hepatomegaly, indicating right-sided heart failure, may be present in the elderly along with splenomegaly, which is nonpalpable.

Neurologic manifestations result from nerve demyelination that may produce neuronal death. The posterior and lateral columns of the spinal cord also may be affected, causing a loss of position and vibration sense, ataxia, and spasticity. These complications pose a serious threat because they are not reversible, even with appropriate treatment. The cerebrum also may be involved with manifestations of affective disorders, most commonly of the depressive types. An increased prevalence of serum vitamin B_{12} deficiency has been reported among individuals with Alzheimer disease.

EVALUATION AND TREATMENT. Diagnosis of PA is based on a variety of tests (see Table 28-3), which include blood tests, bone marrow aspiration, serologic studies, gastric biopsy, and clinical manifestations. A good test for PA was the Schilling test (no longer offered in most laboratories), which indirectly evaluated vitamin B_{12} absorption by administering radioactive B_{12} and measuring excretion in the urine. Low urinary excretion was significant for PA.

Serologic studies, however, have replaced the Schilling test for diagnosing PA. Measuring methylmalonic acid and homocysteine levels, which are elevated early in PA, is more sensitive. The presence of circulating antibodies against parietal cells and intrinsic factor is also useful in diagnosis.[8] Gastric biopsy reveals total achlorhydria (absence of hydrochloric acid), which is diagnostic for PA because it occurs only in the presence of this gastric lesion.

Replacement of vitamin B_{12} (cobalamin) is the treatment of choice. Initial injections of vitamin B_{12} are administered weekly until the deficiency is corrected, followed by monthly injections for the remainder of the individual's life. The effectiveness of cobalamin replacement therapy is determined by a rising

reticulocyte count. Within 5 to 6 weeks, blood counts return to normal. PA cannot be cured so maintenance therapy is lifelong. Conventional wisdom and practice assumed that oral preparations were ineffective because there was no IF to facilitate absorption of vitamin B_{12}. However, recent experience has shown that higher doses of orally administered vitamin B_{12} will be absorbed across the small bowel and is beneficial.

Untreated PA is fatal, usually because of heart failure. Death occurs after a course of remissions and exacerbations lasting from 1 to 3 years. Since 1926, when replacement therapy began, mortality has been reduced significantly. Today, death from PA is rare, and any relapses that occur are usually the result of noncompliance with therapy.

Folate Deficiency Anemia

Folate (folic acid) is an essential vitamin for RNA and DNA synthesis within the maturing erythrocyte. Folates are coenzymes required for the synthesis of thymine and purines (adenine and guanine) and the conversion of homocysteine to methionine. Deficient production of thymine, in particular, affects cells undergoing rapid division (e.g., bone marrow cells undergoing erythropoiesis). Humans are totally dependent on dietary intake to meet the daily requirement of 50 to 200 mcg/day. Increased amounts are required for pregnant and lactating females. Absorption of folate occurs primarily in the upper small intestine and does not depend on the presence of any other facilitating factor, such as IF. After absorption, folate circulates through the liver, where it is stored. Folate deficiency is more common than B_{12} deficiency, particularly in alcoholics and individuals with chronic malnourishment. Alcohol interferes with folate metabolism in the liver, causing a profound depletion of folate stores. Fad diets and diets low in vegetables also may cause folate deficiency because of the absence of plant sources of folate. It is estimated that at least 10% of North Americans have a folate deficiency, although the incidence has been on the decrease in the United States since the fortification of foods with folate and the increased use of folate supplements.

PATHOPHYSIOLOGY. Impaired DNA synthesis secondary to a folate deficiency results in megaloblastic cells with clumped nuclear chromatin. Anemia may result from apoptosis of erythroblasts in the late stages of erythropoiesis. In addition to anemia, folate deficiency in pregnant women is associated with neural tube defects of the fetus. Folate is necessary for the reduction of circulating levels of homocysteine, a risk factor for the development of atherosclerosis (see Chapter 32); thus a folate deficiency increases the risk for developing coronary artery disease. A deficiency of folate also is implicated in the development of cancers, specifically colorectal cancers.

CLINICAL MANIFESTATIONS. Clinical manifestations are similar to the cachectic, malnourished appearance of individuals with PA. Specific symptoms include severe cheilosis (scales and fissures of the lips and corners of the mouth), stomatitis (inflammation of the mouth), and painful ulcerations of the buccal mucosa and tongue, characteristic of burning mouth syndrome. Burning mouth syndrome may be secondary to a large number of disorders (e.g., extremely dry mouth, infection, autoimmune disease, nutritional deficiencies, and other conditions). The mechanisms underlying folate deficiency as a cause remain unknown. Gastrointestinal symptoms may be present and include dysphagia (difficulty swallowing), flatulence, and watery diarrhea, as well as histologic and roentgenographic changes of the GI tract suggestive of sprue (a chronic malabsorption syndrome). Undiagnosed inflammatory bowel disease (e.g., Crohn disease, ulcerative colitis) may be the underlying cause of folate malabsorption in some individuals, and folate deficiency may suppress proliferation of the intestinal mucosa, leading to exacerbation of gastrointestinal damage. Neurologic manifestations, such as those that occur in PA, are generally not seen in folate deficiency anemia. Any neurologic symptoms are usually caused by a thiamine deficiency, which often accompanies folate deficiency.

EVALUATION AND TREATMENT. Evaluation of folate deficiency is based on measurement of serum folate levels and symptoms. Treatment requires daily oral administration of folate preparations until adequate blood levels are obtained and clinical symptoms are reduced or eliminated. One milligram per day is sufficient for most individuals, although persons with alcoholism may require 5 mg. Prophylactic dosages of 0.1 to 0.4 mg/day are sometimes given during pregnancy. Parenteral administration of folic acid (citrovorum factor or leucovorin) generally is not used except in situations in which an individual has been using drugs that inhibit dihydrofolate reductase. After administration of folate, the manifestations of anemia disappear within 1 to 2 weeks.

After the folate deficiency has been corrected, long-term treatment with folate is not necessary if the appropriate dietary adjustments are made to maintain adequate intake. An intake of folate (400 mcg/day) is recommended as a measure to prevent heart disease.

Microcytic-Hypochromic Anemias

The **microcytic-hypochromic anemias** are characterized by abnormally small erythrocytes that contain abnormally reduced amounts of hemoglobin (see Figure 28-1, *B*). Hypochromia occurs even in cells of normal size.

Microcytic-hypochromic anemia can result from (1) disorders of iron metabolism, (2) disorders of porphyrin and heme synthesis, or (3) disorders of globin synthesis. Specific disorders include iron deficiency anemia, sideroblastic anemia, and thalassemia (thalassemia is discussed in Chapter 30).

Iron Deficiency Anemia

Iron deficiency anemia (IDA) is the most common type of anemia worldwide, occurring in both developing and developed countries and affecting as many as one fifth of the world population. Certain populations are at high risk for developing hypoferremia and IDA and include individuals living in poverty, women of childbearing age, and children. Iron deficiency in children is associated with numerous adverse health-related manifestations, especially cognitive impairment, which may be irreversible. Teens with a history of iron deficiency as infants are likely to score lower on cognitive and motor tests, even if the iron deficiency was identified and treated in infancy.

Children in developing countries often are affected by chronic parasite infestations that result in intestinal blood and iron loss that outpaces dietary intake.[9] Treatment of helminth infections results in an improvement in the anemia as well as in appetite and growth. Iron deficiency also occurs in individuals with lead poisoning. Treatment of the iron deficiency is associated with a decrease in lead levels.

Females have a higher incidence of hypoferremia (13.9%) than do males (8.3%), as well as IDA— 4% to 6% in females and 4% in males. The incidence peaks in females during their reproductive years and decreases after menopause. Those at highest risk are black females living in urban poverty.[10] Males have a higher incidence during childhood and adolescence, a decrease occurring during young adulthood, and an upswing during late adulthood. In the United States, 720,000 children (9%) ages 1 to 2 years are estimated to be iron deficient, of whom 240,000 (3%) are anemic, which may be a result of increased iron requirements with growth. An increased prevalence of iron deficiency has been observed in overweight children.

PATHOPHYSIOLOGY. IDA can arise from one of two different etiologies or a combination of both—inadequate dietary intake or excessive blood loss. In both instances there is no intrinsic dysfunction in iron metabolism; however, both deplete iron stores and reduce hemoglobin synthesis. A second category is a metabolic or functional iron deficiency in which various metabolic disorders lead to either insufficient iron delivery to bone marrow or impaired iron use within the marrow. Paradoxically, iron stores may be sufficient but delivery is inadequate to maintain heme synthesis, thus producing a functional or relative iron deficiency.

The most common cause of IDA in developed countries is pregnancy and chronic blood loss.[11] Blood loss of 2 to 4 ml/day (1 to 2 mg of iron) is sufficient to cause iron deficiency and may result from erosive esophagitis, gastric and duodenal ulcers, colon adenomas, or cancers. *H. pylori* infections also have been found to cause IDA of unknown origin, although *H. pylori* impairs iron uptake. In females, menorrhagia (excessive bleeding during menstruation) is a common cause of primary IDA. Other causes of IDA for both genders are (1) use of medications that cause gastrointestinal bleeding (such as aspirin or nonsteroidal anti-inflammatory drugs [NSAIDs]); (2) surgical procedures that decrease stomach acidity, intestinal transit time, and absorption (e.g., gastric bypass); (3) insufficient dietary intake of iron; and (4) eating disorders, such as pica, which is the craving and eating of nonnutritional substances, such as dirt, chalk, and paper.

Iron in the form of hemoglobin is in constant demand by the body. Iron is recyclable; therefore, the body maintains a balance between iron that is contained in hemoglobin and iron that is in storage and available for future hemoglobin synthesis (see Chapter 27). Blood loss disrupts this balance by creating a need for more iron, thus depleting the iron stores more rapidly to replace the iron lost from bleeding.

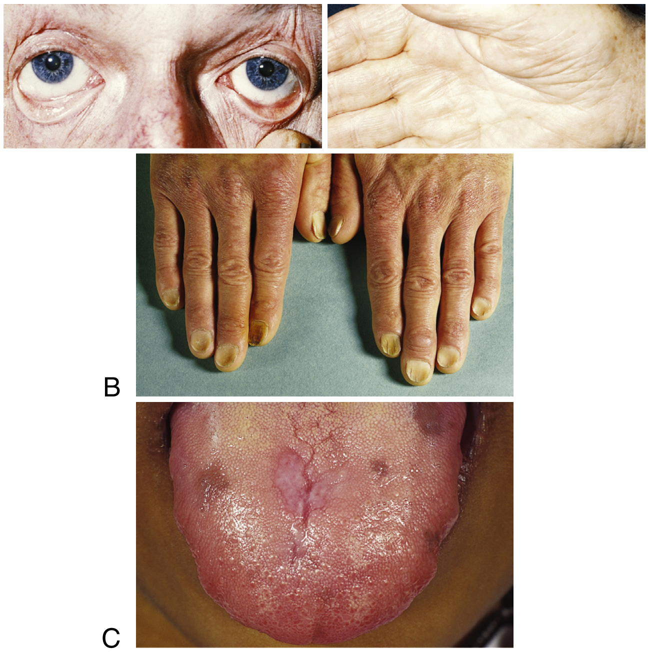
Iron also contributes to immune function by regulating immune effector mechanisms (i.e., cytokine activities [interferon-gamma (IFN-γ)], nitric oxide formation, and T-cell proliferation). Acquired hypoferremia may be part of the body's response to infection. Anemia can be part of the nonspecific acute phase response to any type of inflammation of sufficient degree. Many pathogens require iron for survival; thus hypoferremia would hamper their growth. However, the precise benefits or detriments of iron deficiency and immunity are still controversial.

IDA occurs when the demand for iron exceeds the supply and develops slowly through three overlapping stages. In stage I, the body's iron stores are depleted. Erythropoiesis proceeds normally, with the hemoglobin content of erythrocytes remaining normal. In stage II, iron transportation to bone marrow is diminished, resulting in iron-deficient erythropoiesis. Stage III begins when the small hemoglobin-deficient cells enter the circulation to replace the normal aged erythrocytes that have been removed from the circulation. The manifestations of IDA appear in stage III when there is depletion of iron stores and diminished hemoglobin production.

CLINICAL MANIFESTATIONS. Symptoms of IDA begin gradually, and individuals usually do not seek medical attention until hemoglobin levels have decreased to about 7 to 8 g/dl. Early symptoms are nonspecific and include fatigue, weakness, shortness of breath, and pale earlobes, palms, and conjunctivae (Figure 28-4, *A*).

As the condition progresses and becomes more severe, structural and functional changes occur in epithelial tissue (see Figure 28-4). The fingernails become brittle, thin, coarsely ridged, and "spoon-shaped" or concave (koilonychia) as a result of impaired capillary circulation (Figure 28-4, *B*). IDA also is associated with unexplained burning mouth syndrome, as was

A



B

C

FIGURE 28-4 **Manifestations of Iron Deficiency Anemia. A**, Pallor and iron deficiency. Pallor of the skin, mucous membranes, and palmar creases in an individual with a hemoglobin level of 9 g/dl. Palmar creases become as pale as the surrounding skin when the hemoglobin level approaches 7 g/dl. **B,** Koilonychia. The nails are concave, ridged, and brittle. **C,** Glossitis. Tongue of individual with iron deficiency anemia has bald, fissured appearance caused by loss of papillae and flattening. (From Hoffbrand AV, Pettit JE, Vyas P: *Color atlas of clinical hematology,* ed 4, London, 2009, Mosby; **B** courtesy Dr. S.M. Knowles.)

discussed for folate deficiency. Tongue papillae atrophy and cause soreness along with redness and burning (glossitis) (Figure 28-4, *C*). The degree of pain experienced is directly associated with the amount of iron deficiency, and these changes can be reversed within 1 to 2 weeks of iron replacement therapy. Individuals also experience dryness and soreness in the epithelium at the corners of the mouth, known as *angular stomatitis.* Difficulty in swallowing is associated with an esophageal "web," a thin, concentric, smooth extension of normal esophageal tissue consisting of mucosa and submucosa at the juncture between the hypopharynx and esophagus. The duration of iron deficiency required for web formation is uncertain. Dysphagia also is exacerbated by hyposalivation. The pathophysiology associated with these epithelial lesions is not well understood, but the lesions have the potential to become cancerous.

Nonheme iron is a component of many enzymes in the body (e.g., cytochromes, myoglobin, catalases, peroxidases), particularly those involved in the metabolism of amine neurotransmitters, reduction of nucleotides, and biosynthesis of methionine. Abnormalities and deficiencies of iron-dependent enzymes may account for many of the clinical manifestations of IDA. Individuals with IDA also exhibit gastritis, neuromuscular changes, irritability, headache, numbness, tingling, and vasomotor disturbances. Gait disturbances are rare. The pathogenesis of neurologic symptoms is unknown but may be caused by hypoxia in already compromised cerebral vessels. In the elderly, mental confusion, memory loss, and disorientation are often associated with anemia and may be wrongly perceived as "normal" events related to aging.

EVALUATION AND TREATMENT. Initial evaluation is based on clinical symptoms and decreased levels of hemoglobin and hematocrit. Additional measurements, however, are needed to determine the cause of the anemia (see Table 28-3). Iron stores may be measured directly by bone marrow biopsy and iron staining or indirectly by laboratory tests for serum ferritin, transferrin saturation, or total iron-binding capacity. Serum ferritin is a widely accepted and available measurement of iron status that has been used for the past 25 years; 1 mcg/L serum ferritin corresponds to 8 to 10 mg or 120 mcg of storage iron/kg body weight. A limitation on interpretation of serum ferritin levels is that values may be elevated independently of iron status during acute or chronic inflammation, malignancy, liver disease, or alcoholism. A sensitive indicator of heme synthesis is the amount of free erythrocyte protoporphyrin (FEP) within erythrocytes. A test that determines the concentration of soluble fragment transferrin receptor differentiates primary IDA from IDA that is associated with chronic disease.

An indicator of iron levels is the level of serum transferrin receptor (sTfR). Transferrin receptors are membrane glycoproteins that bind circulating transferrin for transport into cells. Soluble forms of the receptor are found in serum. The ratio of serum levels of transferrin receptor to ferritin (R/F) estimates body iron stores and differentiates primary IDA from anemia secondary to chronic disease. A major drawback, however, is the lack of proper standardization for the sTfR assay.

The first step in treatment of IDA is to identify and eliminate sources of blood loss.[12] With ongoing bleeding, any replacement therapy is likely to be ineffective. Iron replacement therapy is required and very effective. Initial doses are 150 to 200 mg/day. Hematocrit levels should improve within 1 to 2 months of therapy; however, the serum ferritin level is a more precise measurement of improvement and total body stores of iron. Once the serum ferritin level reaches 50 mcg/L, adequate replacement of iron has occurred. A rapid decrease in fatigue, lethargy, and other associated symptoms is generally seen within the first month of therapy. Replacement therapy usually continues for 6 to 12 months after the bleeding has stopped but may continue for as long as 24 months. Menstruating females may need daily oral iron replacement therapy (325 mg/day) until menopause.

Parenteral iron replacement is used in instances of uncontrolled blood loss, intolerance to oral iron, intestinal malabsorption, or poor adherence to oral therapy. Iron dextran has been the only parenteral agent available in the United States. Intramuscular injection is the recommended method; however, intravenous (IV) administration is generally preferred because of the ability to administer larger doses. A significant concern in the use of IV dextran is the potential for severe anaphylactic reaction. Delayed allergic reactions are also major concerns.

Newer medications that have recently been approved for parenteral therapy in treating IDA are sodium ferric gluconate complex in sucrose (Ferrlecit) and iron sucrose injection (Venofer). Iron dextran is recommended as the first choice in spite of its higher rate of adverse reactions. For individuals who are intolerant of iron dextran, the two newer agents are safe and effective alternatives. Drawbacks to their use include higher cost and the need for multiple infusions.

Sideroblastic Anemia

Sideroblastic anemias (SAs) are a heterogeneous group of disorders characterized by anemia of varying severity caused by a defect in mitochondrial heme synthesis.[13] SA is characterized by the presence of ringed sideroblasts within the bone marrow. **Ringed sideroblasts** are erythroblasts that contain iron-laden mitochondria arranged in a perinuclear collar around one third or more of the nucleus (see Figure 28-1, *K*).[14] Individuals with SA also have increased levels of iron in their tissue. The blood contains hypochromic erythrocytes, either microcytic or macrocytic depending on the form of the disease.

PATHOPHYSIOLOGY. SAs have multiple etiologies but all share the commonality of altered heme synthesis in the erythroid cells in bone marrow. Mitochondrial aminolevulinic acid (ALA) synthase uses glycine to convert succinyl CoA into ALA.[15] ALA undergoes further enzymatic modification in the cytoplasm to the porphyrin structure, becoming coproporphyrinogen III, which reenters the mitochondria. Within the mitochondria the molecule is progressively converted to protophorphyrin IX, which has ferrous iron (Fe^{2+}) inserted by the enzyme ferrochelatase. Disruptions to this pathway lead to the accumulation of iron in the mitochondria and the characteristic sideroblasts.

SAs are either acquired or hereditary. **Acquired sideroblastic anemia,** which is the most common, occurs as a primary disorder with no known cause (idiopathic) or is associated with other myeloproliferative or myeloplastic disorders. Another form is described as reversible SAs; these are secondary to various

conditions such as alcoholism, drug reactions, copper deficiency, and hypothermia. **Reversible sideroblastic anemia,** associated with alcoholism, results from nutritional deficiencies of folate. Alcohol impairs heme synthesis by reducing the activity of specific enzymes along the biosynthetic pathway and also by direct effects of alcohol or acetaldehyde, or both, on the heme biosynthetic steps or mitochondrial metabolism. Some specific drugs also cause reversible SA and include antituberculous agents (isoniazid [INH], pyrazinamide, cycloserine, and chloramphenicol) that interfere with B_{12} metabolism or directly injure the mitochondria. Copper deficiency also causes reversible SA by interfering with conversion of ferric iron to ferrous iron. This is extremely rare and is associated with gastrectomy and prolonged parenteral nutrition without copper supplements. Hypothermia causes decreased heme synthesis and incorporation into hemoglobin.

Hereditary sideroblastic anemia is rare and occurs almost exclusively in males, suggesting a predominant recessive X-linked transmission. Hereditary SA (X-linked sideroblastic anemia [XLSA]) has been linked to missense mutations in the erythroid-specific ALAS-E gene *Xp11.21*.[16] More than 25 missense mutations have been identified. ALAS is the first and rate-limiting enzyme in the heme biosynthesis pathway, and mutations lead to reduced synthesis of protoporphyrin IX and the characteristic accumulation of iron in the erythrocyte. An occasional autosomal recessive transmission affecting females occurs with mitochondrial mutations and deficiencies of ferrochelatase. Other genetic, chromosomal, or enzyme dysfunctions also have been associated with hereditary SA. The anemia of hereditary SA is usually present in infancy or childhood, but may remain undetected until midlife. In some instances, other symptoms (e.g., diabetes or cardiac failure resulting from tissue iron overload) may be the first manifestation of SA. Differentiation of SA from idiopathic hemochromatosis needs to be confirmed because both are characterized by tissue iron deposition.

The leading known cause of primary ASA, **myelodysplastic syndrome (MDS),** is a group of disorders of hematopoietic stem cells, with all three stem cell lines demonstrating dysplastic characteristics.[17] Initially, all ASAs associated with myelodysplastic syndrome were considered to be one and the same and identified as refractory anemia with ringed sideroblasts. This classification proved unsatisfactory because different outcomes were observed in individuals who had the same apparent disease. Further investigations discovered morphologic and chromosomal characteristics that predicted different clinical courses. Two subsets of myelodysplastic ringed sideroblasts were identified based on the cell lines that were affected. In one subset, dysplastic features were limited to the erythroid line and it was classified as pure SA. Individuals with pure SA require transfusions, which may produce iron overload.[18] With adequate chelation therapy, they are able to survive and thrive for many years. A significant outcome of this condition is the rare occurrence of conversion to leukemia.

The second subset of MDS was characterized by abnormalities of multiple cell lineages. In addition to SA, major alterations of neutrophil and platelet were observed. Infections, frequently fatal, are common secondary to neutropenia and neutrophil dysfunction. Bleeding from thrombocytopenia and platelet dysfunction also is prevalent. Of those who survive, 40% develop acute (myeloblastic) leukemia.

CLINICAL MANIFESTATIONS. The anemias of SA are generally moderate to severe, with hemoglobin levels varying from 4 to 10 g/dl. In addition to the cardiovascular and respiratory manifestations common to all anemias, individuals with SA may show signs of iron overload **(hemochromatosis).** Mild to moderate enlargement of the spleen (splenomegaly) and liver (hepatomegaly) occurs; however, liver function remains normal or only slightly impaired. Occasionally abnormal skin pigmentation (bronze-tinted) is seen. Neurologic and epithelial alterations commonly associated with other anemias are absent. Hemosiderosis of cardiac tissue resulting in heart rhythm disturbances and congestive heart failure are major life-threatening complications related to cardiac iron overload. These manifestations are fortunately rare and occur late in the progression of the disease. Young children and infants who are severely affected may demonstrate growth and developmental impairment.

EVALUATION AND TREATMENT. Initially, SA may be mistaken for deficiency of stem cells in the marrow **(hypoplastic anemia)** or iron deficiency anemia (laboratory findings are listed in Table 28-3). Bone marrow examination establishes the diagnosis. The marrow is packed with erythrocyte stem cells, and mononuclear phagocytes in the marrow are loaded with iron in the form of hemosiderin. The presence of sideroblasts confirms the diagnosis of SA. Platelet and leukocyte values are generally normal; however, they may be reduced if splenomegaly is evident.

The severity of the anemia is quite variable and qualitative alterations of the erythrocytes (e.g., decreased mean corpuscular volume [MCV] and increased erythrocyte volume distribution width) may be evident even when anemia is not present. **Dimorphism,** in which normocytic and normochromic cells are seen concomitantly with microcytic-hypochromic cells, may be present and is seen more commonly in individuals with mild anemia, in female carriers, or in those receiving treatment with pyridoxine. Anisocytosis and poikilocytosis also are seen on examination of the blood smear.

Initial treatment of SA is directed toward identification of a causative agent (i.e., drugs or toxins).[19] Treatment is supportive, with transfusions being the primary intervention. Following removal of the agent, oral pyridoxine (100 mg/day) may be administered on a trial basis. Acquired SA related to alcohol abuse and pyridoxine antagonists often demonstrates a complete response to pyridoxine. SA caused by other etiologies does not demonstrate the same improvement.

Individuals with hereditary SA are initially treated with pyridoxine therapy (50 to 200 mg/day), which is effective in approximately one third of individuals. An optimal response is reticulocytosis with blood hemoglobin levels and low free erythrocyte protoporphyrin levels also returning to normal within 1 to 2 months. Morphologic abnormalities of cells (microcytosis), however, do not disappear, even in the presence of normal ALA synthase activity and hemoglobin. Hemoglobin levels also may increase in response to therapy but stabilize at less than normal levels. When a response to pyridoxine therapy is observed, lifelong maintenance therapy at a lowered dosage is

instituted. Discontinuing therapy initiates a relapse. Individuals not responding to pyridoxine require blood transfusions to relieve symptoms and permit growth and development.

Evidence of iron overload requires iron depletion therapy to prevent or minimize organ damage. Phlebotomy, or removal of blood from the circulation, is generally well tolerated and preferable for individuals who have a mild to moderate anemia without other complications (e.g., heart disease). Once all the stored iron is removed, maintenance phlebotomies are performed on a continuing basis. Individuals who have severe anemia and/or depend on transfusions become extremely overloaded with iron. When this occurs, therapy with deferoxamine (an iron chelating agent) is necessary to eliminate excess iron.

Individuals with acquired SA infrequently respond to pyridoxine. Fortunately, these individuals are rarely incapacitated by SA. In the absence of abnormalities of other blood cells and without iron overload, progression takes place over years. Transfusion and chelation therapy is the same as for hereditary SA when indicated.

Recent advances in treatment for SAs include prolonged administration of erythropoietin and stem cell transplant. Treatment with recombinant human erythropoietin improves anemia in 30% of those with myelodysplastic syndrome.[20] Individuals with the subset of MDS identified as refractory anemia have the overall best response rate. Congenital SA has been treated successfully with stem cell transplants; however, this treatment is in the early stages of use, and long-term efficacy has not yet been established. Death from SA is rare and often secondary to complications, such as infection, bone marrow failure, liver failure, or cardiac failure or arrhythmias, or both.

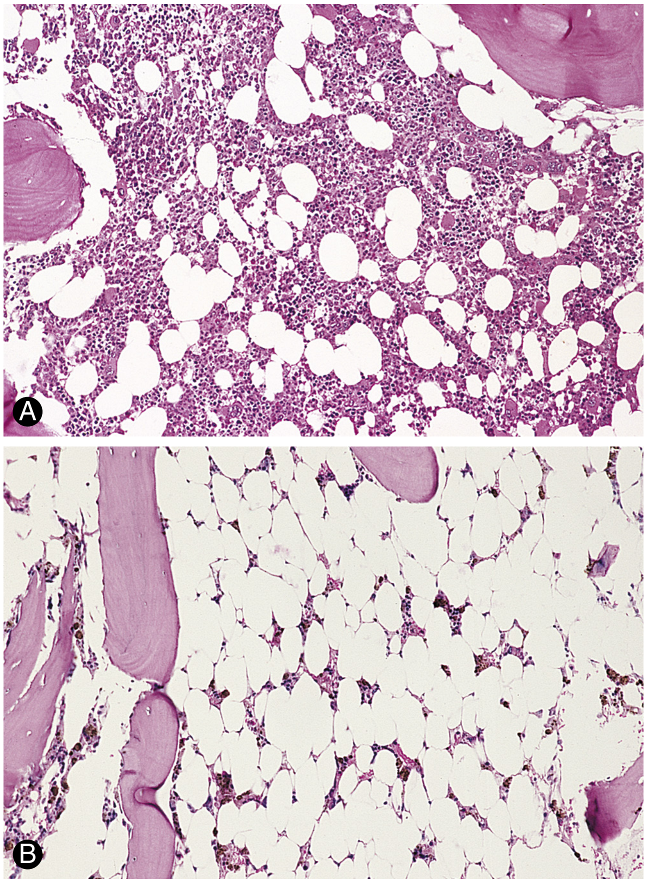


FIGURE 28-5 Aplastic Anemia. **A,** Normal bone marrow of an adult. Hematopoietic cells account for approximately 40% of marrow's cellularity. **B,** There is a marked reduction in hematopoietic cells with expansion of fat cells. (From Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

Normocytic-Normochromic Anemias

Normocytic-normochromic anemias (NNAs) are characterized by erythrocytes that are relatively normal in size and hemoglobin content but insufficient in number. These anemias have no common etiology, pathologic mechanisms, or morphologic characteristics. They are less frequent than macrocytic-normochromic and microcytic-hypochromic anemias. NNAs include five distinct groups: aplastic (damage to bone marrow erythropoiesis); posthemorrhagic (acute blood loss); acquired hemolytic (immune destruction of erythrocytes); hereditary hemolytic, such as sickle cell (destruction by eryptosis); and anemia of chronic inflammation (multiple causes). (Sickle cell anemia is discussed in Chapter 30.)

Aplastic Anemia

Aplastic anemia (AA) is a critical condition characterized by **pancytopenia,** a reduction or absence of all three blood cell types, resulting from failure or suppression of bone marrow to produce adequate amounts of blood cells (Figure 28-5). The rate or decline in the quantity of blood cells is related to their respective life span; thus erythrocytes (life span about 120 days) are last to demonstrate a reduction in numbers.

The incidence of AA is relatively rare (annual rate of 2 to 5 new cases per million per year). The incidence in developing countries is somewhat higher and may be related to greater exposure to certain chemicals known to cause AA. The incidence is bimodal, with one peak occurring between 15 and 25 years of age and a second peak occurring in individuals older than age 60. AA is equally distributed between genders.

AAs are the most common type, with idiopathic AA (primary acquired) accounting for approximately 75% of all confirmed cases and being an autoimmune disease. Secondary AA, which accounts for approximately 15% of cases, is caused by a variety of known chemical agents and ionizing radiation. Chemical agents include benzene, arsenic, and multiple drugs, including chloramphenicol and alkylating and antimetabolite chemotherapeutic drugs (6-mercaptopurine, vincristine, and busulfan).[21] Other drugs known to cause AA are identified in Table 28-4. The development of AA with use of these agents is generally dose related, and the effect can be controlled with diminished dosages. In other instances, AA might develop after the use of small amounts of these drugs (idiosyncratic), with the anemia following a severe, rapid, irreversible progression. Liver disease (seronegative hepatitis) is also recognized as a cause of AA.

AA is constitutional or familial in origin or is associated with one or more somatic abnormalities in approximately 5% to 10% of affected individuals. A subset of these is found to have defective telomerase RNA resulting in shortened telomeres. This abnormality also is found in some individuals with idiopathic AA.

TABLE 28-4 ANEMIAS SECONDARY TO DRUG EFFECTS*

DRUG	HEMOLYTIC	MEGALOBLASTIC	SIDEROBLASTIC	APLASTIC
Antibiotics				
Amphotericin B				X
Trimethoprim-sulfamethoxazole (Bactrim)		X		
Chloramphenicol (Chloromycetin)			XX	XXXX

X, Rare number of reported cases; *XXXX,* substantial number of reported cases; *XX, XXX,* intermediate number of reported cases; *X*,* "pure red cell" aplasia; *X?,* uncertain.

Total body irradiation also causes AA and in certain instances may be used therapeutically for this effect. Infections are also known to cause AA, with viruses being the most common agent. These include infections with the human immunodeficiency virus (HIV), Epstein-Barr virus, and hepatitis (non-A, non-B, non-C, and non-G forms of the virus). Persistent parvovirus B19 infection also has been identified as producing bone marrow failure resulting in AA. Parvovirus B19 has been identified as the cause of aplastic crisis in children who have sickle cell hemoglobinopathies and hereditary spherocytosis.

Another condition associated with AA is **pure red cell aplasia (PRCA),** in which only the erythrocytes are affected. PRCA is a rare disorder and has been associated with autoimmune, viral, and neoplastic (leukemias) disorders; infiltrative disorders of the bone marrow (myelofibrosis); renal failure; hepatitis; mononucleosis; and systemic lupus erythematosus. It also is a well-recognized but infrequent complication of allogeneic bone marrow transplantation, particularly when there is donor-recipient ABO mismatch. A thymoma often is found in association with PRCA and is also present in Diamond-Blackfan syndrome, a congenital disorder.

A very small percentage of AA cases are linked to genetic alterations. **Fanconi anemia** is a rare genetic anemia characterized by pancytopenia resulting from defects in DNA repair.[22] This anemia develops early in life and is accompanied by multiple congenital anomalies.

PATHOPHYSIOLOGY. The characteristic lesion of AA is a hypocellular bone marrow that has been replaced with fat. Most cases of idiopathic AA result from an autoimmune disease directed against hematopoietic stem cells.[23] As with most autoimmune diseases, a genetic predisposition is apparent and has been attributed to polymorphisms in human leukocyte antigens (HLAs) and inhibitory cytokines (e.g., tumor necrosis factor-alpha [TNF-α], transforming growth factor-beta [TGF-β], and interferon-gamma [IFN-γ]).[24] The evidence supporting an autoimmune process includes the response of AA to immunosuppressive therapy including depletion of T cells by antithymocyte antibodies. Cytotoxic T cells (Tc cells) appear to be the main culprits, although the causative antigen has yet to be identified. Th1 cytokines (involved in the differentiation of Tc cells), such as IFN-γ and TNF-α, as well as cellular contact with Tc cells through FasL, induce apoptosis of CD34+ target cells, which includes most of the hematopoietic progenitors.

CLINICAL MANIFESTATIONS. The onset of symptoms is insidious and related to the rapidity with which the bone marrow is destroyed and replaced. Approximately 50% of AA cases progress rapidly, with a high risk of death from overwhelming infection or bleeding. In some cases the rate of decline is slow and the individual may adapt progressively to a new level of hematologic function. This condition is referred to as *hypoplastic anemia* rather than aplastic anemia.

Initial symptoms depend on which cell line is affected. Rapidly progressing disease is usually associated with hypoxemia, pallor (occasionally with a brownish pigmentation of the skin), and weakness along with fever and dyspnea with rapidly developing signs of hemorrhaging if platelets are affected (e.g., unexplained bruising, nosebleeds, bleeding gums, bleeding in the GI tract, prolonged bleeding at sites of minor injury). A slower onset over weeks or months is characterized by progressive weakness and fatigue with developing signs of hemorrhaging. Major hemorrhage may occur from any organ; however, it is generally observed in the late stages and is often secondary to other events. Menorrhagia and purpura also may be evident; however, purpura is not necessarily a classic indication of AA and may not be representative of the degree of thrombocytopenia. In both rapid and slow onset AA, diminished leukocyte production may result in a progressive frequency and prolongation of infections.

Late manifestations of the condition include ulcerations of the mouth and pharynx or a low-grade cellulitis in the neck. Splenomegaly is extremely rare, and if present, other conditions that may imitate AA should be ruled out. Neurologic changes are only evident when hemorrhages have occurred within the system; however, some individuals have complained of paresthesias.

EVALUATION AND TREATMENT. Diagnosis is made by blood tests and bone marrow biopsy. AA is suspected if levels of circulating erythrocytes, leukocytes, and platelets are diminished: a granulocyte count less than 500/μL, a platelet count less than 20,000/μL, and an absolute reticulocyte count less than or equal to 40×10^9/L. The diagnosis is confirmed by a bone marrow biopsy. The bone marrow usually has reduced cellularity (i.e., less than 25% normal cellularity). The morphology of the few remaining hematopoietic cells is usually normal. Occasionally the erythrocytes are macrocytic, with anisocytosis and poikilocytosis, and may appear immature.

Marrow biopsied from individuals with typical AA contains yellowish white material consisting mainly of fat, fibrous tissue, and lymphocytes. Pancytopenia is usually characterized by decreased stem cell and progenitor cell populations to approximately 1% or less of normal.

Up until 20 years ago, treatment involved determining the cause, removal of exposure to the potential causative agent, transfusion, and prevention and treatment of infection and hemorrhage. Stimulation of blood cell production also was used, and in some instances splenectomy was recommended. The prognosis with these forms of treatment was extremely poor. In acute cases, 25% of individuals succumbed within 4 months, and approximately 70% died within 5 years; only about 10% experienced complete recovery. Newer forms of treatment, such as bone marrow transplant (BMT), immunosuppression, and identification of high-risk individuals, have decreased mortality significantly.[25]

Bone marrow and, most recently, peripheral blood stem cell transplantation from a histocompatible sibling often cures the underlying bone marrow failure.[26] Survival rates of 75% to 80% have been reported, and death rates within the first 100 days have decreased. Before transplantation the recipient usually received radiation or chemotherapy to deplete the bone marrow of disease-causing lymphocytes. Thus an unsuccessful transplantation may leave the recipient with a depleted immune system and an increased vulnerability to infection. Graft-versus-host (GVH) disease remains a risk and is a major contributor to premature death.[27] Children demonstrate higher survival than adults.

For those individuals unable to undergo bone marrow transplantation or who lack a suitable sibling donor, immunosuppression remains the treatment of choice. Antithymocyte globulin (ATG) specifically suppresses lymphocytes, including those autoreactive lymphocytes destroying the bone marrow cells. Drugs like cyclosporine, which is often used in combination with ATG, broadly suppress the activity of immune cells. Response rates, that is, increased blood cell counts, of 40% to 50% may occur in individuals who receive ATG. The addition of cyclosporine has increased the response and survival rates to as much as 70% to 80%, with a 5-year survival rate between 80% and 90%. Cyclosporine as a single therapeutic agent is not as effective. Corticosteroids are often used concurrently with ATG and cyclosporine. Cyclophosphamide also has been used as an immunosuppressive agent and has produced the same effects as ATG; however, its use has been discontinued because of its toxicity. The addition of recombinant hematopoietic growth factors, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-6, and epoetin, to immunosuppressive therapy has produced significant additional benefit in both children and adults.

Immunosuppressive therapy is not without risk. Individuals receiving immunosuppressive therapy are at risk of experiencing treatment failure or late clonal/malignant conditions, or both. Late clonal/malignant conditions include paroxysmal nocturnal hemoglobinuria (PNH), MDS, acute leukemia, or solid tumor. Although quite rare (less than 3%), administration of ATG may cause an anaphylactic reaction in some individuals.

Posthemorrhagic Anemia (Acute Blood Loss)

Posthemorrhagic anemia is a normocytic-normochromic anemia caused by acute blood loss. Initial manifestations of this event depend on the severity of blood loss. If blood loss is severe, the significant manifestations are related to loss of blood volume rather than loss of hemoglobin.

A normal, healthy young adult can tolerate a blood loss of 500 to 1000 ml (10% to 20% of volume) without experiencing any symptoms. Additional losses up to 1500 ml do not cause obvious symptoms if the individual is recumbent—symptoms appear only when assuming an upright position. When blood loss exceeds 1500 ml, symptoms are apparent even in a recumbent position (Table 28-5).

TABLE 28-5 CLINICAL MANIFESTATIONS OF ACUTE BLOOD LOSS OF INCREASING SEVERITY*

VOLUME LOST		
% TBV	**ml**	**CLINICAL MANIFESTATIONS**
10	500	None; rarely notice vasovagal syncope in blood donors
20	1000	When person is at rest, it is difficult, if not impossible, to detect volume loss; tachycardia is common with exercise and a slight drop in blood pressure with postural change
30	1500	Neck veins are flat in supine position; exercise tachycardia and postural hypotension are usually present; resting supine blood pressure and pulse can still be normal
40	2000	Central venous pressure, cardiac output, and arterial blood pressure are below normal even at rest and supine position; person commonly has air hunger; a rapid, thready pulse; and cold, clammy skin
50	2500	Severe shock, lactic acidosis, death

Adapted from Hillman RS: Acute blood loss anemia. In Beutler E et al, editors: *Williams hematology,* ed 5, New York, 1995, McGraw-Hill.
*Data based on a 70-kg person with a total blood volume of 5000 ml.
TBV, Total blood volume.

Volume loss reduces mean systemic filling pressure, resulting in decreased venous return. The initial manifestations (increased sympathetic nerve activation and a reduction in blood pressure, cardiac output, and central venous pressure) are caused by cardiovascular adaptations to blood volume depletion. If blood loss exceeds 2000 ml, severe shock, lactic acidosis, and death occur. (Shock is discussed in Chapter 48.)

If the acute blood loss is not severe (does not cause the preceding manifestations), complete recovery is possible. Within 24 hours of blood loss, lost plasma is replaced by mobilizing water and electrolytes from tissues and interstitial spaces into the vascular system. The hemodilution that results lowers the hematocrit value; concurrently, there is often a rapid elevation of circulating neutrophils and platelets. Neutrophils can rise to levels between 10,000 and 30,000/μL within a few hours as a result of a shift of marginated leukocytes into the circulation and a release of leukocytes from the bone marrow. The platelet count can rise to levels of about 1 million/μL. In severe blood loss, more immature cells—metamyelocytes, myelocytes, and nucleated red blood cells—may enter the circulation. Reduction in tissue oxygenation stimulates production of erythropoietin and increasing production of erythrocytes (reticulocytes) in the bone marrow. Iron recovery from destroyed erythrocytes may occur if the acute blood loss is internal; however, if blood is lost externally, iron stores may be depleted and erythropoiesis may be impeded. Hemorrhage that is chronic (occult [i.e., bleeding ulcer or neoplasm]) produces adaptations that are less prominent, but the individual may experience an IDA when iron reserves become depleted.

Initial treatment for acute blood loss is restoration of blood volume by intravenous administration of saline, dextran, albumin, or plasma. Large volume losses may require transfusion of fresh whole blood.

Successful therapy is first indicated by a return of erythrocytes to their normal size and shape. As the bone marrow begins to produce more erythrocytes, an increase in the number of reticulocytes (10% to 15% after 7 days) is seen. Changes in the appearance of erythrocytes (polychromatophilia and macrocytosis) associated with reticulocytosis may give the impression that an underlying hemolytic process is occurring. A normal erythrocyte count is usually noted in 4 to 6 weeks, but hemoglobin restoration may take 6 to 8 weeks.

Hemolytic Anemia

The predominant event in **hemolytic anemias** is premature accelerated destruction of erythrocytes, either episodically or

TABLE 28-6 CAUSES OF HEMOLYTIC ANEMIAS

TYPE OF HEMOLYTIC DISORDER	PRIMARY CAUSE OR ASSOCIATED DISORDER	MECHANISMS OF ERYTHROCYTE DESTRUCTION
Acquired Forms		
Immune system–mediated hemolysis	Transfusion reaction Hemolytic disease of the newborn (see Chapter 30) Autoimmune hemolytic anemia (see text)	Antibody-mediated: intravascular hemolysis by activation of complement system; extravascular hemolysis by phagocytosis of antibody-coated erythrocytes in spleen (see Chapter 9)
Traumatic hemolysis	Presence of prosthetic heart valves Structural abnormalities of the heart Hemolytic uremic syndrome Disseminated intravascular coagulation Hemodialysis	Physical destruction of erythrocytes by "mechanical" means (trauma)
Infectious hemolysis	Bacterial infection Viral infection Protozoal infection Helminthic infection	Bacterial hemolysins (e.g., *Escherichia coli* 0157:H7 shiga toxin; *Clostridium perfringens* toxin) Initiate autoimmune hemolysis (e.g., *Mycoplasma pneumoniae:* cold agglutinin) Affects erythrocytes (e.g., parvovirus B19: infects erythroid progenitors) Infects erythrocytes (e.g., malaria) Intestinal bleeding (e.g., hookworm)
Drug or toxic (chemical) hemolysis	Exposure to toxic chemical agents Hemodialysis or uremia Venoms	Chemical injury of erythrocytes (see Chapter 2)
Physical hemolysis	Burns Radiation	Heat or radiation injury (see Chapter 2)
Hypophosphatemic hemolysis	Hypophosphatemia (phosphate deficiency in plasma; see Chapter 3)	Diminished cellular production of substances required for erythrocyte life and function
Hereditary Forms		
Structural defects	Plasma membrane defects	Fragility of the erythrocyte
Plasma membrane protein mutation	Deficient complement regulatory proteins (i.e., paroxysmal nocturnal hemoglobulinuria)	Complement activation on erythrocyte surface, intravascular lysis
Enzyme deficiencies	Deficiency of glycolytic enzymes Deficiency of metabolic enzymes (i.e., glucose-6-phosphate dehydrogenase deficiency)	Diminished cellular function
Defects of globin synthesis or structure	Sickle cell anemia	Increased membrane fragility and deformation during sickle crises
	Thalassemia	Defective hemoglobin structure and function
	Miscellaneous hemoglobin defects	Defective hemoglobin structure and function

From Lee GR et al: *Wintrobe's clinical hematology,* ed 9, Philadelphia, 1993, Lea & Febiger.

continuously. The consequences of the anemia are elevated levels of erythropoietin to induce accelerated production of erythrocytes and an increase in the products of hemoglobin catabolism.

Hemolytic anemias may be either congenital or acquired. Congenital hemolytic anemias result from intrinsic defects in erythrocytes, including the red cell membrane (e.g., hereditary spherocytosis, paroxysmal nocturnal hemoglobinuria), enzymatic pathways (e.g., glucose-6-phosphate dehydrogenase deficiency), and hemoglobin synthesis (e.g., the thalassemia syndromes, sickle cell anemia). (Glucose-6-phosphate dehydrogenase deficiency, thalassemia, and sickle cell disease are discussed in Chapter 30.) Acquired hemolytic anemias are usually immunologic (immune hemolytic anemias), such as erythrocyte destruction caused by autoantibodies against erythrocyte antigens (e.g., autoimmune hemolytic anemia), isohemagglutinins (e.g., mismatched erythrocyte transfusions), or allergic reactions against drug antigens adsorbed onto the erythrocyte surface (drug-induced hemolytic anemia). (Isohemagglutinins, erythrocyte antigens, autoantibodies, and allergic reactions are discussed in Chapter 9.) Acquired hemolytic anemia may also be secondary to erythrocyte damage caused by cardiac valve prostheses or by increased shear stresses in narrowed small vessels (e.g., during disseminated intravascular coagulation). Causes of acquired and hereditary hemolytic anemias are listed in Table 28-6.

PATHOPHYSIOLOGY. Hemolytic anemias can be classified by a variety of parameters, although no system is entirely satisfactory. Dividing these anemias into inherited or acquired is the preferred and most useful method. Pathophysiologic mechanisms also can be discussed in the context of where hemolysis occurs. Hemolysis occurs within blood vessels (intravascular)

or lymphoid tissues (extravascular) that filter blood—that is, spleen and liver. Intravascular hemolysis is the least common and typically caused by physical destruction of erythrocytes in the circulation, frequently by antibody and complement. Extravascular hemolysis results from removal of damaged or opsonized erythrocytes by cells of the mononuclear phagocyte system (MPS). Erythrocytes continuously circulate through the spleen, passing through the thin-walled splenic cords into the splenic sinusoids, a spongelike labyrinth of macrophages with long dendritic processes. Normally, erythrocytes are able to alter their shape to allow passage through openings in the splenic cords. Macrophages will phagocytose erythrocytes with structure alterations of the membrane surface or that have become more rigid and are incapable of maneuvering through this network. In some cases, IgG antibodies or complement component C3b can coat erythrocytes without causing hemolysis, but can function as opsonins that are recognized by macrophages.

Paroxysmal nocturnal hemoglobinuria may be congenital or acquired secondarily to acquired aplastic anemia. The disease results from a mutation in the X-linked gene for phosphatidylinositol glycan—class A *(PIG-A),* which results in a defect in expression of glycosylphosphatidylinositol (GPI) in hematologic stem cells.[28] GPI is a lipid anchor that is necessary for attachment of a large number of proteins to the plasma membrane. Several GPI-anchored proteins on erythrocytes are complement regulatory proteins, including CD55 (decay-accelerating factor) and CD59 (membrane attack complex [MAC] inhibitory protein). Normally low levels of complement are activated on cell surfaces through the alternative pathway (see Chapter 7). Erythrocytes are protected from complement-mediated damage by CD55, which accelerates the degradation of any C3 convertase that forms on the cell surface, and by CD59, which prevents C9 aggregation and pore formation by the membrane attack complex. Thus erythrocytes deficient in CD55 and CD59 undergo complement-mediated intravascular lysis and release of hemoglobin.[29] In addition to anemia and hemoglobinuria, affected individuals also present with severe fatigue, abdominal pain, and thrombosis.[30] The cause of death is usually thrombosis of the abdominal or cerebral veins.[31] Thrombosis most likely results from a depletion of vascular nitric oxide (NO) by free hemoglobin, which has a high affinity for NO. The result is dysregulation of normal hemostasis and increased platelet vascular adherence and clot formation (see Chapter 27).

Autoimmune hemolytic anemias (AIHAs) are acquired disorders caused by autoantibodies against antigens normally on the surface of erythrocytes.[32] Three types of AIHAs have been described: (1) warm reactive antibody type, (2) cold agglutinin type, and (3) cold hemolysin type (paroxysmal cold hemoglobinuria). This classification is based on the optimal temperature at which the antibody binds to erythrocytes and the mechanism of erythrocyte destruction.

Warm autoimmune hemolytic anemia is uncommon (incidence of about 1 per 80,000 population annually), although it is the most common form of AIHA (80% to 90% of cases), and generally occurs in individuals older than the age of 40.[33] Approximately half of the cases are secondary to other diseases, especially lymphomas but also chronic lymphocytic leukemia, other neoplastic disorders, or systemic lupus erythematosus (SLE). The anemia is caused by IgG that binds optimally to erythrocytes at normal body temperature (37° C, 98.6° F). Most cases are related to antibody against Rh-related antigens other than the D epitope (Rh antigens are discussed in Chapter 9). The spectrum of antibody specificities includes antibodies against the e, E, or c antigens of the Rh complex. Other cases are caused by IgG antibodies against erythrocyte antigens outside the Rh complex and include antibodies against Wr^b, En^a, the Kell blood group, and many others. The warm reactive IgG antibodies usually do not activate complement because of the rather sparse distribution of antigens on the erythrocyte surface. (Activation of complement by antibody is discussed in Chapters 7, 8, and 9.) Erythrocyte destruction is caused by extravascular processes. The IgG-coated erythrocytes bind to the Fc receptors on monocytes and splenic macrophages and are removed by phagocytosis.

Cold agglutinin autoimmune hemolytic anemia is mediated by immunoglobulin M (IgM) antibodies and occurs less often than warm antibody hemolysis, affecting mostly middle-aged and older adults. Cold antibodies optimally bind to erythrocytes at colder temperatures (lower than 31° C [87.8° F]) with maximal binding capacity at 4° C (39.2° F). Cold agglutinin autoantibodies may appear acutely during recovery of certain infectious disorders, particularly infectious mononucleosis, mycoplasma pneumonia, and disseminated tuberculosis.[34] With these conditions, the individuals are usually younger than those with primary disease; the anemia may be severe but may be self-limiting. Chronic cold agglutinin AIHAs also can occur in association with lymphoid neoplasm and other unknown or idiopathic conditions.[35]

The IgM autoantibody is usually monoclonal and directed against erythrocyte carbohydrate antigens of the I system (i.e., i, I) or the P system (i.e., Pr).[36] In the colder areas of the body, particularly during cold weather (e.g., fingers, toes, nose, ears, exposed skin), the IgM autoantibodies bind to circulating erythrocytes. The IgM is rapidly released when the blood recirculates and warms. IgM is an extremely efficient activator of complement, resulting in the stable deposition of C3b on the cell surface. If an adequate amount of complement is deposited, the erythrocytes become vulnerable to recognition and rapid phagocytosis by mononuclear phagocytes in the liver and spleen (also see Chapter 9). The severity of hemolysis is variable and may result in a progressive chronic anemia. If the level of antibody is high or has particularly strong binding, hemagglutination may occur in the capillaries of exposed sites, such as fingers, toes, and ears, when temperatures are below 30° C (86° F). Obstruction of blood flow caused by erythrocyte agglutination may lead to a bluish discoloration of the skin (acrocyanosis) that resolves as the skin is warmed. Prolonged exposure to the cold may lead to gangrene.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) is a disorder in which exposure to cold initiates acute and severe intravascular hemolysis that, unlike cold agglutinin anemia, results in hemoglobulinuria. The chronic form of this anemia is extremely rare, but an acute form of paroxysmal cold hemoglobinuria is frequently observed

(30% to 40% of cases) in AIHA of childhood. The acute form occurs primarily in children younger than the age of 10 years and is usually preceded by an upper respiratory tract infection or flulike symptoms. Infections with measles, mumps, *Mycoplasma* (pneumonia), and *Varicella* have also been linked to an onset of paroxysmal cold hemoglobinuria. The anemia may be rapidly progressing and severe and associated with fever, reddish brown urine, hemoglobinuria, jaundice, abdominal pains, and pallor, with about 25% of individuals presenting with hepatomegaly and splenomegaly.

Paroxysmal cold hemoglobinuria is generally caused by IgG autoantibodies against the P blood group antigen. Antibody binding occurs in the colder portions of the body. As the erythrocyte recirculates, enzymes of the complement cascade are activated, and cells are destroyed in the vasculature by complement-mediated lysis. The involved antibody, also called *Donath-Landsteiner antibody,* was first recognized in individuals with anemia secondary to chronic syphilis infection. A transfusion reaction is an example of alloimmune hemolytic anemia (also see Chapter 9). Transfused blood that is mismatched for ABO antigens is destroyed by preexisting isohemagglutinins in the recipient. Isohemagglutinins, which are generally IgM antibodies, activate complement, resulting in a rapid intravascular hemolysis. The individual may immediately experience fever, chills, dyspnea, and hypotension and may progress to shock. In some cases the hemolytic reaction may be delayed and develop 3 to 10 days after transfusion. The delayed reaction is caused by a low titer of preexisting antibodies to minor erythrocyte antigens.

Drug-induced hemolytic anemia is a form of immune hemolytic anemia usually resulting from an allergic reaction against foreign antigens (e.g., antibiotics)[37] (also see Chapter 9). Usually the drug is low molecular weight, functions as a hapten, and binds to proteins on the surface of erythrocytes. This is sometimes called the *hapten model* and is based on anemia caused by penicillin, cephalosporins (more than 90% of cases), and, very recently, hydrocortisone (Figure 28-6, *A*).[38] IgG antibody against the drug or against the unique antigen formed by the interface of the drug and erythrocyte protein is formed and binds to the erythrocyte at normal body temperature. Hemolysis is usually extravascular because the opsonized erythrocytes are removed by phagocytes in the spleen and liver, although complement-dependent intravascular hemolysis may occur in some individuals. This form of drug-induced anemia usually follows a large intravenous infusion of an antibiotic and occurs 1 to 2 weeks after the initiation of therapy. Cessation of administration of the drug results in rapid resolution of the anemia.

The erythrocyte plasma membrane contains receptors of components of the complement system, such as C3b, and can bind circulating immune complexes that have activated the complement cascade (see Chapter 9 for a discussion of immune complexes). This forms the basis for the *immune complex model* of drug-induced hemolytic anemia and was first described for anemia resulting from administration of the drug quinidine (Figure 28-6, *B*). The drug or a metabolite of the drug, both of which are haptens, initially binds to plasma proteins and becomes immunogenic (see Chapter 8).

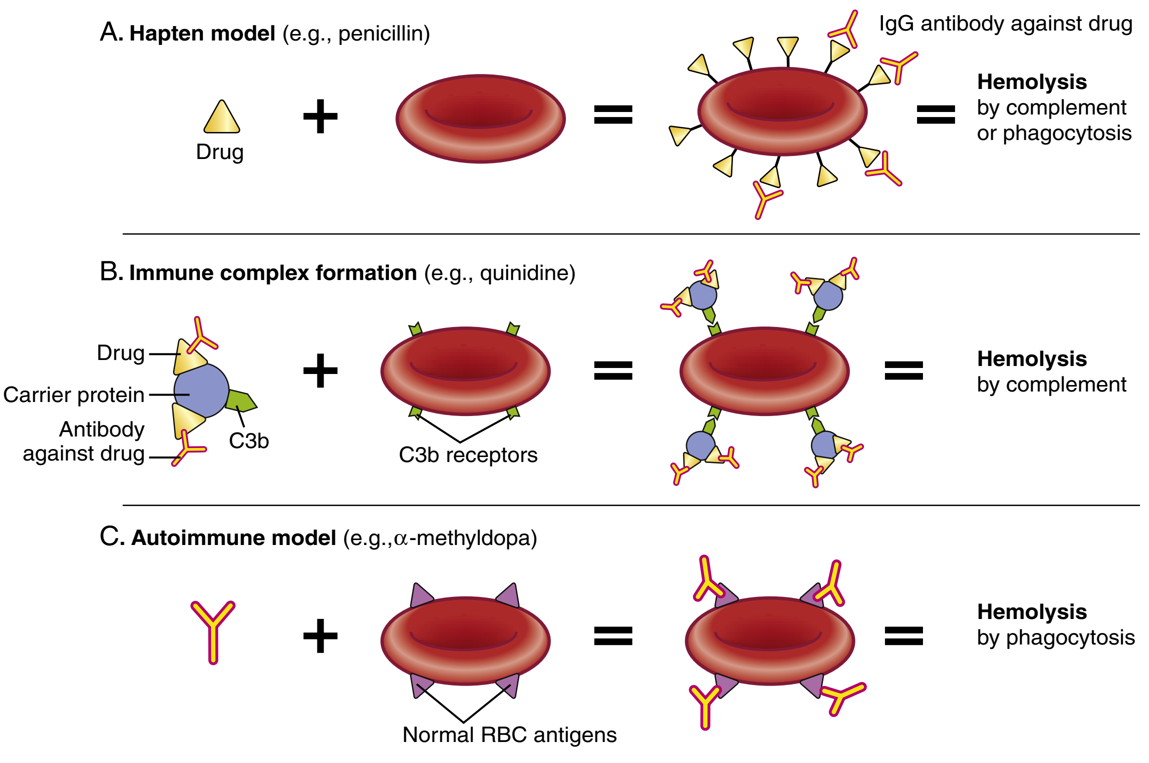

FIGURE 28-6 **Models of Drug-Induced Hemolytic Anemia.** See discussion in text. *IgG,* Immunoglobulin G; *RBC,* red blood cell.

The circulating drug/protein complex reacts with the resultant antibody (usually IgM, although IgG complexes have also been described) and activates the complement system, resulting in the deposition of C3b into the complex. Binding of the immune complexes to the erythrocyte surface results in further complement activation and intravascular hemolysis. This mechanism also may explain some of the anemia observed in other immune complex conditions, such as SLE.

In at least one instance, administration of the drug α-methyldopa induces an immune response against normal erythrocyte antigens and thus initiates a true AIHA *(autoimmune model)* (Figure 28-6, *C*). The autoantibody is usually against Rh blood group antigens. It is estimated that 20% of individuals taking α-methyldopa develop detectable antibodies, but only 1% actually develop clinically significant anemia. The mechanism by which α-methyldopa induces autoantibodies against the erythrocytes is unknown.

CLINICAL MANIFESTATIONS. The presence and severity of signs and symptoms of hemolytic anemia depend on the degree of anemia and hemolysis and the success of compensatory erythropoiesis. Adaptation to red cell destruction is facilitated by increased red cell production. Bone marrow is capable of increasing red cell production up to eight times its normal rate. Accelerated erythrocyte production that is incapable of keeping up with destruction develops into a true hemolytic anemia.

The severity of anemia varies widely from individual to individual, even in individuals who have the same illness. Severe disease is commonly diagnosed shortly after birth or within the first year of life. Mild to moderate anemia is more common because the shortened erythrocyte survival time is offset by increased erythropoiesis. Some individuals have no symptoms of anemia, and the underlying hemolytic process remains undetected unless some other complications develop during the course of the disease.

Jaundice (icterus) is present when heme destruction exceeds the liver's ability to conjugate and excrete bilirubin. Jaundice is first noticed in the neonatal period. Children and adults with congenital hemolytic anemia may not have icterus, or it may be mild enough that it remains unnoticed. In some individuals, faint scleral icterus may be the only indication of hemolytic disease.

Acute conditions that disrupt the delicate equilibrium of accelerated erythropoiesis and erythrocyte destruction may precipitate a crisis. The most common type of crisis is aplastic and results from failure of bone marrow erythrocyte production. The most common cause of aplastic crisis is human parvovirus B19 infection.

Commonly, individuals with congenital hemolytic disorders demonstrate splenomegaly, which is often only mild in nature. In some cases the spleen may become quite enlarged and may cause discovery of the underlying hemolytic disorder. Another underlying condition that may be the cause of inadvertently determining the presence of the anemic disorder is the development of gallstones.

Children who have hemolytic anemia often demonstrate skeletal abnormalities caused by expansion of erythroid bone marrow during the active phase of growth and development. These alterations are more pronounced in the bony structures of the face and skull and may result in pathologic fractures (see Chapter 30). Cardiovascular and respiratory manifestations vary with the degree of anemia. In spite of the disorder being characterized as hemolytic in nature, thromboembolism may occur. Pulmonary embolism is a common finding during autopsies of individuals with immune hemolytic anemia.

EVALUATION AND TREATMENT. Diagnosis is based on clinical manifestations, bone marrow studies, and blood tests (see Table 28-3). Abnormally increased numbers of erythrocyte stem cells are found in the marrow, a finding termed *erythroid hyperplasia*. Accelerated erythropoiesis causes large numbers of fragile and immature erythrocytes (stem cells and reticulocytes) to be released prematurely into the circulation. These cells are observed in blood smears. If the bone marrow is able to consistently maintain adequate compensation, the hemoglobin may remain stable. The mean corpuscular volume, however, may be decreased in the presence of reticulocytes. A blood smear is helpful in determining the presence of spherocytes or schistocytes, as well as examining white blood cells and platelets for coexisting hematologic or malignant conditions.

Acquired hemolytic anemias are treated by removing the cause or treating the underlying disorder. Corticosteroids are used for initial treatment. Approximately 75% of individuals initially respond to treatment with corticosteroids, but many of these relapse within a year. The most commonly used second-line treatments are splenectomy and administration of rituximab. Splenectomy is performed if the spleen is the major site of hemolysis and splenomegaly is significant. Analysis of multiple studies confirms that some response (complete or partial) is achieved in between 59% and 100% of individuals.[39] Although some individuals relapse after splenectomy, most achieve long-term remission.

The therapeutic use of monoclonal antibody has proven beneficial in individuals who relapse or are resistant to the effects of corticosteroids. Rituximab is a monoclonal antibody directed against the CD20 antigen and specifically depletes or suppresses B cells throughout the body. CD20 is expressed on most cells in the B-cell lineage, except hematopoietic stem cells and plasma cells. Rituximab is used to treat a variety of leukemias and lymphomas and autoimmune diseases (e.g., rheumatoid arthritis, idiopathic thrombocytopenia, multiple sclerosis, type 1 diabetes mellitus, systemic lupus erythematosus). It is used successfully in several types of immune hemolytic anemias, although, as with most other therapies, individuals vary in the degree of response, potential to relapse, the optimal dose and timing for an optimal response, and complications.[40] Eculizumab is a monoclonal antibody against complement protein C5, which blocks the enzymatic activation of C5 to C5a and C5b, and thus may be useful to treat paroxysmal nocturnal hemoglobinuria. Treatment with eculizumab prevents the formation of the membrane attack complex and complement-mediated cell lysis (see Chapter 7). In multiple trials, use of eculizumab resulted in reduced hemolysis, the need for transfusion, and the risk for thrombosis, as well as diminished other symptoms, including fatigue and abdominal pains.[41] Blockage of C5 activation mimics individuals who have congenital deficiencies in C5

(see Chapter 9). Lack of C5 increases the risk for disseminated infections with *Neisseria* sp., particularly *Neisseria meningitidis;* thus immunization with the meningococcal vaccine is recommended before treatment with eculizumab.[42]

Acute fulminating hemolytic anemia (hemolytic crisis) is treated with fluid and electrolyte replacement to prevent shock and renal damage, which may be caused by erythrocyte debris clogging the kidney tubules. Transfusions of blood products sometimes are given. Folate also is used in treating chronic hemolytic disease to prevent megaloblastic crisis because long-term erythrocyte turnover increases folate requirements.

Anemia of Chronic Disease

Anemia of chronic disease (ACD) is a mild to moderate anemia resulting from decreased erythropoiesis in individuals with conditions of chronic systemic disease or inflammation (e.g., infections, cancer, and chronic inflammatory or autoimmune diseases). These conditions include acquired immunodeficiency disease (AIDS), malaria (particularly that caused by *Plasmodium falciparum*), rheumatoid arthritis, systemic lupus erythematosus (SLE), acute and chronic hepatitis, and chronic renal failure (a condition in which almost all affected individuals are anemic).[43] This form of anemia also is commonly noted in the presence of congestive heart failure (CHF). The anemia develops after 1 to 2 months of disease activity. The initial severity is related to that of the underlying disorder but, although persistent, it usually does not progress. Individuals may be asymptomatic, or the anemia may be a coincidental clinical finding.

ACD is one of the most common conditions encountered in medicine and is probably only secondary to IDA in overall incidence. In individuals older than age 65, anemia is present in 10% of those who live in the community and more than 50% of those who reside in nursing homes, two thirds of which is ACD or unexplained anemia. The elderly may be predisposed to ACD related to age-associated hematopoietic restriction and generally have increased concentrations of inflammatory cytokines, which play a significant role in the development of ACD. The elderly who present with characteristics of ACD without an underlying malignancy or inflammatory condition are described as having primary defective iron-utilization syndrome.

PATHOPHYSIOLOGY. ACD results from a combination of (1) decreased erythrocyte life span, (2) suppressed production of erythropoietin, (3) ineffective bone marrow erythroid progenitor response to erythropoietin, and (4) altered iron metabolism and iron sequestration in macrophages.[44] During chronic inflammation a large variety of cytokines are released by lymphocytes, macrophages, and the affected tissue.[45] These include TNF-α, IFN-γ, interleukin-1β (IL-1β), IL-3, and IL-6 (also see Chapters 7 and 8).[46]

Impaired iron metabolism is partially the result of iron sequestration.[47] IL-6 in particular affects hepatocytes and increases the release of the peptide hepcidin, which regulates the activity of ferroportin. Ferroportin is the primary transporter for the export of iron from macrophages to the plasma, and increased levels of hepcidin result in decreased ferroportin activity and suppression of iron release (Figure 28-7).

Erythrocyte destruction is the result of eryptosis (described earlier in this chapter). Most of the diseases responsible for ACD damage erythrocytes, resulting in increased efflux of plasma membrane phosphatidylserine and susceptibility to removal by macrophages. Normal iron transport by transferrin also may be decreased as a result of competitive iron binding by inflammation-related increases in the levels of circulating lactoferrin and apoferritin. **Lactoferrin** is a member of the transferrin family of nonheme iron-binding glycoproteins, and under normal conditions is present in the blood in only small amounts. During inflammation neutrophils release lactoferrin to bind iron and reduce its availability for bacteria. However, the affinity of iron for lactoferrin is 260 times greater than that for transferrin. Lactoferrin-bound iron is removed by the mononuclear-phagocyte system and converted into ferritin, the storage form of iron. **Apoferritin** also has a higher affinity for iron and affects available iron in a similar manner.

The erythropoietic defect in ACD is failure to increase erythropoiesis in response to decreased numbers of erythrocytes. In part, decreased erythropoiesis results from diminished production of erythropoietin by the kidneys. The kidney is frequently affected by chronic inflammatory processes caused by circulating immune complexes and other factors that deposit in the kidney and activate secondary inflammatory mechanisms. In addition, the failure in erythropoiesis may reflect decreased responsiveness of erythroid progenitors to erythropoietin. Decreased availability of iron would diminish the rate of erythropoiesis. Proliferation of erythroid cells is also inhibited by proinflammatory cytokines, especially TNF-α, IFN-γ, and IL-1β. TNF-α also directly induces apoptosis of erythroid progenitors, thus diminishing the number of responsive cells. In individuals who had anemia secondary to rheumatoid arthritis, the bone marrow contained elevated levels of IL-3, which correlated with diminished expression of integrins on the surface of cells of the erythroid series.[48] Loss of integrins may prevent adequate interaction with stromal cells and matrix proteins and inhibit erythropoiesis.

Anemia associated with chronic renal failure may result from a variety of simultaneous mechanisms. Damage to the kidney affects the secretion of erythropoietin, a necessary hormone for production of erythrocytes in the bone marrow, thus resulting in diminished bone marrow erythropoiesis.[49] Uremic toxins (e.g., uric acid, sulfates, phosphates) that increase in the blood secondarily to renal failure may suppress bone marrow function and damage erythrocytes, which undergo eryptosis. Platelet function also may be defective in these individuals, which results in chronic bleeding and loss of erythrocytes.

Anemia may arise from the direct action of bacterial toxins. For example, *Clostridium perfringens* (gas gangrene and a cause of food poisoning) produces an alpha-toxin. This toxin has enzymatic activity (phospholipase C, sphingomyelinase) that disrupts the membrane of cells. If the cells are erythrocytes, hemolysis will result.

CLINICAL MANIFESTATIONS. The anemia of ACD is usually in the mild to moderate range, with few additional complications. If hemoglobin levels drop significantly, clinical manifestations of IDA appear.

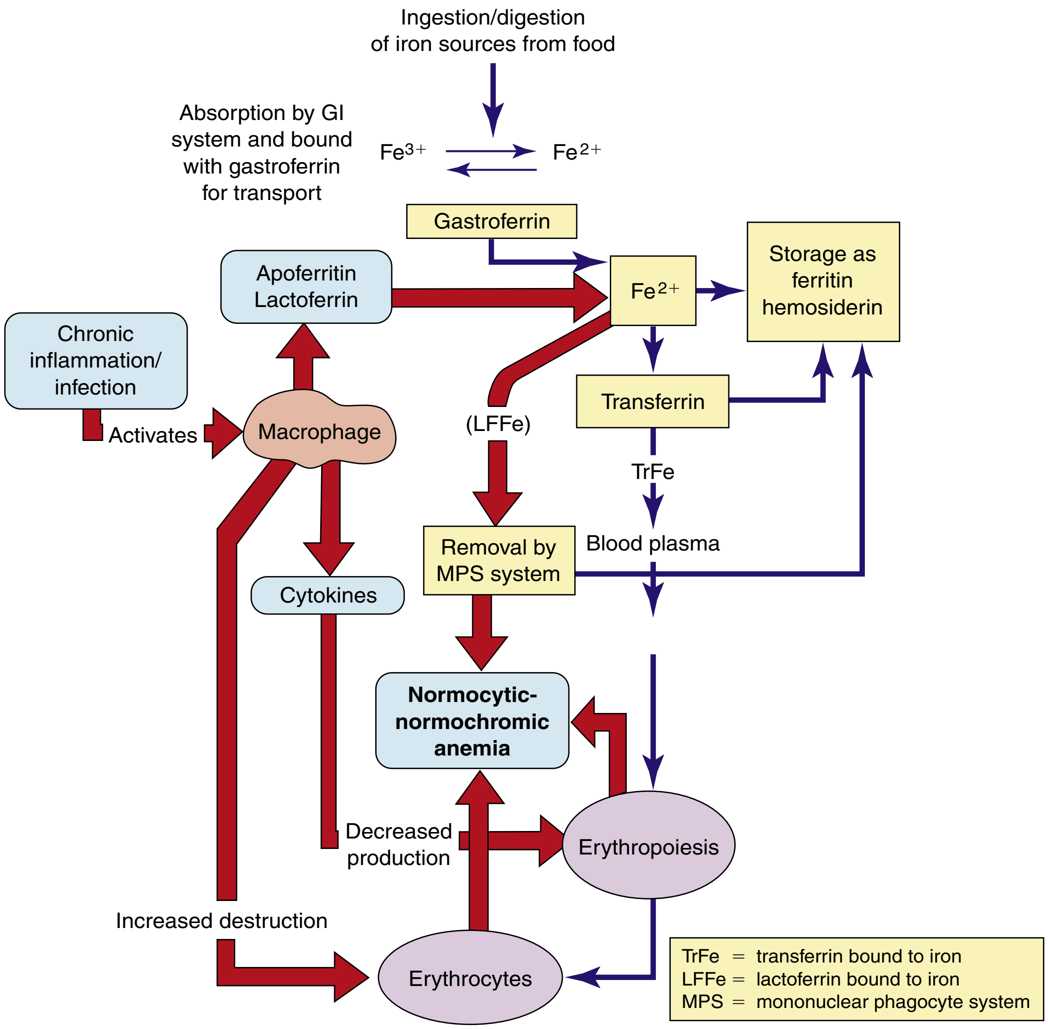

FIGURE 28-7 **Pathophysiology of Anemia of Chronic Disease.** Normal iron metabolism is indicated by the narrow arrows. Abnormal mechanisms that are instrumental in the development of anemia of chronic inflammation are indicated by thick arrows. (See discussion in text.) *GI,* Gastrointestinal.

EVALUATION AND TREATMENT. Morphologically, ACD is initially normocytic-normochromic, but as the condition persists it becomes hypochromic and microcytic. ACD is characterized by abnormal iron metabolism with low levels of circulating iron (less than 60 mcg/dl) and reduced levels of transferrin. The most significant finding of ACD is a very high total body iron storage, although inadequate iron is released from the bone marrow for erythropoiesis. Very often the first indication of ACD is a failure to respond to conventional iron replacement therapy. Levels of erythropoietin are generally lower than expected for the degree of anemia. The affected individuals also frequently present with low or normal total iron-binding capacity (TIBC), normal or high serum ferritin levels, and low concentrations of soluble transferrin receptor (blood test findings are listed in Table 28-3). Occasionally it may be difficult to differentiate ACD from IDA; however, measurement of sTfR may be useful. Levels of sTfR do not respond to iron supplementation in ACD but do so in IDA.

Use of erythropoietin in treatment of ACD associated with arthritis, malignancies, and AIDS has met with limited success. Individuals with severe anemia secondary to chronic kidney disease can be treated successfully with erythropoietin and treatments to increase iron stores.[43] However, the optimal degree of restoration of hemoglobin levels (a measure of anemia) has not been determined; achievement of normal levels increases the risk of hypertension, stroke, and death.[50] Transfusion of critically ill individuals may worsen the outcome and increase morbidity and mortality.[51] The principal treatment is alleviation of the underlying disorder. Individuals who have ACD but demonstrate no evidence of inflammatory or infectious conditions are screened for the presence of malignancies.

MYELOPROLIFERATIVE RED BLOOD CELL DISORDERS

Hematologic dysfunction results from an overproduction of cells as well as a deficiency. One or more hematopoietic lines may be overproduced in the marrow in response to exogenous (e.g., exposure to radiation, drugs) or endogenous (e.g., physiologic compensatory responses, immune disorders) signals. Excessive

red blood cell production is classified as **polycythemia.** Polycythemia exists in two forms: relative and absolute. **Relative polycythemia** results from hemoconcentration of the blood associated with dehydration that may be caused by decreased water intake, diarrhea, excessive vomiting, or increased use of diuretics. Its development is usually of minor consequence and resolves with fluid administration or treatment of the underlying condition.

Absolute polycythemia consists of two forms: primary or secondary. *Secondary polycythemia,* the more common type, is a physiologic response resulting from increased erythropoietin secretion in response to chronic hypoxia. This hypoxia is noted in individuals who live at higher altitudes (i.e., above 10,000 feet), smokers with increased levels of carbon monoxide (CO), and individuals with chronic obstructive pulmonary disease or congestive heart failure, or both. Abnormal types of hemoglobin (e.g., $Hb_{San\ Diego}$ or $Hb_{Chesapeake}$), which have a greater affinity for oxygen, also can cause secondary polycythemia, as does secretion of erythropoietin by certain tumors (e.g., renal cell carcinoma, hepatoma, and cerebral hemiangioblastoma).

Polycythemia Vera

Polycythemia vera (PV) (also known as primary polycythemia) is one of several disorders collectively known as *chronic myeloproliferative disorders* (CMPDs).[52] Others in this group include essential thrombocytosis, chronic idiopathic myelofibrosis, chronic myeloid leukemia, chronic neutrophilic leukemia, and chronic eosinophilic leukemia. All result from abnormal regulation of the multipotent hematopoietic stem cells. The major characteristics shared by these disorders are: (1) involvement of a multipotent hematopoietic progenitor cell; (2) overproduction of one or more of the formed elements of the blood in the absence of a defined stimulus; (3) dominance of a transformed progenitor cell over the nontransformed progenitor cells; (4) marrow hypercellularity or fibrosis; (5) cytogenetic abnormalities; (6) predisposition to thrombus formation and hemorrhage; and (7) spontaneous transformation to acute leukemia. Determining a precise distinction between the CMPDs is difficult if not impossible because of overlapping clinical features and a lack of specific molecular markers. As a result, diagnosis is quite challenging.

PV is quite rare with an estimated incidence of 2.3 per 100,000 individuals; peak incidence is between the ages of 60 and 80 years, with a median incidence of 55 to 60. However, PV has been observed in individuals younger than the age of 40. Males are twice as likely as females to develop PV. PV is more common in whites, particularly those of Eastern European Jewish ancestry, than in blacks. PV is rarely found in children or in multiple members of a single family; however, an autosomal dominant form exists that is characterized by increased production of erythropoietin.

PATHOPHYSIOLOGY. **Polycythemia vera (PV)** is a chronic neoplastic, nonmalignant condition characterized by overproduction of red blood cells (frequently with increased levels of white blood cells [leukocytosis] and platelets [thrombocytosis]) and splenomegaly. Erythrocytosis is the essential component of PV. Clonal proliferation of erythroid progenitors occurs in the bone marrow independent of erythropoietin, although the cells express a normal erythropoietin receptor. However, more than 95% of individuals with PV possess an acquired mutation in Janus kinase 2 *(JAK2)*.[53] *JAK2* increases the activity of the erythropoietin receptor and is self-regulatory so that *JAK2* activity diminishes over time. The mutation associated with PV negates the self-regulatory activity of *JAK2* so that the erythropoietin receptor is constitutively active regardless of the level of erythropoietin.[54] These red blood cell precursors also demonstrate sensitivity to other growth factors, such as interleukin-3 (IL-3), granulocyte-macrophage colony-stimulating factor (GM-CSF), or insulin-like growth factor

CLINICAL MANIFESTATIONS. Almost every individual initially presents with an enlarged spleen, frequently with abdominal pain and discomfort. As the disease progresses many of the symptoms are related to the increased blood cellularity and viscosity. Increased viscosity, as well as thrombocythemia and increased platelet dysfunction, leads to a hypercoagulable state with formation of venous and arterial thrombosis and vessel occlusion.[55] Thrombi with occlusion of major and minor blood vessels lead to tissue and/or organ injury (ischemia) and death (infarction). Extreme thrombocythemia (greater than $1,500,000/mm^3$ of blood) increases the risk for excessive bleeding, rather than thrombosis.

Increased blood viscosity results in a variety of circulatory alterations in PV, such as plethora (ruddy, red color of the face, hands, feet, ears, and mucous membranes) and engorgement of the retinal and cerebral veins. Individuals also may experience headache, drowsiness, delirium, mania, psychotic depression, chorea, and visual disturbances. Death from cerebral thrombosis is increased approximately fivefold in individuals with PV.

Cardiac workload and output remain essentially unchanged; however, increased blood volume may lead to elevated blood pressure. Coronary blood flow may be affected, precipitating angina, although cardiovascular infarctions are relatively rare. Other evidence of cardiovascular involvement is the development of Raynaud phenomenon and thromboangiitis obliterans.

Additionally, gastrointestinal gastric and duodenal thrombosis may occur with resultant hemorrhaging. The development of mesenteric thrombosis requires immediate medical intervention. Splenomegaly and hepatomegaly result from pooling of blood in these organs; consequently, individuals may develop portal hypertension. The respiratory system is generally not affected by PV, unless thrombosis and embolization occur.

A unique feature of PV, one helpful in diagnosis, is the development of intense, painful itching that is intensified by heat or exposure to water (aquagenic pruritus), particularly warm water when bathing or showering. The intensity of the itching is related to the concentration of mast cells in the skin and is generally not responsive to antihistamines or topical lotions.

EVALUATION AND TREATMENT. PV is frequently suspected on the basis of clinical features, such as a thrombotic event, splenomegaly, or aquagenic pruritus. Diagnosis of PV is made from blood and laboratory findings (Box 28-2). An absolute increase in the number of red blood cells and in total blood volume confirms the diagnosis. Hematocrit levels may range from 18 to 24 g/dl and red blood cell counts may range from 7×10^{12} to

BOX 28-2 DIAGNOSTIC CRITERIA FOR POLYCYTHEMIA VERA

Major Criteria (A)

Increased total red blood cell (RBC) volume (RBC mass):
>25% above normal predicted value
M ≥36 ml/kg (Hb >18.5 g/dl)
F ≥32 ml/kg (Hb >16.5 g/dl)
O_2 saturation ≥92%
Splenectomy
Clonal genetic abnormality other than Philadelphia chromosome or *bcr/abl* fusion gene in marrow*
Endogenous erythroid formation in vitro*

Major Criteria (B)

Platelets ≥400,000/μL
WBC count ≥12,000/μL
LAP score >100
Serum B_{12} >900 pg/ml
$UB_{12}BC$ >2200 pg/ml
Panmyelosis (myeloid metaplasia with abnormal immature blood cells in spleen and/or liver) with prominent erythroid/megakaryocytic hyperplasia on marrow biopsy*
Decreased serum erythropoietin levels*

*World Health Organization (WHO) Criteria for Diagnosis: Elevated red cell mass (RCM) and any other major criteria or elevated RCM and any two minor criteria.
LAP, Leukocyte alkaline phosphatase; *$UB_{12}BC$,* unbound B_{12}-binding capacity; *WBC,* white blood cell.

$7 \times 10^{13}/mm^3$. Erythrocytes appear normal but anisocytosis may be present. A bone marrow examination may be done but is not very valuable unless performed in association with cytogenetic and molecular studies for relevant mutations in *JAK2*.[56] The presence of a *JAK2* mutation confirms the diagnosis.[57] Typically the marrow is hypercellular but not in such a manner as to differentiate it from other myeloproliferative disorders. Additional observations on abnormal megakaryocyte morphologies, formation of clusters of abnormal cells, and increased fibrosis add more specificity and usefulness to bone marrow analysis. Elevated serum levels of erythropoietin are not helpful because most individuals with PV have normal or low levels.

Treatment of PV is challenging and directed toward minimizing the risk of thrombosis and preventing progression to myelofibrosis and acute leukemia. In low-risk individuals (e.g., those younger than age 60 or with no history of thrombosis and without risk factors for cardiovascular disease), the recommended therapy is phlebotomy (300 to 500 ml at a time to reduce erythrocytosis and blood volume) and low-dose aspirin. Initial phlebotomies are done two or three times a week until the hematocrit drops sufficiently, and repeated every 3 to 4 months to maintain a safe hematocrit (less than 45%). Aspirin is used for its antithrombotic (decrease in thromboxane) properties.

Hydroxyurea, an antimetabolite that blocks DNA synthesis and reduces vascular cellularity, is the drug of choice for myelosuppression. Unlike other similar drugs, hydroxyurea reduces the risk of thrombotic complications, but does not increase the risk for developing leukemia.[53] Radioactive phosphorus (^{32}P) has been used to suppress erythropoiesis. Its effects may last up to 18 months. Side effects of ^{32}P treatment include suppression of hematopoiesis resulting in anemia, leukopenia, or thrombocytopenia. Acute leukemia also is a side effect, although most often it occurs after 7 or more years of treatment, making this therapy more useful in the elderly.

Interferon-alpha (IFN-α) has been used when other forms of treatment have failed. Interferon inhibits the growth of the abnormal progenitors and inhibits the actions of cytokines that may lead to the development of myelofibrosis. Therapy with IFN-α is complicated by its proinflammatory activities; thus fever, flulike symptoms, and more severe complications are common. IFN-α is not consistently effective in high-risk adult cases, but is considered in individuals who are intolerant to hydroxyurea, younger individuals, and individuals who are pregnant.

Treatment with inhibitors of the *JAK2* pathway has resulted in reduction of many associated disease symptoms (e.g., thrombosis) and a significant improvement in the quality of life.[58] However, the optimal target defining successful treatment (hematocrit) and the effects on life span have not yet been determined. Recent studies comparing the effects of phlebotomy or hydroxyurea, or both, concluded that a goal of maintaining a hematocrit of less than 45% was preferable to the goal of 45% to 50%.[59] The lower target goal resulted in a significantly lower rate of death from cardiovascular causes or major thrombotic events.

Survival for 10 to 15 years is common. However, without proper treatment, 50% of individuals with PV die within 18 months of the onset of initial symptoms. The primary cause of death is thrombosis, which is more prevalent in elderly individuals and those with prior vascular complications. Death because of hemorrhage is rare but more common in individuals with high platelet counts and those taking antiplatelet drugs. Conversion to acute myeloid leukemia (AML) occurs spontaneously in 10% of individuals within 15 years, increasing to 50% within 20 years. This leukemia is generally refractory to conventional treatment. Conversion to AML is most likely related to treatment with cytotoxic myelosuppressive agents, such as chlorambucil.[57] Those individuals treated only with IFN or hydroxyurea had the same incidence of conversion as those who received no treatment. Although PV is a chronic disorder, appropriate therapy results in remissions and prevention of significant morbidity.

Iron Overload

Iron overload can be primary, as in hereditary hemochromatosis, or secondary. The secondary causes of iron overload include anemias with inefficient erythropoiesis (e.g., sideroblastic anemia, aplastic anemia), dietary iron overload, or conditions that require repeated blood transfusions or iron dextran injections.

Hereditary hemochromatosis (HH) is a common inherited, autosomal recessive disorder of iron metabolism and is characterized by increased gastrointestinal iron absorption with subsequent tissue iron deposition. Excess iron is deposited in the liver, pancreas, heart, joints, and endocrine glands, causing tissue damage that can lead to diseases such as cirrhosis, diabetes, heart failure, arthropathies, and impotence.[60]

HH is caused by two genetic base-pair alterations, C282Y and H63D. These are mutations in the *HFE* gene on chromosome 6. Homozygosity of C282Y is the most common genotype and accounts for 82% to 90% of HH cases. The remaining cases appear to be caused by environmental factors or other genotypes. *HFE* mutations are common in the United States with 1 in 10 white individuals heterozygous for the *HFE* C282Y mutation and 4.4 in 1000 homozygous for the C282Y mutation. C282Y homozygosity is much lower among Hispanics (0.27 in 1000), Asian Americans (<0.001 per 1000), Pacific Islanders (0.12 per 1000), and blacks (0.14 per 1000).

PATHOPHYSIOLOGY. Studies in mice have confirmed that the *HFE* gene is responsible for HH. HFE protein, found in the crypt cells of the duodenum, facilitates transferrin receptor–dependent iron uptake into crypt cells. Mutant HFE protein loses its functional ability and causes a relative iron deficiency in duodenal crypt cells. The deficiency results in an increase in the expression of an iron transport protein, divalent metal ion transporter 1 (DMT-1), which is responsible for dietary iron absorption in the villus cells of the small intestine. This inappropriate intestinal iron absorption leads to iron overload and, eventually, end-organ damage that can result in cirrhosis, diabetes mellitus, hypothyroidism, cardiomyopathies, and arthritis.

Although the natural history of HH is not well understood, there appears to be a long latent period with individual variation in biochemical expression modified by environmental factors, such as blood loss from menstruation or donation, alcohol intake, and diet. Cirrhosis is a late-stage development of HH that can shorten life expectancy. Cirrhosis also is a risk factor for hepatocellular carcinoma that occurs between 40 and 60 years old. Cirrhosis prevention is a major goal of HH screening and treatment.

CLINICAL MANIFESTATIONS. Clinical manifestations of HH include symptoms such as fatigue, malaise, abdominal pain, arthralgias, and impotence, and clinical findings of hepatomegaly, abnormal levels of liver enzymes, bronzed skin, diabetes, and cardiomegaly. Many individuals are diagnosed as a result of serum iron studies as part of a health screening panel. Most (>75%) are asymptomatic and have a low frequency (<25%) of cirrhosis, diabetes, or skin pigmentation.

EVALUATION AND TREATMENT. Laboratory findings in individuals with HH show elevations in serum iron levels, transferrin saturation, and ferritin levels. Documentation of iron overload relies on quantitative phlebotomy with calculation of the amount of iron removed, or liver biopsy with determination of quantitative hepatic iron. With the advent of genetic testing, individuals who are C282Y homozygous or compound heterozygous, less than 40 years old, and have normal liver functions, no further workup is necessary.

Treatment of HH is simple and consists of phlebotomy of 550 ml of whole blood, which is equivalent to 200 to 250 mg of iron. Frequency of phlebotomy depends on ferritin levels and should continue until the ferritin level is between 20 and 50 ng/ml. Initially, phlebotomy may be needed weekly but once therapeutic ferritin levels are reached, phlebotomy may only be needed every 2 to 3 months. Blood banks now accept blood donations from persons with documented HH. Iron chelating agents are sometimes used in addition to phlebotomy, but this is not the mainstay of treatment. Individuals with HH should be instructed to refrain from taking iron and vitamin C supplements and consuming raw shellfish; in addition, alcohol should be used in moderation. Family screening is recommended and necessary for all first-degree relatives of a person with HH.

SUMMARY REVIEW

Anemia

1. Anemia is defined as a reduction in the number or volume of circulating erythrocytes or a decrease in hemoglobin level. Polycythemias are excessive levels of erythrocytes or volume.
2. Anemias can be classified according to (a) erythrocyte size or concentration of hemoglobin or (b) their cause.
3. Clinical manifestations of anemia may be demonstrated in all organs and tissues (tissue hypoxia) throughout the body. Decreased oxygen delivery to tissues causes fatigue, dyspnea, syncope, angina, compensatory tachycardia, and organ dysfunction.
4. Macrocytic-normochromic, or megaloblastic-normochromic, anemias are characterized by larger than normal erythrocytes with normal levels of hemoglobin. They most commonly are caused by deficiency of vitamin B_{12} (PA) or folate.
5. PA results from inadequate vitamin B_{12} absorption because of autoantibodies against the B_{12} transporter IF. Folate deficiency anemia is caused by inadequate dietary intake of folate. Both anemias respond to replacement therapy.
6. Microcytic-hypochromic anemias are characterized by abnormally small erythrocytes with insufficient hemoglobin content. This disorder results from disorders of (a) iron metabolism (IDA), (b) porphyrin and heme synthesis (SAs), or (c) globin synthesis (thalassemia).
7. IDA is the most common type of anemia worldwide. It usually develops slowly, with gradual insidious onset of symptoms. Fatigue, weakness, dyspnea, alteration of various epithelial tissues, and vague neuromuscular complaints result.
8. IDA is usually a result of blood loss or poor nutritional intake. Individuals at highest risk for developing IDA include older adults, women, infants, and those living in poverty. Anemia is also recognized as part of the nonspecific acute phase response to any type of inflammation. Once the source of blood loss is identified and corrected, oral iron replacement therapy can be initiated.
9. SA results from defects in mitochondrial metabolism leading to ineffective iron uptake and dysfunctional heme synthesis. The characteristic cell in the bone marrow, a ringed sideroblast, is an erythroblast containing iron granules arranged around the nucleus. SAs may be hereditary or acquired, and treatment varies depending on the cause.
10. Normocytic-normochromic anemias are characterized by insufficient numbers of normal erythrocytes. Included in this category are aplastic, posthemorrhagic, and hemolytic anemias and ACD.

SUMMARY REVIEW—cont'd

11. AA is a critical condition characterized by a reduction or absence of all three blood cell types (pancytopenia). Unless the cause is determined, bone marrow aplasia results in death.
12. Acute blood loss from hemorrhage results in posthemorrhagic anemia with the severity depending on the amount of hemorrhage. Restoration of blood volume by plasma expanders or transfusions may diminish subjective symptoms of anemia. Hemoglobin restoration may take 6 to 8 weeks.
13. Hemolytic anemia is a result of excessive destruction of erythrocytes and may be acquired or hereditary. Of the acquired forms, autoimmune reaction (immunohemolytic) and drug-induced hemolysis are the most common.
14. AIHAs include (a) warm reactive antibody type, (b) cold agglutinin type, and (c) cold hemolysin type (paroxysmal cold hemoglobinuria).
15. ACD results from decreased erythropoiesis secondary to chronic diseases. The anemia is mild to moderate and one of the most common conditions encountered in medicine.
16. Mechanisms associated with ACD include (a) decreased erythrocyte life span, (b) reduced production of erythropoietin, (c) ineffective bone marrow response to erythropoietin, and (d) iron sequestration in macrophages. In particular, the proinflammataory cytokine IL-6 increases hepatocyte release of hepcidin, which suppresses ferroportin transport of iron out of macrophages.

Myeloproliferative Erythrocyte Disorders (Polycythemia)

1. Polycythemia vera is a myeloproliferative disorder characterized by excessive proliferation of erythrocyte precursors in the bone marrow. Signs and symptoms result directly from increased blood volume and viscosity and a predisposition to thrombosis.
2. Therapeutic phlebotomy to remove excessive blood volume and the use of hydroxyurea have been helpful in decreasing the excessive erythrocyte population.

CHAPTER OUTLINE

There are many disorders involving leukocytes, ranging from deficiencies in the quality and quantity of leukocytes (leukopenia) to increased numbers of leukocytes (leukocytosis) in response to infections or proliferative disorders, such as leukemia. Many hematologic disorders are malignancies, and many nonhematologic malignancies act like malignancies and can metastasize to bone marrow, affecting leukocyte production. Because of the complexity of hematologic disorders a large portion of this chapter is devoted to malignant disease.

The primary role of clotting (hemostasis) is to stop bleeding through an interaction among the vascular endothelium, platelets, and the clotting system. Many disease states are associated with clinically significant aberrations in any of these three necessary components of clotting. This chapter discusses various components of clotting and their control systems.

ALTERATIONS OF LEUKOCYTE FUNCTION

Leukocyte function is affected if too many or too few white cells are present in the blood or if the cells that are present are structurally or functionally defective. **Quantitative leukocyte disorders,** such as infections and leukemias, result from decreased production in the bone marrow or accelerated destruction of cells in the circulation. Other quantitative alterations, however, occur in response to infections.

Qualitative leukocyte disorders consist of disruptions of leukocyte function. Phagocytic cells (granulocytes, monocytes, macrophages) may lose their phagocytic capacity to function. Lymphocytes may lose their capacity to respond to antigens. (Qualitative disruptions of inflammatory and immune processes caused by leukocyte disorders are described in Chapter 9.) Other leukocyte alterations include infectious mononucleosis and cancers of the blood—leukemia and multiple myeloma.

Quantitative Alterations of Leukocytes

Leukocytosis is a leukocyte count that is higher than normal; conversely, **leukopenia** is a count that is lower than normal. Leukocytosis or leukopenia may affect all cell types or only a specific type of leukocyte and may result from a variety of physiologic conditions and alterations.

Leukocytosis occurs as a normal protective response to physiologic stressors, such as infection, strenuous exercise, emotional changes, temperature changes, anesthesia, surgery, pregnancy, and some drugs, hormones, and toxins. It is also caused by pathologic conditions, such as malignancies and hematologic disorders. Leukopenia is never normal and is defined as an absolute blood cell count less than 4000 cells/mm^3. Leukopenia is associated with a decrease in neutrophils, which increases risk for infection. The absolute neutrophil count (ANC) is calculated by multiplying the white blood cell count by the percent of band and segmented neutrophils. The ANC is classified as mild (1000 to 1500 cells/mm^3), moderate (500 to 1000 cells/mm^3), or severe (<500 cells/mm^3). When the ANC is less than 500/mm^3, the possibility for life-threatening infections is high. Leukopenia can be caused by radiation, anaphylactic shock, autoimmune disease (e.g., systemic lupus erythematosus), immune deficiencies (see Chapter 9), and exposure to certain drugs and chemotherapeutic agents.

Granulocytes and Monocytes

Increased numbers of circulating granulocytes (neutrophils, eosinophils, basophils) and monocytes are primarily a response to infection. Increased numbers also occur as a result of myeloproliferative disorders (i.e., polycythemia vera, chronic myelogenous leukemia, chronic neutrophilic leukemia, chronic eosinophilic leukemia) that increase stem cell proliferation in bone marrow.

Decreased numbers occur when infectious processes exhaust the supply of circulating granulocytes and monocytes by drawing them out of the circulation and into infected tissues faster than they can be replaced. Decreases also can be caused by disorders that suppress marrow function.

Granulocytosis—an increase in the number of granulocytes (neutrophils, eosinophils, basophils)—begins with the release of stored leukocytes from the venous sinuses of the marrow. **Neutrophilia** is another term that may be used to describe *granulocytosis* because neutrophils are the most numerous of the granulocytes (Table 29-1). Neutrophilia occurs in the early stages of infection or inflammation and is established when the absolute neutrophil count exceeds 7500/μL. Stored neutrophils are approximately 20 to 40 times greater in number than circulating neutrophils. On rare occasions when the neutrophil count increases greatly—more than 100,000/μL (usually seen only in those with myelocytic leukemia)—the blood viscosity may increase greatly so that thrombosis or occlusion of blood vessels occurs. Release and depletion of stored neutrophils from the venous sinuses stimulate granulopoiesis to replenish neutrophil reserves. Specific conditions associated with neutrophilia are identified in Table 29-1.

When the demand for circulating mature neutrophils exceeds the supply, the marrow begins to release immature neutrophils (and other leukocytes) into the blood. Premature release of the immature white cells is responsible for the phenomenon known as a **shift-to-the-left** or **leukemoid reaction.** This refers to the microscopic detection of disproportionate numbers of immature leukocytes in peripheral blood smears. Many diagrams present cellular differentiation and maturation progressing from left to right within the drawing, instead of vertically as shown in Figure 27-10. When immature leukocytes are released prematurely they cause a shift in the distribution of cells in the blood toward the left side, or immaturity side, of the diagram. This phenomenon is also seen in the blood smear of individuals with leukemia as well, hence the term *leukemoid reaction.* As infection or inflammation diminishes and as granulopoiesis replenishes circulating granulocytes, a shift back to normal occurs.

Neutropenia is a condition associated with a reduction in the number of circulating neutrophils. Clinically, neutropenia exists when the neutrophil count is less than 2000/μL.[1] The absolute neutrophil count reflects not only the degree of neutropenia but also the risk for infection (see preceding discussion of leukocytosis). A reduction in the number of neutrophils can occur in severe, prolonged infections when production of granulocytes cannot keep up with demand.

Other causes of neutropenia, in the absence of infection, may be (1) decreased neutrophil production or ineffective granulopoiesis, (2) reduced neutrophil survival, and (3) abnormal neutrophil distribution and sequestration. Neutropenia also is categorized as primary or secondary; primary disorders are further identified as congenital or acquired.

Congenital defects in neutrophil production include cyclic neutropenia and neutropenia with congenital immunodeficiency diseases, as well as multiple syndromes (e.g., Kostmann, Shwachman-Diamond, Diamond-Blackfan, Griscelli, Chédiak-Higashi, and Barth syndromes). Primary acquired neutropenia is associated with multiple conditions, for example, hypoplastic anemia or aplastic anemia, leukemia (acute myelogenous leukemia [AML]/chronic lymphocytic leukemia [CLL]), lymphomas (Hodgkin, non-Hodgkin), and myelodysplastic syndrome (MDS). The megaloblastic anemias (vitamin B_{12} and folate deficiency) as well as starvation and anorexia nervosa cause neutropenia because of an inadequate supply of vitamins and nutrients for protein production.

Reduced neutrophil survival and abnormal distribution and sequestration are usually secondary to other disorders. Neutropenia occurs in a variety of immunologic disorders, particularly systemic lupus erythematosus, rheumatoid arthritis, Felty and Sjögren syndromes, splenomegaly, and drug-related causes.

Severe neutropenia, **granulocytopenia** (less than 500/μL), or **agranulocytosis** (complete absence of granulocytes in the blood) is usually secondary to arrested hematopoiesis in the bone marrow or massive cell destruction in the circulation.

Chemotherapeutic agents used to treat hematologic and other malignancies cause generalized bone marrow suppression. Several other drugs and large doses of ionizing radiation cause agranulocytosis, which occurs rarely but carries a high mortality (10% to 50%). Clinical manifestations of agranulocytosis

include recurrent and persistent life-threatening infection (particularly of the respiratory system) leading to septicemia, general malaise, fever, tachycardia, and ulcers in the mouth and colon. If untreated, sepsis caused by agranulocytosis results in death within 3 to 6 days.

Eosinophilia is an absolute increase (more than 450/μL) in the total numbers of circulating eosinophils. Allergic disorders (type I hypersensitivity) associated with asthma, hay fever, and drug reactions, as well as parasitic infections (particularly with metazoal parasites) are often cited as causes. Hypersensitivity

TABLE 29-1 OTHER CONDITIONS ASSOCIATED WITH NEUTROPHILS, EOSINOPHILS, BASOPHILS, MONOCYTES, AND LYMPHOCYTES

CONDITION	CAUSE	EXAMPLE
Neutrophil		
Neutrophilia (granulocytosis)	Inflammation or tissue necrosis	Surgery, burns, MI, pneumonitis, rheumatic fever, rheumatoid arthritis
	Infection	Bacterial: gram-positive (staphylococci, streptococci, pneumococci), gram-negative (*Escherichia coli, Pseudomonas* species)
	Physiologic	Exercise, extreme heat or cold, third-trimester pregnancy, emotional distress
	Hematologic	Acute hemorrhage, hemolysis, myeloproliferative disorder, chronic granulocytic leukemia
	Drugs or chemicals	Epinephrine, steroids, heparin, histamine, endotoxin
	Metabolic	Diabetes (acidosis), eclampsia, gout, thyroid storm
	Neoplasm	Liver, GI tract, bone marrow
Neutropenia	Decreased marrow production	Radiation, chemotherapy, leukemia, aplastic anemia, abnormal granulopoiesis
	Increased destruction	Splenomegaly, hemodialysis, autoimmune disease
	Infection	Gram-negative (typhoid), viral (influenza, hepatitis B, measles, mumps, rubella), severe infections, protozoal infections (malaria)
Eosinophil		
Eosinophilia	Allergy	Asthma, hay fever, drug sensitivity
	Infection	Parasites (trichinosis, hookworm), chronic (fungal, leprosy, TB)
	Malignancy	CML, lung, stomach, ovary, Hodgkin disease
	Dermatosis	Pemphigus, exfoliative dermatitis (drug-induced)
	Drugs	Digitalis, heparin, streptomycin, tryptophan (eosinophilia-myalgia syndrome), penicillins, propranolol
Eosinopenia	Stress response	Trauma, shock, burns, surgery, mental distress
	Drugs	Steroids (Cushing syndrome)
Basophil		
Basophilia	Inflammation	Infection (measles, chickenpox), hypersensitivity reaction (immediate)
	Hematologic	Myeloproliferative disorders (CML, polycythemia vera, Hodgkin lymphoma, hemolytic anemia)
	Endocrine	Myxedema, antithyroid therapy
Basopenia	Physiologic	Pregnancy, ovulation, stress
	Endocrine	Graves disease
Monocyte		
Monocytosis	Infection	Bacterial (subacute bacterial endocarditis, TB), recovery phase of infection
	Hematologic	Myeloproliferative disorders, Hodgkin disease, agranulocytosis
	Physiologic	Normal newborn
Monocytopenia	Rare	
Lymphocyte		
Lymphocytosis	Physiologic	4 months to 4 years
	Acute infection	Infectious mononucleosis, CMV infection, pertussis, hepatitis, mycoplasma pneumonia, typhoid
	Chronic infection	Congenital syphilis, tertiary syphilis
	Endocrine	Thyrotoxicosis, adrenal insufficiency
	Malignancy	ALL, CLL, lymphosarcoma cell leukemia
Lymphocytopenia	Immunodeficiency syndrome	AIDS, agammaglobulinemia
	Lymphocyte destruction	Steroids (Cushing syndrome), radiation, chemotherapy, Hodgkin lymphoma, CHF, renal failure, TB, SLE, aplastic anemia

AIDS, Acquired immunodeficiency syndrome; *ALL,* acute lymphocytic leukemia; *CHF,* congestive (left) heart failure; *CLL,* chronic lymphocytic leukemia; *CML,* chronic myelogenous leukemia; *CMV,* cytomegalovirus; *GI,* gastrointestinal; *MI,* myocardial infarction, *SLE,* systemic lupus erythematosus; *TB,* tuberculosis.

reactions and the normal defense against parasites trigger the release of eosinophil chemotactic factor of anaphylaxis (ECF-A) from mast cells, attracting eosinophils to the area. (These processes are described and illustrated in Chapters 8 and 9.) Tissues with abundant mast cells, such as the respiratory and gastrointestinal tracts, are particularly common sites for eosinophil invasion. Mast cells also release interleukin-5 (IL-5), which stimulates the bone marrow to produce and release more eosinophils into the blood. Eosinophilia may also be associated with dermatologic disorders, such as atopic dermatitis, eczema, and pemphigus. Various types of eosinophilic scleroderma-like diseases also have been reported to occur in association with hemato-oncogenic disorders (i.e., eosinophilic cellulitis [Wells syndrome] and eosinophilic fasciitis [Shulman syndrome]). Increased numbers of eosinophils have been observed in individuals with eosinophilia-myalgia syndrome (EMS), which is associated with ingestion of the supplement L-tryptophan. EMS may develop in individuals with fibromyalgia syndrome as an allergic reaction to L-tryptophan.[2]

Eosinopenia, a decrease in circulating numbers of eosinophils, generally is caused by migration of eosinophils into inflammatory sites. It also may be seen in Cushing syndrome and as a result of stress caused by surgery, shock, trauma, burns, or mental distress. Other conditions causing eosinopenia are detailed in Table 29-1.

Basophilia, an increase in circulating numbers of basophils, is rare and generally is a response to inflammation and immediate hypersensitivity reactions. Basophils contain histamine that is released during an allergic reaction. An increase in the levels of basophils is seen also in myeloproliferative disorders, such as chronic myeloid leukemia and myeloid metaplasia. Other conditions associated with basophilia are listed in Table 29-1.

Basopenia (also known as *basophilic leukopenia*), a decrease in circulating numbers of basophils, is seen in hyperthyroidism, acute infection, and long-term therapy with steroids. A decrease in the number of basophils may be seen during ovulation and pregnancy. Other conditions associated with basopenia are listed in Table 29-1.

Monocytosis is an increase (generally greater than 800/μL) in numbers of circulating monocytes. The condition is often transient and not related to a dysfunction of monocyte production. When present, it most commonly occurs with neutropenia associated with bacterial infections, particularly in the late stages or recovery stage, when monocytes are needed to phagocytize surviving microorganisms and debris. Monocytosis often is seen in chronic infections, usually with intracellular bacteria, such as tuberculosis (TB), brucellosis, listeriosis, and subacute bacterial endocarditis (SBE). Peripheral monocytosis has been found to correlate with the extent of myocardial damage following myocardial infarction. Increased numbers of monocytes also may indicate marrow recovery from agranulocytosis. Other conditions associated with monocytosis are identified in Table 29-1.

Monocytopenia, a decrease in numbers of circulating monocytes, is rare, and not much is known about this condition because of the small numbers of monocytes generally present in the blood. Monocytopenia, however, has been identified with hairy cell leukemia and prednisone therapy.

Lymphocytes

Quantitative alteration of lymphocytes occurs when lymphocytes are activated by antigenic stimuli, usually microorganisms (see Chapter 8). **Lymphocytosis** is rare in acute bacterial infections and occurs most commonly in acute viral infections, particularly those caused by the Epstein-Barr virus (EBV), a causative agent in infectious mononucleosis. Other specific disorders associated with lymphocytosis are listed in Table 29-1.

Lymphocytopenia may be attributable to (1) abnormalities of lymphocyte production associated with neoplasias and immune deficiencies, and (2) destruction by drugs, viruses, or radiation. It also can occur in individuals for no apparent reason. Other conditions associated with lymphocytopenia are identified in Table 29-1. The lymphocytopenia associated with heart failure and other acute illnesses may be caused by elevated levels of cortisol. Lymphocytopenia is a major problem in acquired immunodeficiency syndrome (AIDS) in which the human immunodeficiency virus (HIV) is cytopathic for T helper lymphocytes. (For a more detailed discussion of AIDS, see Chapter 10.)

Infectious Mononucleosis

Infectious mononucleosis (IM) is an acute, self-limiting, neoplastic lymphoproliferative clinical syndrome characterized by acute viral infection of B lymphocytes (B cells). The most common etiologic agent is EBV, a ubiquitous, lymphotrophic, gamma-group herpesvirus that was first recognized as the causative agent in IM in the late 1960s. EBV accounts for approximately 85% of all IM cases. Other etiologic agents that may cause symptoms resembling IM are viruses (cytomegalovirus [CMV], adenovirus, HIV, hepatitis A, influenza A and B, and rubella), as well as the bacteria *Toxoplasma gondii, Corynebacterium diphtheriae,* and *Coxiella burnetii.* IM caused by CMV is generally noted in older individuals, with fever and malaise the major complaints; the major manifestations of EBV-induced IM are the classic triad of symptoms of pharyngitis, lymphadenopathy, and fever.

Approximately 50% to 85% of children are infected with EBV by age 4, and more than 90% of adults have indications of subclinical EBV infections. These early infections are usually asymptomatic and provide immunity to EBV; thus early EBV infections rarely develop into IM. IM may arise when the initial infection occurs during adolescence or later, but still only results in IM in 35% to 50% of these individuals. Symptomatic IM usually affects young adults between ages 15 and 35 years, with the peak incidences occurring between 15 and 24 years; males have a later peak (18 to 24 years) than females. The overall incidence rate for this age group is 6 to 8 cases per 1000 persons per year. Children from low socioeconomic environments are particularly susceptible to infections with EBV. IM is uncommon in individuals older than age 40, but if it does occur, it is more commonly caused by CMV.

Transmission of EBV is usually by saliva through personal contact (e.g., kissing, hence the term "kissing disease"). The virus also may be present in other mucosal secretions of the genital, rectal, and respiratory tract, as well as blood. No evidence of aerosol transmission through sneezing or coughing has been documented. The disease begins with widespread infection of B lymphocytes, all of which possess receptors for EBV. The virus initially infects the oropharynx, nasopharynx, and salivary epithelial cells with later spread to the lymphoid tissue and B cells. Infection of B cells permits the virus to enter the bloodstream, which spreads the infection systemically.

PATHOPHYSIOLOGY. In the immunocompetent individual, unaffected B cells produce antibodies (IgG, IgM, IgA) against the virus. Concomitantly, there is a massive activation and proliferation of cytotoxic T cells (CD8) directed against EBV-infected cells; CD8 lymphocytes can account for greater than 50% of the total circulating lymphocytes. The immune response against EBV-infected cells (cellular infiltration, production of cytokines) is largely responsible for the cellular proliferation in the lymphoid tissues (lymph nodes, spleen, tonsils, occasionally liver). Sore throat and fever, two of the earliest manifestations, are caused by inflammation at the site of viral entry and initial infection (the mouth and throat).

CLINICAL MANIFESTATIONS. The incubation period of IM is approximately 30 to 50 days (4 to 8 weeks) followed by a 3- to 5-day prodrome of fever, malaise, and arthralgias that are often attributed to viral infection, although some individuals remain asymptomatic. These symptoms may vary in severity for the next 7 to 20 days. At the time of diagnosis the individual usually has the classic triad of symptoms: fever, pharyngitis, and lymphadenopathy of the cervical lymph nodes. The pharyngitis is usually diffuse and often accompanied by a whitish or grayish green, thick exudate. It also is quite painful and is the symptom that most often causes the individual to seek treatment. IM is usually self-limiting, and recovery occurs in a few weeks. Fatigue may last for 1 to 2 months after resolution of the infection.

Although severe clinical complications are rare, as the condition progresses generalized lymph node enlargement may develop and enlargement of the spleen and liver also may occur. Splenomegaly is clinically evident 50% of the time and is demonstrated radiologically 100% of the time. Difficulty in detecting splenomegaly with physical examination contributes to the underestimation of actual enlargement. Splenic rupture is rare (only 0.1% to 0.5% of all cases) and can occur spontaneously as a result of mild trauma, occurring primarily in men younger than 25 years of age and between days 4 and 21 after the onset of symptoms. It is the most common cause of death related to IM. Other causes of fatalities are hepatic failure, extensive bacterial infection, or viral myocarditis.

Other organ systems are rarely involved, but such involvement may result in additional symptoms, such as meningitis, encephalitis, Guillain-Barré syndrome, Bell palsy, optic neuritis, mental impairment, transverse myelitis, cerebellar ataxia, and demyelinating diseases. Ocular manifestations may include eyelid and periorbital edema, dry eyes, keratitis, uveitis, conjunctivitis, retinitis, oculoglandular syndrome, choroiditis, papillitis, and ophthalmoplegia. In children, Reye syndrome also has been associated with EBV infection.

Pulmonary involvement is rare, but when present may include hilar and mediastinal lymphadenopathy, interstitial pneumonitis, and pleural effusion. Pneumonia and respiratory failure have been documented; however, they are more likely to develop in immunocompromised individuals. Approximately 3% to 10% of adults older than 40 years of age have never been infected with EBV and are susceptible to IM later in life. In these individuals the classic symptoms are not generally present, making diagnosis more difficult. If an older individual has an elevated temperature that cannot be explained and persists for more than 2 weeks, EBV infection should be suspected, particularly in the presence of abnormal liver function tests with hepatomegaly and jaundice. Other neurologic manifestations that may be present include peripheral neuropathy and Guillain-Barré syndrome.

EVALUATION AND TREATMENT. The blood of affected individuals contains an increased number of atypical lymphocytes (Figure 29-1). Diagnosis of IM is commonly based on Hoagland's criteria of at least 50% lymphocytes and at least 10% atypical lymphocytes in the blood in the presence of fever,

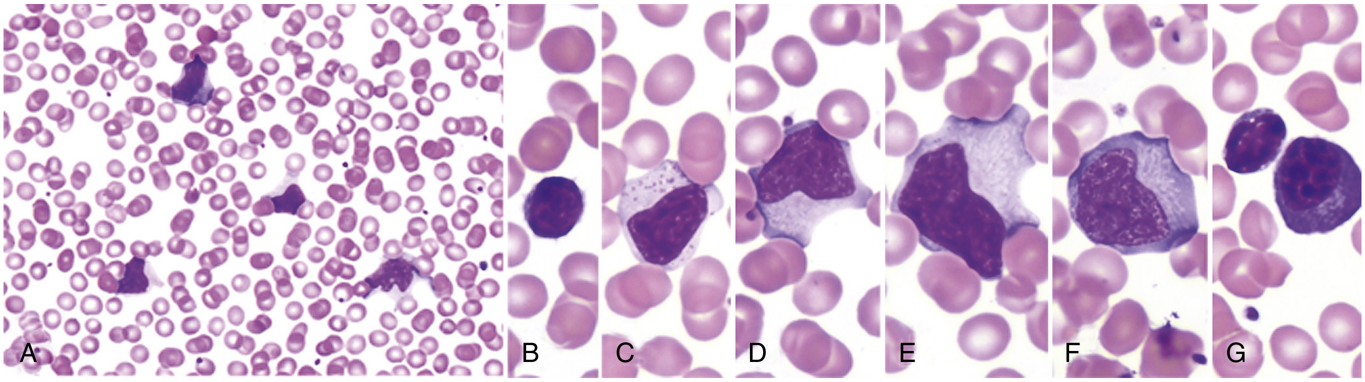

FIGURE 29-1 Peripheral Blood Smear in Infectious Mononucleosis. Low power **(A)** shows moderately high white blood cell count and high number of reactive, or "atypical," lymphocytes. Higher power **(B-G)** illustrates the spectrum of lymphoid morphology, including small resting lymphocyte **(B)** for comparison, large granular lymphocyte **(C),** atypical forms **(D-F),** also referred to as "reactive" lymphs, and circulating plasma cell **(G).** (From Hoffman R et al: *Hematology: basic principles and practice,* ed 6, Philadelphia, 2013, Churchill Livingstone.)

pharyngitis, and adenopathy confirmed by a positive serologic test. Serologic tests are used to determine a heterophile antibody response.[3] **Heterophile antibodies** are a heterogeneous group of immunoglobulin M (IgM) antibodies that are agglutinins against nonhuman red blood cells (e.g., sheep, horse) and are detected by qualitative (Monospot) or quantitative methods (heterophile antibody test).

The Monospot test is limited because other infections (e.g., CMV, adenovirus) and toxoplasmosis also produce heterophilic antibodies. Thus 5% to 15% of Monospot tests yield false-positive results. Levels of heterophilic antibodies in the blood increase as the condition progresses, although some individuals and children younger than age 4 years do not produce them. These individuals give a false-negative result. Specificity for diagnosis of EBV infection may be increased with viral-specific serologic tests that identify EBV-specific antibodies (e.g., IgG or IgM against the viral capsid antigen [VCA], or IgG against the EBV nuclear antigen [EBNA]). These tests are more expensive and labor intensive; therefore they are reserved for instances in which the Monospot test is not appropriate.

Because IM is usually self-limiting, medical intervention is rarely required. Treatment of IM is supportive and includes rest and alleviation of symptoms with analgesics and antipyretics. Ibuprofen, *not aspirin,* is used with children and adolescents because of the reported incidence of Reye syndrome associated with EBV infection. Pharyngitis of streptococcal origin, which occurs in 20% to 30% of cases, is treated with penicillin or erythromycin. Ampicillin is contraindicated because it causes a rash in most individuals with IM.

Bed rest and avoidance of strenuous activity should be included in the therapy. Steroids may be used, but only in the presence of severe complications (e.g., impending airway obstruction) or other organ system involvement (e.g., nervous system manifestations, thrombocytopenic purpura, myocarditis, pericarditis). Acyclovir has been used with immunosuppressed individuals; however, clinical improvement has been minimal and therefore it is not recommended for standard treatment.

In the rare event of splenic rupture, the treatment has been removal of the spleen and continues to be the choice in hemodynamically unstable individuals. However, new research is suggesting that it may be better to repair the spleen to avoid overwhelming post-splenectomy infection (OPSI). Children are at greater risk of OPSI than adults. Post-splenectomy vaccinations for *Streptococcus pneumoniae, Haemophilus influenzae,* and *Meningococcus* are essential because these microorganisms are responsible for 92% of fatal infections. Treatment may also be necessary for airway obstruction from massive edema of the Waldeyer ring or for autoimmune hemolytic anemia, which occurs in approximately 3% to 5% of cases.

Fatal IM also is expressed with the inherited X-linked lymphoproliferative (XLP) syndrome (Duncan disease). Duncan disease is a rare disorder characterized by severe dysregulation of the immune system, often in response to EBV. The underlying cause leading to death is the absence of a functional SAP protein that allows for the unregulated proliferation of cytotoxic T cells and the concomitant production and release of cytokines.

Leukemias

Leukemia is a clonal malignant disorder of leukocytes in the blood and blood-forming organs. The common feature of all forms of leukemia is an uncontrolled proliferation of malignant leukocytes, causing an overcrowding of bone marrow and decreased production and function of normal hematopoietic cells. The first description of a "leukemic" individual was written by Velpeau in 1827.[4] Virchow, a pathologist, coined the term *white blood (Weissus blut)* and later originated the term *leukemia.* Since Virchow's initial discovery, the overall classification of leukemia has become increasingly complex and undergone several permutations.

The current classification of leukemia is based on (1) the predominant cell of origin (either myeloid or lymphoid) and (2) the rate of progression, which usually reflects the degree at which cell differentiation was arrested when the cell became malignant (acute or chronic) (Figure 29-2). **Acute leukemia** is characterized by undifferentiated or immature cells, usually a blast cell, and the onset of disease is abrupt and rapid with a short survival time. In **chronic leukemia** the predominant cell is more differentiated but does not function normally, with a relatively slow progression. There are four types of leukemia: acute lymphocytic (ALL), acute myelogenous (AML), chronic lymphocytic (CLL), and chronic myelogenous (CML). In 1976 the French-American-British Cooperative Group developed more extensive criteria for the classification of acute leukemias. This system is based on characteristics that may provide significant therapeutic prognostic information, such as structure, number of cells, genetics, identification of surface markers, and histochemical staining. Since this time, the World Health Organization has developed a classification that incorporates more recent research on the genetics and clinical features of AML that have prognostic and therapeutic relevance.[5]

Leukemia occurs with varying frequencies at different ages and is more common in adults than children (Figure 29-3). It is estimated that more than 44,600 cases of leukemia were newly diagnosed in 2011, with males having a slightly higher incidence than females (Table 29-2).[6] In all types of leukemia males have a higher incidence rate (56%) as do Americans of European descent. White children have higher rates of leukemia than children of other racial groups. ALL is the least common type overall, but is the most common in children (approximately 66% of ALL cases are diagnosed before the age of 20). Leukemia accounts for about 34% of all childhood cancers, and ALL accounts for almost 78% of all new cases of leukemia in children. CLL and AML are the most common types in adults. CML is found mostly in adults.

Over the past two decades the rates of induced remission and survival in most forms of leukemia have increased. Current survival rates range from 24% for AML to 81% for CLL, and as high as 91% for children and adolescents younger than 15 years of age with ALL.[7]

This progress is the result of more effective chemotherapeutic agents, improved blood product and antimicrobial support,

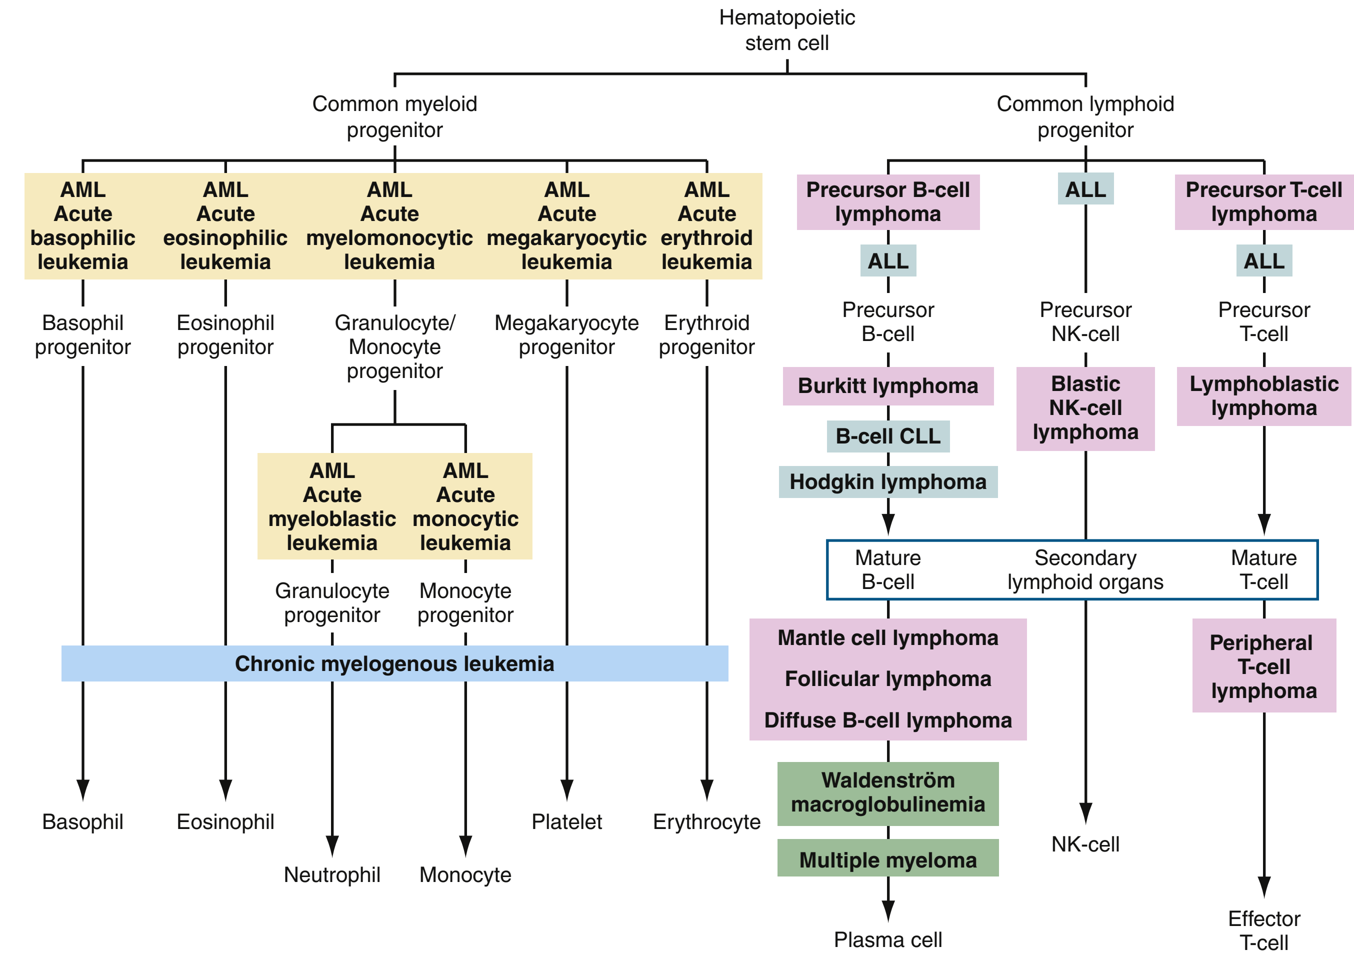

FIGURE 29-2 Origins of Leukemias and Lymphomas. Differentiation pathways of blood-forming cells and reported sites from which specific leukemias and lymphomas originate. Tumors of similar types are given the same background coloring. *ALL,* Acute lymphocytic leukemia; *AML,* acute myelogenous leukemia; *CLL,* chronic lymphocytic leukemia; *NK,* natural killer.

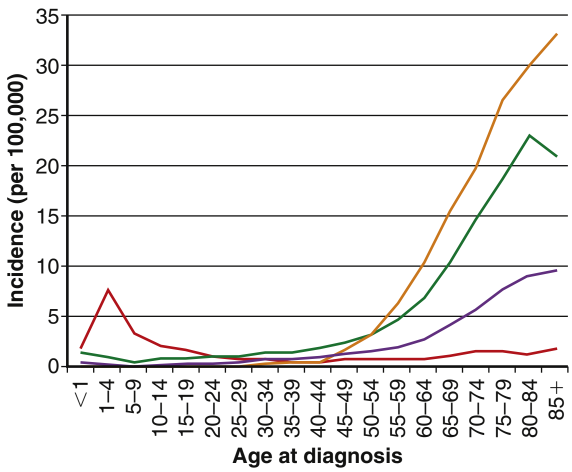

FIGURE 29-3 Age-Related Incidence at Diagnosis of Leukemias. The incidences of acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myelogenous leukemia (CML) are relatively stable until middle age and then increase dramatically. The incidence of acute lymphocytic leukemia (ALL) peaks in childhood, and then diminishes until middle age when the incidence begins rising slowly with age. (Data obtained from Howlader N et al, editors: *SEER cancer statistics review, 1975-2009 [vintage 2009 populations],* Bethesda, MD, 2012, National Cancer Institute. Available at http://seer.cancer.gov/csr/1975_2009_pops09/.)

and specialized nursing care. Chemotherapy and bone marrow transplants have significantly increased the survival time for individuals with acute leukemia.

PATHOPHYSIOLOGY. All leukemias have certain pathophysiologic features in common. Although the exact cause of leukemia is unknown, several risk factors and related genetic aberrations are associated with the onset of malignancy. There is a statistically significant tendency for leukemia to reappear in families. There is also an increased incidence of leukemia in association with other hereditary abnormalities such as Down syndrome, Fanconi aplastic anemia, Bloom syndrome, trisomy 13, Patau syndrome, and some immune deficiencies (i.e., ataxia-telangiectasia, Wiskott-Aldrich syndrome, and congenital X-linked agammaglobulinemia; see Chapter 9).

Genetic translocations (mitotic errors) are observed in leukemic cells. The most common genetic abnormality is the reciprocal translocation between chromosomes 9 and 22 t(9;22)(q34;q11), the **Philadelphia chromosome.**[8]

The Philadelphia chromosome was first observed in persons with CML, and is present in 95% of those with CML, 3% of individuals with AML, and 25% to 30% of adults with ALL and 2% to 10% of children with ALL.[9] This translocation results in the novel fusion of the *BCR1* gene region from

TABLE 29-2 ESTIMATED NEW CASES AND DEATHS: LEUKEMIA AND LYMPHOMA IN THE UNITED STATES IN 2013*

	ESTIMATED NUMBER AND PROPORTION (%) OF NEW CASES			ESTIMATED NUMBER OF DEATHS			5-YEAR SURVIVAL RATE (2005-2009)	
TYPE	TOTAL	MALE	FEMALE	TOTAL	MALE	FEMALE	OVERALL	<5 YEARS OF AGE
Leukemias	48,610	27,880	20,730	23,720	13,660	10,060	58%	
Acute lymphocytic leukemia	6050	3450	2600	1440	820	620	65.2%	90%*
Chronic lymphocytic leukemia	15,680	9720	5960	4580	2750	1830	78.8%	
Acute myelogenous leukemia	14,590	7820	6770	10,370	5930	4440	23.5%	55.2%
Chronic myelogenous leukemia	5920	3420	2500	610	340	270	59.1%	
Other leukemia	6350	3570	2780	6730	3820	2910		
Lymphomas	79,030	42,670	36,360	20,200	11,250	8950	70.6%	
Hodgkin lymphoma	69,740	5070	4220	1180	660	520	87%	
Non-Hodgkin lymphoma	19,020	37,600	32,140	19,020	10,590	8430	71%	
Multiple myeloma	22,350	12,440	9910	10,710	6070	4640	41.1%	

*Based on SEER Stat Fact Sheet, posted to the SEER website, NCI, 2013.

chromosome 22 and the proto-oncogene *ABL1* from chromosome 9 (Figure 29-4). The *BCR-ABL1* joining results in the expression of a unique fused oncoprotein, BCR-ABL1.[8] The ABL1 protein is a tyrosine kinase in the signaling pathway that promotes cell proliferation. The BCR-ABL1 variant possesses greater tyrosine kinase activity and has proven to be essential for transformation into leukemic cells. BCR-ABL1 appears to excessively activate intracellular pathways, leading to increased proliferation, decreased sensitivity to apoptosis, and premature release of immature cells into the circulation. In most leukemias and lymphomas a single major genetic abnormality, such as the t(9;22) translocation, does not lead to an aggressive malignancy. The initial event is usually followed by a series of secondary genetic changes.[10] Thus the original tumor becomes genetically unstable and diverse.

Risk factors for the onset of leukemia include environmental factors as well as other diseases. Increased risk in adults has been linked to exposure to cigarette smoke, benzene, and ionizing radiation. Large doses of ionizing radiation particularly result in an increased incidence of myelogenous leukemia. There is growing concern about the effect of low-dose radiation on subsequent risk of leukemia.[11] Infections with HIV or hepatitis C virus increase the risk for leukemia, and it is now widely accepted that some types of leukemia are caused by infection with the human T-cell leukemia/lymphoma virus type 1 (HTLV-1). Drugs that cause bone marrow depression (e.g., chloramphenicol, phenylbutazone, and certain alkylating agents, such as cytoxan) also can predispose an individual to leukemia. AML is the most frequently reported secondary cancer after high doses of chemotherapy for Hodgkin lymphoma, non-Hodgkin lymphoma, multiple myeloma, ovarian cancer, and breast cancer. Acute leukemia also may develop secondary to certain acquired disorders, including CML, CLL, polycythemia vera, myelofibrosis, Hodgkin lymphoma, multiple myeloma, ovarian cancer, and sideroblastic anemia.

Leukemias are considered clonal disorders in that a single progenitor cell undergoes malignant transformation. The leukemia blasts literally "crowd out" the marrow and cause cellular proliferation of the other cell lines to cease. Normal granulocytic-monocytic, lymphocytic, erythrocytic, and megakaryocytic progenitor cells cease to function, resulting in **pancytopenia** (a reduction in all cellular components of the blood). An interesting observation is that leukemic cells apparently divide more *slowly* and take longer to synthesize deoxyribonucleic acid (DNA) than other blood precursors. Leukemic cells accumulate relentlessly in the bone marrow causing overcrowding of the marrow, and they compete with cellular proliferation and function of normal hematopoietic cells. Thus leukemia has been termed an *accumulation* disorder, as well as a *proliferation* disorder. In the majority of cases, leukemic cells are ejected into the blood, where they accumulate. These cells also may infiltrate and accumulate in the liver, spleen, lymph nodes, and other organs throughout the body. The presentation of large numbers of leukemic cells in the blood may be one of the most dramatic indicators of leukemia; however, leukemia is still a primary disruption of the bone marrow.

Acute Leukemias

Acute leukemias consist of two types: **acute lymphocytic leukemia** (ALL) and **acute myelogenous leukemia** (AML). Acute leukemias are seen in both genders and in all ages, with the

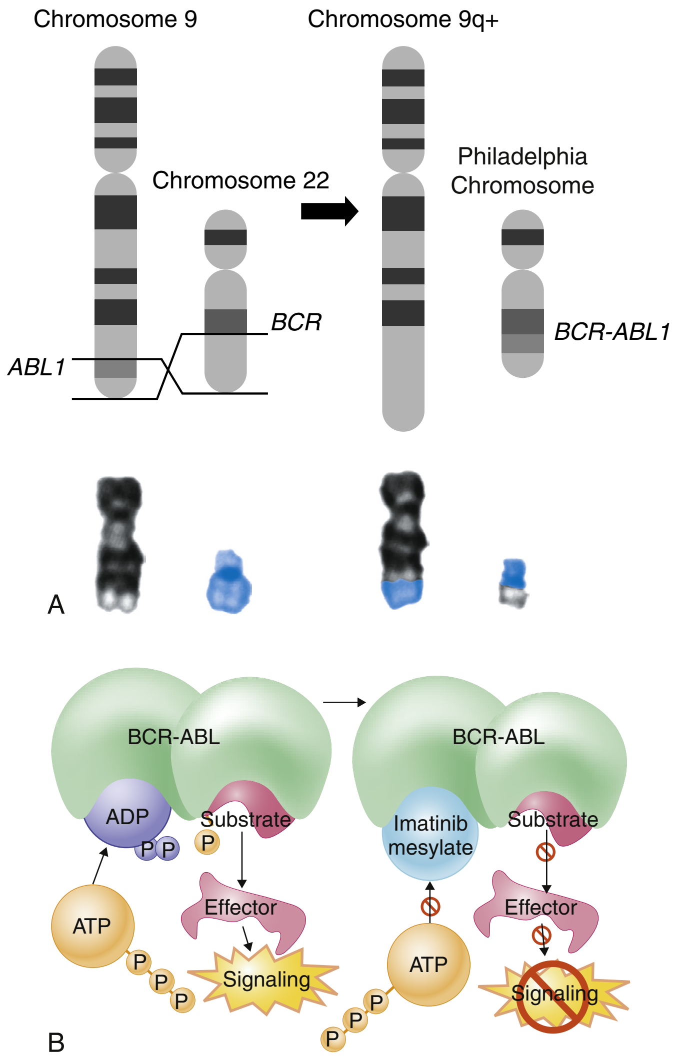

FIGURE 29-4 **Philadelphia Chromosome.** The Philadelphia chromosome is an example of a reciprocal chromosomal translocation that results in an abnormal gene product responsible for a clinical disorder. **A,** An exchange occurs between the long arm of chromosome 9 (black chromosome) and the long arm of chromosome 22 (blue chromosome); t(9;22)(q34;q11). **B,** Mechanism of action of imatinib. By occupying the ATP-binding pocket of the ABL kinase domain, imatinib prevents substrate phosphorylation and downstream activation of signals, thus inhibiting the leukemogenic effects of BCR-ABL on cells in chronic myelogenous leukemia. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *P,* phosphate group. (**A,** Top portion from Rakel R, Bope E: *Conn's current therapy 2008,* Philadelphia, 2008, Saunders. incidence increasing dramatically in individuals older than 50 years. Mortality for all acute leukemias in the United States is about 7 per 100,000. In children younger than 15 years, leukemia accounts for one third of all deaths from cancer. North American and Scandinavian countries have the highest mortality; Eastern European countries, Asia (except Japan), and Central America have the lowest mortality. Japan's higher mortality is the result of the atomic bombs dropped in World War II. Blacks have consistently shown a lower mortality than whites. More than 6070 new cases of ALL and 14,590 cases of AML are estimated in 2013, with more than 1430 deaths attributed to ALL and 10,370 to AML.[6,12,13]

PATHOPHYSIOLOGY. ALL is a progressive neoplasm defined by the presence of greater than 30% lymphoblasts in the bone marrow or blood. Most cases of ALL occur in children (80% of ALL), and it is the most common leukemia in children, most often occurring in the first decade. The median age of diagnosis of ALL is age 13. Although adults with ALL account for only 20% of all cases, their mortality is significantly higher (see Table 29-2). The 5-year survival rate for individuals 20 to 59 years old is about 30% to 40%, about 15% to 16% for persons older than 60 years, and 5% for persons older than 70 years. The survival rate in children is about 78%. The significant difference between the incidence of ALL in adults and children is thought to be determined by differences in the biology of the disease. Children with the highest survival rate (82% to 83%) have no radiographic manifestations, whereas children with five or more skeletal lesions have a survival rate of about 72% to 73%.[14]

Immunotyping of leukemic blast cells allows for the identification of subtypes of ALL. Approximately 75% of ALL cases in children originate from transformed precursor B cells, whereas adult ALL is a mixture of cancers of precursor B-cell or precursor T-cell origin (Table 29-3). A small percentage of ALL cases have neither B- nor T-cell origination and are called *null cell.* Precursor B-cell ALL can be subdivided into different phenotypes, depending on their progression through the B-cell maturation process before becoming malignant.[15,16] The general phenotype of precursor B-cell ALL expresses CD19, human leukocyte antigen DR (HLA-DR), and other B-cell–associated antigens in the cytoplasm. The most immature form (pro–B-cell ALL) occurs in about 5% of precursor B-cell ALL and is characterized by lack of expression of CD10. CD10 (common acute lymphocytic leukemia antigen [CALLA]) is a cell surface metalloprotease. Lack of CD10 is frequently associated with translocation of the myeloid/lymphoid leukemia *(MLL)* gene and a poor prognosis. The common precursor B-cell ALL comprises approximately 80% of precursor B-cell ALL cases; these express surface CD10, but have not yet undergone rearrangement of the immunoglobulin genes. The remaining individuals have a more mature form of precursor B-cell ALL (pre–B-cell ALL) in which the cells express immunoglobulin molecules in the cytoplasm. Less common variations include cells that are intermediate between the common precursor and pre–B-cell phenotypes and express immunoglobulin heavy chain, but no light chain, and cells that are more mature than the pre–B-cell ALL and express surface immunoglobulin and do not stain for the enzyme terminal deoxynucleotidyl transferase (TdT).

The T-cell lineage ALL (precursor T-cell ALL) is distinguished by T-cell–associated markers.[15,16] Cytoplasmic CD3 is the most common T-cell lineage specific marker, but CD7, CD2, and CD5 are frequently used. In addition to lymphoid markers, T-cell receptor (TCR) gene rearrangements are the most common genetic alteration in T-cell ALL. No specific cytogenetic abnormality, however, has been linked to the subtype of T-cell ALL. ALL blast cells also can express myeloid markers in 15% to 50% of adults and 5% to 35% of children.

Precursor B-cell ALL is strongly associated with aneuploidy of various types, ranging from hypodiploid to hyperdiploid with more than 50 chromosomes.[9,15,16] Individuals with hyperdiploid ALL usually have a better prognosis than those with fewer than 46 chromosomes. Individuals with precursor T-cell ALL generally have fewer cytogenetic abnormalities, and the majority of cases involve deletions. Genetic translocations between the *MYC* locus on chromosome 8 and one of the loci for the immunoglobulin (Ig) heavy- or light-chain genes (14q32, 2p12, and 22q11) are characteristic (also see Chapters 8 and 12). Several other translocations are commonly observed in ALL, including the Philadelphia chromosome and translocations involving the *ETV6 (formerly TEL)* and *MLL* genes (Figure 29-5).[9] Philadelphia chromosome–positive ALL carries the worst prognosis of all types of ALL and is found in 25% to 30% of adult ALL cases but less than 5% of childhood ALL cases. A translocation between chromosomes 12 and 21 (t[12;21]) results in fusion of the *ETV6* oncogene from chromosome 12 with the *AML1* (acute myeloid leukemia 1) gene on chromosome 21 to produce a fusion protein, ETV6-AML1. AML1 is a transcription factor for several genes important in hematopoiesis (e.g., IL-3, granulocyte-macrophage colony-stimulating factor [GM-CSF], CSF1 receptor).[9] The t(12;21) translocation occurs in 25% to 30% of childhood pre–B-cell ALL cases but in only 2% of adult ALL cases. This translocation significantly affects the prognosis of childhood ALL; children younger than 10 years with pre–B-cell ALL and the *ETV6-AML1* translocation have a 5-year cure rate of 90%, compared with 60% to 65% in those without the translocation.

Translocations of the *MLL* gene on chromosome 11 occur in about 10% of individuals with ALL and in 70% of infants with AML or ALL.[9] Infants and adults with this translocation develop a very aggressive form of leukemia with a very poor prognosis and frequent treatment failure, although children with this abnormality have better outcomes. The most common translocations involving *MLL* are t(4;11) and t(11;19). The t(4;11) translocation results in a fusion of *MLL* with the *AFF1* (ALL1 fused gene from chromosome 4) gene, and the t(11;19) translocation fuses *MLL* with the *MLLT1 (formerly ENL)* gene.

Specific causes of ALL are unknown, but multiple factors may contribute to its development.[15,16] Risk factors for childhood ALL include prenatal exposure to x-rays and postnatal exposure to high-dose radiation. Viral infections with HTLV-1 can cause a rare form of ALL and Epstein-Barr virus is linked to a form of ALL.[17]

Individuals with Down syndrome have an increased risk for developing ALL and AML. Increased risk for ALL is also seen in individuals with other genetic conditions, including neurofibromatosis, Shwachman syndrome, Bloom syndrome, and ataxia-telangiectasia (see Chapter 9). A unique characteristic of ALL, unlike other forms, is that ALL develops at different rates in different geographic locations, although the reason for this is unclear. Individuals in developed countries and in higher socioeconomic categories have an increased incidence of ALL. Prevention is almost impossible because there are no known causes.

AML is the most common adult leukemia; the mean age of diagnosis is 67 years of age. Approximately 60% to 70% of adults with AML can expect to attain complete remission status following appropriate induction therapy. Remission rates in adult AML are inversely related to age; remission rates for those younger than 60 years are more than 65%. AML[18] results from an abnormal proliferation of myeloid precursor cells, a decreased rate of apoptosis, and an arrest in cellular differentiation.[13] Therefore, the bone marrow and peripheral blood are characterized by leukocytosis and a predominance of blast cells. As the number of immature blasts increases, they replace normal myelocytic cells, megakaryocytes, and erythrocytes. This displacement eventually leads to complications of bleeding, anemia, and infection. AML increases with age, peaking in the sixth decade of life. Certain risk factors have been identified as possible causes, including exposure to radiation, benzene, and chemotherapy. Hereditary conditions, such as Down syndrome, Fanconi aplastic anemia, Bloom syndrome, ataxia-telangiectasia, trisomy 13 (Patau syndrome), Wiskott-Aldrich syndrome, and congenital X-linked agammaglobulinemia, are known to be associated with a higher risk for AML (see Table 29-2). AML subtypes are classified based on the stage of development the myeloblasts have reached at the time of diagnosis. These subtypes are included in Box 29-1.

More than 150 structural chromosomal abnormalities and several duplications or deletions within genes have been identified in AML.[9] The most common abnormalities are balanced translocations or inversions that disrupt genes critical to hematopoiesis of myeloid cells. The most common translocation is between chromosomes 8 and 21 in which the *RUNX1T1* (formerly *ETO*) (encodes a transcription factor) gene on chromosome 8 is fused with the *AML1* gene on chromosome 21, resulting in an *AML1-RUNX1T1* fusion gene and a fusion gene product, AML1-RUNX1T1. Production of AML1-RUNX1T1 disrupts the normal hematopoiesis process for myeloid cells and directly leads to the AML malignant phenotype.

Many kinds of mutations have been found in AML; however, a mutation in the receptor tyrosine kinase FLT3 occurs in about one third of persons affected by AML. FLT3 conveys a proliferation signal normally expressed early in the development of bone marrow stem cells, but mutated FLT3 remains active and promotes blast cell proliferation. Several FLT3 inhibitors are in various stages of clinical development. Another mutation in receptor tyrosine kinases is *KIT*, which also provides a proliferative and/or survival signal to progenitor cells. Together these mutations result in proliferation but not differentiation.

CLINICAL MANIFESTATIONS. The clinical manifestations of all the varieties of acute leukemia are generally similar. (Mechanisms associated with common manifestations are summarized in Table 29-4.) Signs and symptoms related to bone marrow depression include fatigue caused by anemia, bleeding resulting from thrombocytopenia (reduced numbers of circulating platelets), and fever caused by infection. Sites of infection include the oral cavity, throat, respiratory tract, lower colon, urinary tract, and skin. Common organisms include the gram-negative bacilli *Escherichia coli*, *Pseudomonas aeruginosa,* and *Klebsiella pneumoniae.* Fever is an early sign, often accompanied by chills. Bleeding can occur in skin, gums, mucous membranes, and gastrointestinal and genitourinary tracts. Visible signs of bleeding

BOX 29-1 CLASSIFICATION OF ACUTE MYELOID LEUKEMIAS

Acute myeloblastic leukemia, minimally differentiated (AML-M0)
Acute myeloblastic leukemia without maturation (AML-M1)
Acute myeloblastic leukemia with maturation (AML-M2)
Acute promyelocytic leukemia (AML-M3)
- Hypergranular type
- Microgranular variant

Acute myelomonocytic leukemia (AML-M4)
- Increased marrow eosinophils (AML-M4-EO)

Acute monocytic leukemia (AML)
- Acute monoblastic leukemia (AML-M5A)
- Acute monocytic leukemia, differentiated (AML-M5B)

Erythroleukemia (AML-M6)
Acute megakaryoblastic leukemia (AML-M7)

From Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.

include petechiae and ecchymosis, as well as discoloration of the skin, gingival bleeding, hematuria, and midcycle or heavy menstrual bleeding.

Anorexia can occur in all varieties of acute leukemia and is associated with weight loss, diminished sensitivity to sour and sweet tastes, muscle atrophy, and difficulty in swallowing. Liver, spleen, and lymph node enlargement is more common in ALL than in AML (Figure 29-6). Splenomegaly and hepatomegaly usually occur together. The leukemic individual often experiences abdominal pain and tenderness and breast tenderness. Pain in the bones and joints is thought to result from leukemia infiltration with secondary stretching of the periosteum.

Central nervous system (CNS) involvement is common and may be caused by either leukemic infiltration or cerebral bleeding. Headache, vomiting, papilledema, facial palsy, blurred vision, auditory disturbances, and meningeal irritation can occur if leukemic cells infiltrate the cerebral or spinal meninges. CNS involvement at the time of diagnosis is rare, and less than 5% of children and less than 10% of adults are affected. Without CNS prophylaxis, approximately one third of individuals will develop CNS complications. Interventions associated with CNS prophylaxis include cranial irradiation, chemotherapy, and high doses of systemic chemotherapy. Specific treatment modalities or combinations of treatment vary and are determined by age and risk status.

EVALUATION AND TREATMENT. Leukemia is often confused with other conditions, making early detection difficult. Persistent symptoms need intensive medical investigation. The diagnosis is made through examination of blood cells and bone marrow. A stained peripheral blood smear will exhibit low red blood cell and platelet counts along with the presence of leukemic blast cells (Figure 29-7). Examination of bone marrow demonstrates hypercellularity with 60% to 100% blast cells, an occasional normal myeloid, erythroid precursors, and few to no megakaryocytes.

Chemotherapy, used in varying combinations, is the treatment of choice for leukemia.[15,16,19] Supportive measures include blood transfusions, antibiotics, antifungals, and antivirals. Allopurinol is used for preventing production of uric acid (which is elevated from cellular death because of treatment). Stem cell transplantation is now considered standard therapy for selected individuals with leukemia.

Bone marrow transplantation as a treatment has been increasing during the past two decades for both ALL and AML. Studies examining arsenic trioxide with *all-trans*-retinoic acid in combination with chemotherapy found that 80 of 85 subjects achieved remission. *all-trans*-Retinoic acid is made in the body from vitamin A and helps cells to grow and develop. In the leukemic individual, retinoic acid drives cells to develop into functional cells to alleviate the disease. It is a chemotherapeutic agent used to treat some forms of leukemia. In one study in which this chemical was utilized, although there were five deaths, the 5-year event-free survival rate was 89%, a remarkable improvement over historically bleak survival rates.[20]

The 5-year survival rate for those with leukemia is 38%, largely because of poor survival rates of individuals with certain types of leukemia (e.g., acute myelogenous). Since the 1970s, 5-year survival rates for those with ALL have increased from 38% to 65% for adults and from 53% to 85% for children. Factors influencing increased survival rate include the use of combined and multimodality treatment methods, improved supportive services such as blood banking and nutritional

TABLE 29-4 CLINICAL MANIFESTATIONS AND RELATED PATHOPHYSIOLOGY IN LEUKEMIA

CLINICAL MANIFESTATIONS	LABORATORY ABNORMALITIES	CAUSE	COMMENTS
Anemia	Key is the relative *proportion* of erythroblasts to total count (decreased in anemia)	Decreased stem cell input or ineffective erythropoiesis or both	In acute leukemia, anemia is usually present from the beginning, often the first symptom noticed, and severe; mild form without symptoms is common in CML and CLL; hemorrhage common in acute forms, occasional in CML, but rare in CLL
Bleeding (purpura, petechiae, ecchymosis, hemorrhage)	Decreased and possibly abnormal platelets	Reduction in megakaryocytes leading to thrombocytopenia	Bleeding more common in acute than in chronic leukemia
Infection	Increased multisegmented neutrophils	Opportunistic organisms; decreased protection resulting from granulocytopenia or immune deficiency secondary to chemotherapy, corticosteroids, and the disease process	Major sites of infection: oral cavity, throat, lower colon, urinary tract, lungs, and skin; prevention of infection focuses on restoration of host defenses, decreasing invasive procedures, and reducing colonization of organisms
Weight loss	Decreased 24-hr urinary creatinine excretion; hypoalbuminemia	Condition can be attributed to pain, depression, chemotherapy, radiation therapy, loss of appetite, and alterations in taste	Severe weight loss may be related to excess production of TNF-α
Bone pain	Often no radiographic evidence of bone problems	Result of bone infiltration by leukemic cells or intramedullary infection	If combination drug regimens are ineffective, radiation therapy is used
Liver, spleen, and lymph node enlargement	Biopsy abnormal for liver and spleen	Leukemic cell infiltration; lymph nodes also undergo leukemia proliferation in CLL	
Elevated uric acid	Normal excretion of uric acid is 300-500 mg/day; the leukemic individual can excrete 50 times more	Increased catabolism of protein and nucleic acid; urate precipitation increased from dehydration caused by anorexia or fever and drug therapy	Hyperuricemia is present in both acute leukemia and CML; increasing urine pH or decreasing acid production with the drug allopurinol

CLL, Chronic lymphocytic leukemia; *CML,* chronic myelogenous leukemia; *TNF,* tumor necrosis factor.

support, and the implementation of antimicrobial treatment. The presence of the Philadelphia chromosome (observed in about 5% of children with ALL, in 30% of adults with ALL, and occasionally in AML) is a poor prognostic indicator.

Myelosuppression is both a consequence of leukemia and its treatment. Hematologic support with blood products and granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) has effectively shortened the time of neutropenia and improved survival by reducing the risk for infection. A trial of individuals with CML demonstrated improved disease-free survival in the group receiving GM-CSF (23 months vs. 11 months; 2-year disease-free survival 48% vs. 21%).[21] The administration of colony-stimulating factors (CSFs) can increase white cell numbers and afford protection from infections.

Chronic Leukemias

The two main types of chronic leukemia are (1) **chronic myelogenous leukemia (CML)** and (2) **chronic lymphocytic leukemia (CLL)** (see Table 29-2). Several forms of CML can occur, depending on the lineage of the malignant cells (e.g., chronic neutrophilic leukemia [CNL], chronic eosinophilic leukemia [CEL]). Unlike cells in acute leukemia, chronic leukemic cells are well differentiated and can be readily identified. Individuals with chronic leukemia have a longer life expectancy, usually extending several years from the time of diagnosis.

The chronic leukemias account for the majority of cases in adults, comprising approximately 30% of leukemias in the Western world. It is estimated that in 2012 more than 15,680 cases of CLL and 5920 cases of CML were newly diagnosed in the United States.[22,23,23a] The incidences of CLL and CML increase significantly in individuals older than 40 years, with prevalence in the sixth through eighth decades. CML is a group of diseases called *myeloproliferative disorders,* which also include polycythemia vera, primary thrombocytosis, and idiopathic myelofibrosis (invasion of bone marrow by fibrous tissue).

PATHOPHYSIOLOGY. CLL involves malignant transformation and progressive accumulation of monoclonal B lymphocytes; rarely (less than 5%) are CLL malignancies of T-cell origin. The characteristic immunophenotype is expression of CD5, CD19, and CD23 molecules and low amounts of surface membrane Ig and CD20 molecules.[24] CD5 is a signal transduction molecule linked to the B-cell receptor (BCR); CD19 is a low-affinity antigen receptor expressed on maturing B cells, but is lost in plasma cells; and CD23 is a low-affinity receptor for the Fc portion of IgE. CLL is derived from a transformation of a partially mature B cell that has not yet encountered antigen. The gene for the variable region of the antibody heavy chain *(IGHV)* is frequently mutated (30% to 40% of persons). (See Chapter 8 concerning immunoglobulin heavy-chain structure.) Individuals with a mutated *IGHV* tend to have a more benign condition with a more slowly developing and less malignant disease.

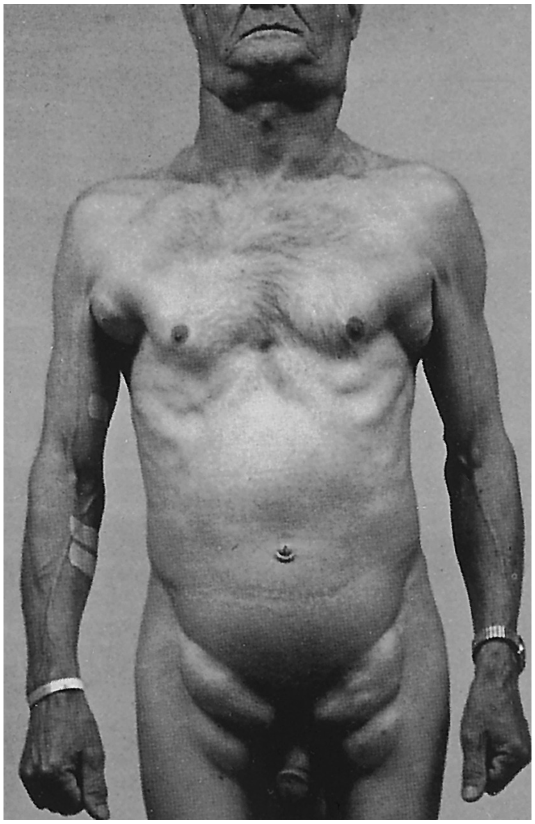

FIGURE 29-6 **Lymphadenopathy.** Individual with lymphocyte leukemia with extreme but symmetric lymphadenopathy. (Courtesy Dr. A.R. Kagan, Los Angeles. From Del Regato JA, Spjut HJ, Cox JD: *Ackerman and Del Regato's cancer,* ed 2, St Louis, 1985, Mosby.)

Significant numbers of this mutation are associated with a median survival in excess of 20 to 25 years, whereas the absence of mutations is associated with a poorer survival rate (median survival 8 to 10 years).[25]

The etiology of CLL is unknown. A familial tendency suggests a genetic linkage; first-degree relatives have a three times greater risk of developing the disease. It is rare in individuals younger than 45 years of age, and when diagnosed, 95% of individuals are older than age 50. Genetic anomalies occur in approximately 90% of cases, frequently as deletions, although none has been linked to the etiology of CLL.

CLL cells that accumulate in the marrow do not interfere with normal blood cell production to the extent found in acute leukemias. This is a significant feature explaining the reduced severity in the beginning stage of disease. Accumulation of malignant B cells is the result of cell cycle arrest in the G_0/G_1 phase. CLL cells tend to express increased levels of anti-apoptotic proteins (e.g., BCL2) and suppress pro-apoptotic proteins (e.g., BAX), which reduces their sensitivity to apoptosis. Because the major pathophysiologic deficit in CLL is the failure of B cells to mature into plasma cells that synthesize immunoglobulin, this often results in hypogammaglobulinemia (60% of clients).

CML is a member of the family of myeloproliferative disorders that also includes polycythemia vera (see Chapter 28), essential thrombocythemia, chronic idiopathic myelofibrosis (invasion of bone marrow by fibrous tissue), chronic neutrophilic leukemia, and chronic eosinophilic leukemia. CML is clonal and thought to arise from a hematopoietic stem cell. The cells observed in CML are heterogeneous in differentiation, depending on the stage of the disease.[26] During the chronic phase the predominant cell is a long-lasting hematopoietic stem cell. A leukemic granulocyte-monocyte progenitor cell is seen. The Philadelphia chromosome is present in more than 95% of CML, and the presence of the BCR-ABL1 protein is responsible for initiation of CML. In advanced disease, the accumulation of additional mutations leads to the more aggressive leukemic phenotype.

CLINICAL MANIFESTATIONS. Chronic leukemia advances slowly and insidiously. Approximately 70% of individuals with CLL are asymptomatic at the time of diagnosis. When symptoms do appear, the most common finding is lymphadenopathy. The most significant effect of CLL is suppression of humoral immunity and increased infection with encapsulated bacteria. Frequently the level of neutrophils is depressed, which adds to the risk of infection. Invasion of most organ cells is uncommon but infiltration does occur in lymph nodes, liver, spleen, and salivary glands. CNS involvement is rare. Approximately 10% of individuals develop a more aggressive malignancy, usually a diffuse large B-cell lymphoma. In these individuals, extreme fatigue, weight loss, night sweats, low-grade fever, elevated levels of the enzyme lactic dehydrogenase, hypercalcemia, anemia, and thrombocytopenia are common.

Individuals with CML may progress through three phases of the disease: a chronic phase lasting 2 to 5 years during which symptoms may not be apparent; an accelerated phase of 6 to 18 months during which the primary symptoms develop; and a terminal blast phase ("blast crisis") with a survival of only 3 to 6 months. The accelerated phase is characterized by excessive proliferation and accumulation of malignant cells. Splenomegaly is the most common finding, which may be prominent and painful, but lymphadenopathy generally is not present. Liver enlargement also occurs, but liver function is rarely altered. Hyperuricemia is common and produces gouty arthritis. Infections, fever, and weight loss also are frequent. The terminal blast phase is characterized by rapid and progressive leukocytosis with an increase in the number of basophils. In the later stages of the terminal phase, which then resembles AML, blast cells or promyelocytes predominate, and the individual experiences a blast crisis.

The acute effects of CML resemble those of acute leukemia but with more prominent and painful splenomegaly. Liver function rarely is altered despite enlargement, and lymphadenopathy generally is found only in the acute phase of the disease. Hyperuricemia invariably is present and produces gouty arthritis. Infections, fever, and weight loss are common findings in clients with CML.

EVALUATION AND TREATMENT. Diagnosis of chronic leukemia depends on laboratory analyses of peripheral blood and bone marrow samples. Diagnosis of CLL is based on detection of a monoclonal B-cell lymphocytosis in the blood. The cells must have the immunophenotype characteristic of CLL (CD5+, CD19+, CD20 [weak], CD23+), at levels in excess of 5000 cells/μL, over a sustained period of time (usually 4 weeks). Bone

marrow may contain more than 30% lymphocytes and be normocellular or hypercellular.

Treatment is frequently based on prognostic indicators and ranges from observation with treatment of infection, hemorrhage, or immune complications to a variety of drug therapies. Because this disease typically occurs in older adults and the rate of progression is slow, it is often simply observed until the disease progresses. Meta-analysis of randomized trials shows no survival advantage for immediate vs. delayed treatment for those individuals with early stage disease.[27]

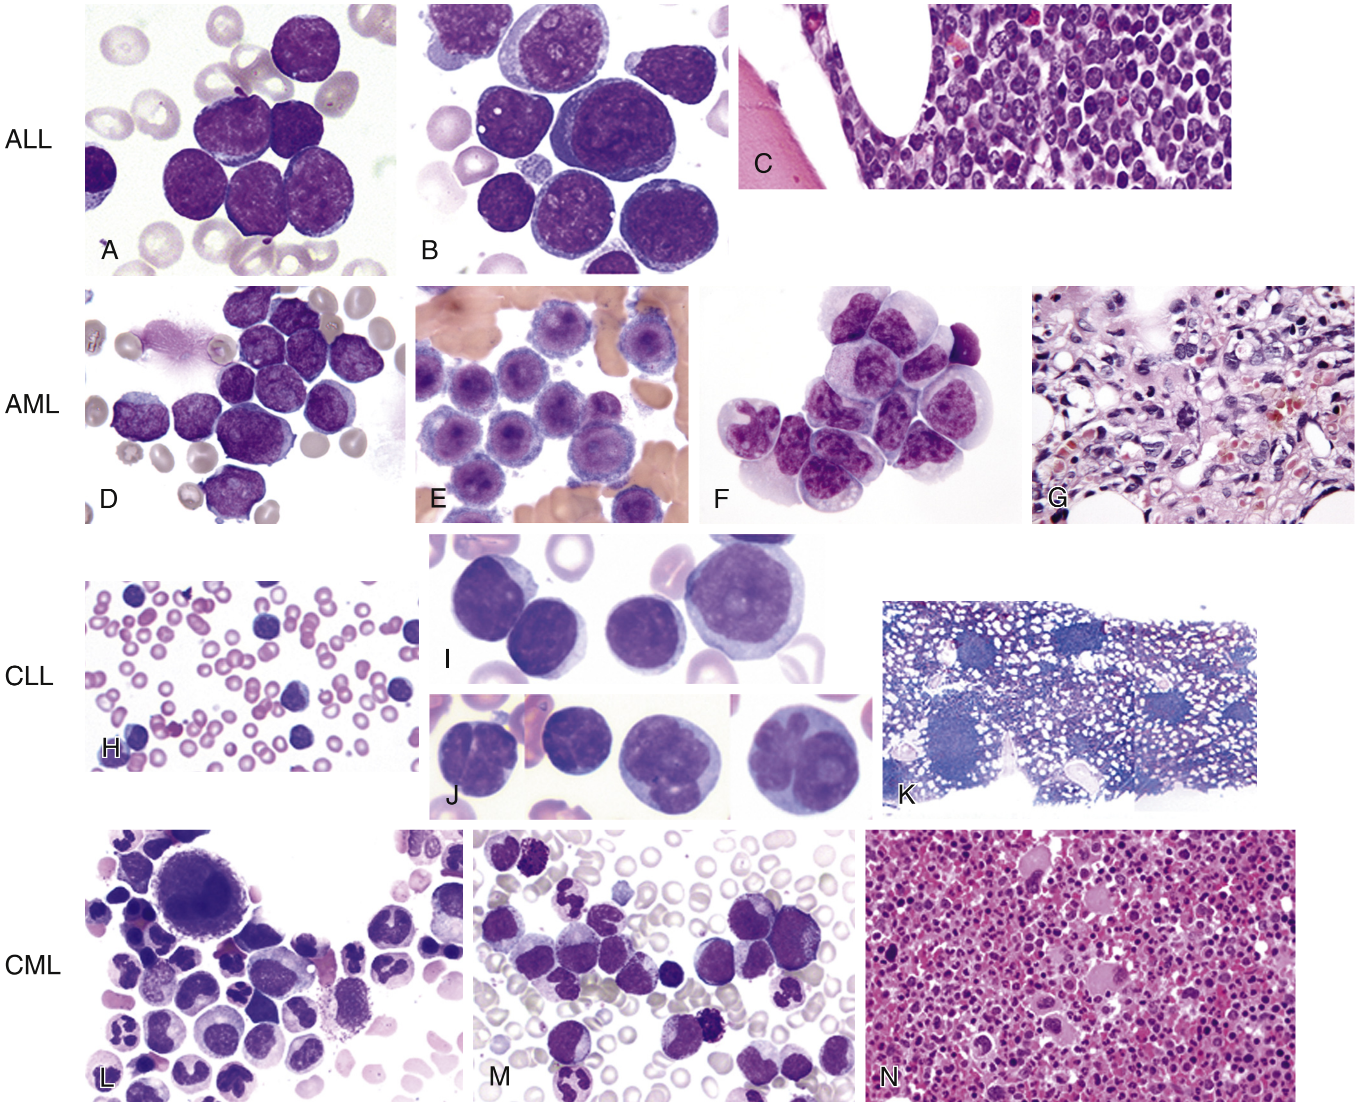

FIGURE 29-7 Morphologic Aspects of Leukemia Cells. *Acute lymphocytic leukemia (ALL)* **(A-C). A,** Typical uniform lymphoblasts with intermediate-sized nuclei, fine but "smudgy" chromatin, absence of nucleoli, and scant cytoplasm. **B,** Lymphoblasts with more cytologic variation, including variability in size, number of nucleoli, and amount of cytoplasm. **C,** Histologic features of ALL in bone core biopsy. *Acute myeloid leukemia (AML)* **(D-G). D,** Acute myeloblastic leukemia with minimal or no maturation. The cells are myeloblasts with dispersed chromatin and variable amounts of agranular cytoplasm. Some display medium-sized, poorly defined nucleoli. **E,** Acute monoblastic leukemia; characteristic monoblasts with round nuclei and delicate chromatin and prominent nucleoli. Cytoplasm is abundant. **F,** Acute monocytic leukemia with most of the cells in this field being promonocytes. Monoblasts and an abnormal monocyte also are present. **G,** Marrow biopsy of acute megakaryoblastic leukemia containing large and small blasts and atypical megakaryocytes. *Chronic lymphocytic leukemia (CLL)* **(H-K). H,** Peripheral blood smear typically shows lymphocytosis. Cytologic features of CLL cells differ. **I,** Classic cells have a small nucleus with a "soccer ball" chromatin pattern. **J,** Some cases have increased large cells, or prolymphocytes, with more open chromatin and prominent "punched-out" nucleoli (prolymphocyte, right side). **K,** The bone marrow can show nodular infiltrates of CLL cells. *Chronic myelogenous leukemia (CML)* **(L-N). L,** Peripheral smear shows marked leukocytosis attributable to a granulocytic proliferation of all stages with particularly increased myelocytes and absolute basophilia. **M,** Bone core biopsy illustrates markedly hypercellular marrow attributable to granulocytic proliferation and increased small hypolobated megakaryocytes. **N,** Bone marrow aspirate shows granulocytic proliferation and small, "dwarf" megakaryocyte. (**A-C, H-N** from Hoffman R et al: *Hematology: basic principles and practice,* ed 6, Philadelphia, 2013, Churchill Livingstone. **D-G** from Abeloff M et al: *Abeloff's clinical oncology,* ed 4, Philadelphia, 2008, Churchill Livingstone.)

Typically, individuals with CLL survive 10 years or more. However, those with certain risk markers have a more aggressive form of the disease that shortens survival to less than 3 years. Markers of high risk include anemia, thrombocytopenia, and the absence of mutations in the *IGHV* gene. Mutations in *IGHV* correlate very closely with levels of intracellular ZAP-70, detection of which may be substituted for tests of *IGHV* mutation. ZAP-70 is a tyrosine kinase that is linked to the T-cell receptor (see Chapter 8). ZAP-70 negativity is associated with improved mean survival.[28] It is not normally detected in CLL cells with mutated *IGHV*, but is easily detectable by immunohistologic analysis in cells with an unmutated *IGHV*.

Chlorambucil, administered with or without corticosteroids, on a daily or intermittent schedule is the most common treatment for individuals with the most aggressive disease. Relief of symptoms is often achieved, but there is no substantial effect on survival. Combination therapy (CHOP) that includes **c**yclophosphamide, **h**ydroxydaunomycin (Adriamycin), vincristine (**O**ncovin), and **p**rednisone has an improved response rate but still does not demonstrate improved survival. Fludarabine, a purine analog, has a higher response rate and disease-free intervals, although survival is not affected. Rituximab, a murine anti-CD20 monoclonal antibody, has shown limited promise in CLL (20% response rate). Ofatumumab is a human anti-CD20 monoclonal antibody that has shown overall response rates of 50% in persons with CLL.

Present treatment modalities for CML do not cure the disease, prevent blastic transformation, or prolong the average survival time. Standard treatment consists of combined chemotherapy, biologic response modifiers, and allogeneic stem cell transplant. Although transplantation is potentially curative, its use is limited by donor availability and high toxicity in older adults, thus limiting use to those older than 65 years. Allogeneic bone marrow transplantation has increased survival time significantly (20% to 30%) when used after high-dose radiation and chemotherapy and with concurrent treatment with interferon. Traditional chemotherapy agents used are hydroxyurea and busulfan. The development and introduction of the tyrosine kinase inhibitor imatinib mesylate (Gleevec) as a treatment modality have changed current management of CML. Imatinib mesylate is highly specific for CML and suppression of BCR-ABL kinase activity, and it produces a complete cytogenetic response in more than 80% of newly diagnosed persons. Suppression of hematologic symptoms occurs in 97% of treated individuals, and the use of imatinib mesylate has become the standard of care for CML. A small percentage of clients develop additional mutations in BCR-ABL that confer resistance to imatinib mesylate.[29] Several new tyrosine kinase inhibitors are under investigation as treatments for CML.

ALTERATIONS OF LYMPHOID FUNCTION

Lymphadenopathy

Lymphadenopathy is characterized by enlarged lymph nodes. Lymph node enlargement is caused by an increase in size and number of its germinal centers caused by proliferation of lymphocytes and monocytes or invasion by malignant cells. Normally, lymph nodes are not palpable or are barely palpable. Enlarged lymph nodes are characterized by being palpable and often also may be tender or painful to touch, although not in all situations (see Figure 29-6).

Localized lymphadenopathy usually indicates drainage of an area associated with an inflammatory process or infection (reactive lymph nodes). Generalized lymphadenopathy is generally a result of malignant or nonmalignant disease, particularly in adults. Palpable nodes, however, do not always indicate serious disease and may indicate only a reaction to minor trauma or infection of a specific structure. The location and size of the enlarged nodes are important factors in diagnosing the cause of the lymphadenopathy, as are the individual's age, gender, and geographic location. Generalized lymphadenopathy occurs with non-Hodgkin lymphomas, chronic lymphocytic leukemia, histiocytosis, and disorders that produce lymphocytosis. In general, lymphadenopathy results from one of four types of conditions: (1) neoplastic disease, (2) immunologic or inflammatory conditions, (3) endocrine disorders, or (4) lipid storage diseases. Diseases of unknown cause, including reactions to drugs, also may lead to generalized lymphadenopathy.

Malignant Lymphomas

Lymphomas consist of a diverse group of neoplasms that develop from the proliferation of malignant lymphocytes in the lymphoid system. The classification of lymphomas was published by the World Health Organization (WHO) and is derived from the Revised European-American Lymphoma (REAL) classification. This classification is based on the cell type from which the lymphoma probably originated (Box 29-2).[30] The groups include Hodgkin lymphoma and two that were previously classified as non-Hodgkin lymphoma (B-cell neoplasms, T-cell, and natural killer [NK] cell neoplasms). With the new classification, multiple myeloma, which was previously classified independently, is included as a B-cell lymphoma.

Incidence rates of lymphoma differ with respect to age, gender, geographic location, and socioeconomic class. The estimated number of new cases of lymphoma for 2013 is more than 79,030 individuals (see Table 29-2). It is estimated that more than 20,200 individuals will have died from lymphoma in 2013. Since the early 1970s, the incidence of non-Hodgkin lymphoma has nearly doubled. The exact reason for this increase remains a mystery; however, a modest portion of the increase had been attributed to lymphomas developing in association with immune deficiencies, including AIDS and organ transplants. Conversely, the incidence of Hodgkin lymphoma has declined over the same time period, especially among older adults.

In general, lymphomas are the result of genetic mutations or viral infection. Malignant transformation produces a cell with uncontrolled and excessive growth that accumulates in the lymph nodes and other sites, producing tumor masses. Lymphomas usually start in the lymph nodes or lymphoid tissues of the stomach or intestines.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) is a malignant lymphoma first characterized by Thomas Hodgkin in 1832. It is estimated that more

BOX 29-2 WORLD HEALTH ORGANIZATION CLASSIFICATION OF LYMPHOID NEOPLASMS

B-Cell Neoplasms

Precursor B-Cell Neoplasms

- Precursor B-lymphoblastic leukemia/lymphoma
- Precursor B-cell acute lymphoblastic leukemia

Mature (Peripheral) B-Cell Neoplasms

- B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma
- B-cell prolymphocytic leukemia
- Lymphoplasmacytoid lymphoma
- Splenic marginal zone B-cell lymphoma (with/without villous lymphocytes)
- Hairy cell leukemia
- Plasma cell myeloma/plasmacytoma
- Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MAL type)
- Nodal marginal zone B-cell lymphoma (with/without monocytoid B cells)
- Follicular lymphoma
- Mantle-cell lymphoma
- Diffuse large B-cell lymphoma
  - Mediastinal large B-cell lymphoma
  - Primary effusion lymphoma
- Burkitt lymphoma/Burkitt cell leukemia

T-Cell and NK-Cell Neoplasms

Precursor T-Cell Neoplasms

- Precursor T-lymphoblastic lymphoma/leukemia
- Precursor T-cell acute lymphoblastic leukemia

Mature (Peripheral) T-Cell Neoplasms

- T-cell prolymphocytic leukemia
- T-cell granular lymphocytic leukemia
- Aggressive NK-cell leukemia
- Adult T-cell lymphoma/leukemia (HTLV-1 positive)
- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy-type T-cell lymphoma
- Hepatosplenic gamma-delta T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Mycosis fungoides/Sézary syndrome
- Anaplastic large-cell lymphoma, T/null cell, primary cutaneous type
- Peripheral T-cell lymphoma, not otherwise characterized
- Angioimmunoblastic T-cell lymphoma
- Anaplastic large-cell lymphoma, T/null cell, primary systemic type

Hodgkin Lymphoma (Hodgkin Disease)

Nodular lymphocyte predominant Hodgkin lymphoma

Classic Hodgkin lymphoma

- Nodular sclerosis Hodgkin lymphoma (grades 1 and 2)
- Lymphocyte-rich classic Hodgkin lymphoma
- Mixed cellularity Hodgkin lymphoma
- Lymphocyte depletion Hodgkin lymphoma

than 9290 individuals will be newly diagnosed with HL in 2013 (see Table 29-2). The incidence of HL is approximately 26.6 per 100,000 men and 18.9 per 100,000 women.[31] The median age of diagnosis is 64. Incidence rates for HL have declined, especially among older adults. The decrease in incidence in older adults is attributed to improved diagnostic accuracy. The incidence is greater in whites than blacks. Denmark, the Netherlands, and the United States have the highest incidence of HL, and Japan and Australia have the lowest incidence. HL peaks at two different ages: early in life in the second and third decades and later in life during the sixth and seventh decades.

PATHOPHYSIOLOGY. HL is characterized by its progression from one group of lymph nodes to another, the development of systemic symptoms, and the presence of **Reed-Sternberg (RS) cells** (Figure 29-8). It is widely accepted that the RS cell represents the malignant transformed lymphocyte. The RS cells are often large and binucleate, with occasional mononuclear variants. RS cells are the hallmark of HL. RS cells are necessary for the diagnosis of HL; however, they are not specific to HL. In rare instances, cells resembling them can be found in benign illnesses, as well as in other forms of cancer, including non-Hodgkin lymphomas and solid tissue cancers and in infectious mononucleosis.

The triggering mechanism for the malignant transformation of cells remains unknown. Classic HL appears to be derived from a B cell in the germinal center that has not undergone successful immunoglobulin gene rearrangement (see Chapter 8) and would normally be induced to undergo apoptosis. Survival

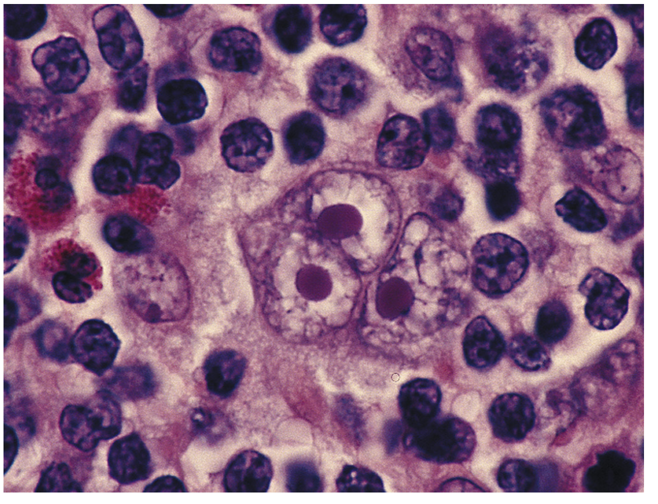

FIGURE 29-8 **Reed-Sternberg Cell.** A large multinucleated or multilobed cell *(center of photograph)* with inclusion body–like nucleoli surrounded by a halo of clear nucleoplasm. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

of this cell may be linked to infection with EBV. Laboratory and epidemiologic studies have linked HL with EBV infections and EBV DNA. RNA and proteins are frequently observed in HL cells. The RS cells secrete and release cytokines (e.g., IL-10, transforming growth factor-beta [TGF-β]) that result in the accumulation of inflammatory cells that produces the local and

TABLE 29-5 SUBTYPES OF HODGKIN LYMPHOMA

SUBTYPE	INCIDENCE	PRESENTATION
Nodular sclerosis Hodgkin lymphoma (HL)	Most common subtype in developing countries Found in all ages but most common in adolescents and young adults (median age of onset is about 28 years) Incidence in females exceeds that in males	Large tumor nodules with RS cells surrounded by collagen and fibrous bands
Mixed cellularity HL	Second most common subtype Incidence in males exceeds that in females	RS cells with mixed inflammatory cell (lymphocytes, monocytes/macrophages, eosinophils, plasma cells) infiltrates
Lymphocyte-rich classic HL	Uncommon subtype Found in all ages but most common in adults Incidence in males exceeds that in females	Few RS cells and predominantly lymphocytic infiltration Usually localized at diagnosis Survival is long with or without treatment
Lymphocyte depletion HL	Uncommon subtype Most common type in older adults, HIV-positive individuals, and persons in nonindustrialized countries Incidence in males exceeds that in females	Large number of RS cells with less additional cellular infiltrate Usually widespread disease: abdominal lymphadenopathy; spleen, liver, and bone marrow involvement, without peripheral lymphadenopathy Stage is usually more advanced at diagnosis

HIV, Human immunodeficiency virus; *RS,* Reed-Sternberg.

systemic effects. HL is subcategorized into two main types: classic Hodgkin and nodular lymphocyte–predominant Hodgkin. Classic HL is subclassified into four types (Table 29-5) based on the morphology of RS cells, and the characteristics of the inflammatory cell infiltrate in the tumor. Lymphocyte-predominant disease presents with earlier-stage disease, longer survival, and fewer treatment failures than classic HL.[32] However, despite a more favorable prognosis, lymphocyte-predominant HL has a tendency to histologically transform into diffuse large B-cell lymphoma by 10 years in approximately 10% of people.[33]

The molecular events causing malignant transformation remain controversial; although RS cells are apparently from B-cell lineage, they express very few B-cell markers and express markers normally not found on B cells. For instance, RS cells do not express immunoglobulin, but do express CD15 (a carbohydrate adhesion molecule found on neutrophils), TARC (a Th2-cell specific chemokine), and T-cell–associated antigens (e.g., β-chain of the T-cell receptor).[30] The precise genetic defects leading to development of HL are unknown, although several have been suggested. These generally include defects in immunoglobulin variable region gene rearrangement or defects in other B-cell–specific differentiation genes.

CLINICAL MANIFESTATIONS. Many of the characteristic clinical features (Box 29-3) of HL can be explained by the complex action of cytokines and other growth factors that are secreted by the malignant cells. These substances induce infiltration and proliferation of inflammatory cells, resulting in an enlarged, painless lymph node in the neck (often the first sign of HL) (Figure 29-9). The discovery of an asymptomatic mediastinal mass on routine chest x-ray is not uncommon and is often an initial sign of HL. The cervical, axillary, inguinal, and retroperitoneal lymph nodes are commonly affected in HL (Figure 29-10). Local symptoms caused by pressure and obstruction of the lymph nodes are the result of the lymphadenopathy.

About one third of individuals will have some degree of systemic symptoms.[34] Intermittent fever, without other symptoms

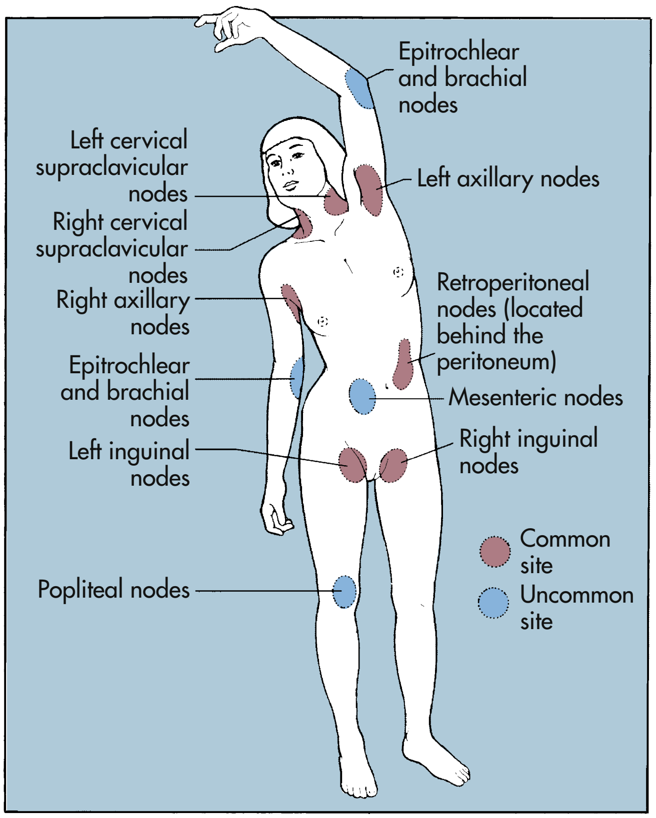

FIGURE 29-10 Common and Uncommon Involved Lymph Node Sites for Hodgkin Lymphoma.

TABLE 29-6 COTSWOLD STAGING CLASSIFICATION SYSTEM

STAGE	CRITERIA
I	Involvement of a single lymph node region or single extranodal organ or site
II	Involvement of two or more lymph node regions on the same side of the diaphragm or a single extranodal organ or site and its regional lymph nodes
III	Involvement of lymph node regions or structures on both sides of the diaphragm
IV	Disseminated involvement of one or more extralymphatic organs or an isolated extralymphatic organ with distant nodal involvement
	Modifying characteristics for all four stages:
	A: No B symptoms
	B: Unexplained fever of >38° C (100.4° F), drenching night sweats, unexplained loss of >10% of body weight in the 6 months preceding diagnosis
	E: Large mediastinal mass with direct extension into extranodal sites

Data from Lister TA, Crowther D: *Semin Oncol* 17:696, 1990.

of infection, drenching night sweats, itchy skin (pruritus), and fatigue are relatively common. These constitutional symptoms accompanied by weight loss are associated with a poor prognosis. The Cotswold staging classification system used for HL is able to establish a correlation between the anatomic extent of the disease and prognosis (Table 29-6). This classification system is based on the individual's medical history, examination (presence of symptoms and palpable lymph nodes), and other radiologic and hematologic results. Prognostic indicators include clinical stage, histologic type, tumor cell concentration and tumor burden, constitutional symptoms, and age.

Although HL rarely arises in the lung, mediastinal and hilar node adenopathy can cause secondary involvement of the trachea, bronchi, pleura, or lungs. Retroperitoneal nodes can involve vertebral bodies and nerves, causing displacement of ureters. Spinal cord involvement is more common in the dorsal and lumbar regions than in the cervical region. Although uncommon, skin manifestations include psoriasis and eczematoid lesions, causing itching and scratching.

As a result of direct invasion from mediastinal lymph nodes, pericardial involvement can cause pericardial friction rub, pericardial effusion, and engorgement of the neck veins. The gastrointestinal (GI) tract and urinary tract rarely are involved. Anemia often is found in individuals with HL, accompanied by a low serum iron level and decreased iron-binding capacity. Other laboratory findings include elevated sedimentation rate, leukocytosis, and eosinophilia. Leukopenia occurs in advanced states of HL.

Splenic involvement of HL depends on histopathologic type (see Table 29-5). The spleen is involved in 60% of cases of mixed cellularity and lymphocytic depletion types. With lymphocyte predominance and nodular sclerosis types, only 34% of cases reveal splenic involvement.

EVALUATION AND TREATMENT. Because of the variability in symptoms, early definitive detection may be difficult. Asymptomatic lymphadenopathy can progress undetected for several years. Careful evaluation, including chest x-rays, lymphangiography, and biopsy, should be carried out for individuals with fever of unknown origin and peripheral lymphadenopathy.[34] A lymph node biopsy with scattered RS cells and a cellular infiltrate is highly indicative of HL. The effectiveness of treatment is related to the age of the individual and the extent of the disease. Approximately 75% of individuals diagnosed with HL are cured, largely because of successful combined treatment with radiation therapy and chemotherapy (Figure 29-11). Over the past 50 years, the death rate has fallen more rapidly for HL than for any other malignancy. More recent treatments include high-dose chemotherapy with bone marrow or stem cell transplantation. Monoclonal antibodies also are being developed and nonmyeloablative allogeneic stem cell transplant has been found to help certain individuals even though this treatment is still under development.

The 5-year survival rate varies depending on the stage that is identified at diagnosis.[34] The 5-year survival rate for stages I and II is 90% to 95%, 80% to 85% for stage III, and 75% for stage IV. Those with stage I or II disease are candidates for chemotherapy, radiation therapy, or a combination of these treatment modalities. Individuals with stage III or IV disease, bulky disease (more than 10-cm mass or mediastinal disease with a transverse diameter exceeding 33% of the transthoracic diameter), or presence of B symptoms require combined chemotherapy with or without additional radiation treatment. Other factors, if

present, have an influence on survival. Poorer survival is related to a high white blood cell count (greater than 15,000/μL) or low hemoglobin (Hb) level (less than 10.5 g/dl); low lymphocyte count (less than 600/μL); and male gender. Cure for HL can be achieved in 75% of cases with current therapies.

Non-Hodgkin Lymphoma

The previously used generic classification of **non-Hodgkin lymphoma (NHL)** has been reclassified in the WHO/REAL scheme into **B-cell neoplasms,** which include a variety of lymphomas including myelomas that originate from B cells at various stages of differentiation, and **T-cell** and **NK-cell neoplasms,** which include lymphomas that originate from either T or NK cells. These cancers are differentiated from HL by lack of RS cells and other cellular changes not characteristic of HL.

More than 69,740 cases of NHL and 19,020 deaths are predicted for 2013 (see Table 29-2).[35] The median age of diagnosis is 67 years of age. The incidence of NHL has increased from 8 persons per 100,000 in 1973 to 19.6 per 100,000 in 2009. Lymphomas from HIV and EBV have accounted for some of the increase but an actual cause has yet to be determined. Conversely, the mortality rate has risen at a slower rate. It is thought that newer treatment modalities are improving survival rates.

PATHOPHYSIOLOGY. NHL is best described as a progressive clonal expansion of B cells, T cells, or NK cells. The genetic lesions affecting proto-oncogenes or tumor-suppressor genes result in cell immortalization and the resultant increase in malignant cells. Oncogenes may be activated by chromosomal translocations or the tumor-suppressor loci may be inactivated by deletion or mutation of chromosomes. Oncogenic viruses also may alter the genome of certain subtypes. The various subtypes of NHL may be identified by specific diagnostic markers related to various cytogenic lesions.

Lymphomas most likely originate from mutations in cellular genes (many of which are environmentally induced) in a single cell that lead to loss of control of proliferation and other aspects of cell growth. The most common type of chromosomal alteration in NHL is translocation, which disrupts the genes encoded at the breakpoints. Risk factors include family history, exposure to a variety of mutagenic chemicals, irradiation, infection with certain cancer-related viruses (e.g., EBV, human herpesvirus-8, HIV, HTLV-1, hepatitis C), and immune suppression related to organ transplantation. Gastric infection with *Helicobacter pylori* increases the risk for gastric lymphomas. NHL is a disease of middle age, usually found in individuals more than 50 years old.

B cells account for 80% to 90% of NHLs, with T cells and NK cells accounting for the remaining percentage. A very small percent originates from macrophages. NHL tumors are categorized by the level of differentiation, cell of origin, and rate of cellular proliferation. Tumor aggressiveness of many B-cell NHLs may be predicted by the pattern of cell growth and size. Tumors with a characteristic nodular pattern, vaguely resembling lymphoid follicular structures, are generally less aggressive than lymphomas with a diffuse pattern of proliferation. Small lymphocyte lymphomas are less aggressive than large cell lymphomas, which are generally intermediate to high grade in aggressiveness. However, small cells are characteristic of some subtypes of high-grade lymphomas.

CLINICAL MANIFESTATIONS. Clinical manifestations of NHL usually begin as localized or generalized lymphadenopathy, similar to HL. The cervical, axillary, inguinal, and femoral chains are the most commonly affected sites. Generally, the swelling is painless and the nodes have enlarged and transformed over a period of months or years. Other sites of involvement are the nasopharynx, gastrointestinal (GI) tract, bone, thyroid, testes, and soft tissue. Some individuals have retroperitoneal and abdominal masses with symptoms of abdominal fullness, back pain, ascites (fluid in the peritoneal cavity), and leg swelling.

Lymphomas are classified as low, intermediate, or high grade. A low-grade lymphoma, which also may be termed *indolent,* has a slow progression. Individuals with low-grade lymphoma commonly present with a painless, peripheral adenopathy. Spontaneous regression of these nodes may occur, mimicking the presence of an infection. Night sweats with an elevated temperature (more than 38° C [100.4° F]) and weight loss, as well

TABLE 29-7 CLINICAL DIFFERENCES BETWEEN NON-HODGKIN LYMPHOMA AND HODGKIN LYMPHOMA

CHARACTERISTIC	NON-HODGKIN LYMPHOMA	HODGKIN LYMPHOMA
Nodal involvement	Multiple peripheral nodes Mesenteric nodes and Waldeyer ring commonly involved	Localized to single axial group of nodes (i.e., cervical, mediastinal, para-aortic) Mesenteric nodes and Waldeyer ring rarely involved
Spread	Noncontiguous	Orderly spread by contiguity
B symptoms*	Uncommon	Common
Extranodal involvement	Common	Rare
Extent of disease	Rarely localized	Often localized

B	Fever, night sweats, weight loss

as extranodular involvement, are not commonly present in the early stages but are common in advanced or end stages of the disease. Cytopenia, reflective of bone marrow involvement, is often observed. Hepatomegaly is common; however, splenomegaly is present in approximately 40% of individuals. Fatigue and weakness are more prevalent with advanced stages.

Immediate and high-grade lymphomas, which are more aggressive, have a more varied clinical presentation. A high-grade lymphoma also may be termed *aggressive.* Adenopathy is common with more than one third of individuals having extranodal involvement. Common sites are the GI tract, skin, bone marrow, sinuses, genitourinary (GU) tract, thyroid, and CNS. Night sweats, with an increased temperature (more than 38° C [100.4° F]), as well as weight loss (more than 10% from baseline within 6 months) are present in approximately 30% to 40% of individuals. Some individuals have retroperitoneal and abdominal masses with symptoms of abdominal fullness, back pain, ascites (fluid in the peritoneal cavity), and leg swelling. Hepatomegaly and splenomegaly are often present. Differences in clinical features are noted in Table 29-7.

EVALUATION AND TREATMENT. Biopsy is considered the primary means for diagnosis of NHL. Staging of NHL is necessary to identify treatment and make a prognosis. In addition to biopsy, computed tomography (CT) scans of the neck, chest, abdomen, and pelvis, as well as bilateral bone marrow aspirate examination, are performed. Data from all three procedures are necessary for appropriate staging. A common finding in NHL is noncontiguous lymph node involvement, which is not common in HL. The Ann Arbor staging system is most commonly used to stage NHL (Table 29-8).

Treatment for NHL is quite diverse and depends on type (B or T cell), tumor stage, histologic status (low, intermediate, or high grade), symptoms, age, and any comorbidities. Depending on the type (B or T cell) of the tumor, the stage of the disease, and the aggressiveness of the tumor, treatment is usually initiated at the time of diagnosis. However, because treatment is not curative for some low-grade indolent lymphomas that are widely disseminated, observation without treatment may be the most appropriate choice. These indolent tumors are often not symptomatic for the individual and this approach improves quality of life. In some cases the disease may be so slow growing that treatment is not needed for an extended period of time.

Success of treatment is dependent on several parameters, including the type of lymphoma, stage of disease, cell type, involvement of organs outside the lymph nodes, age of the person, and the severity of the body's reaction to the disease (e.g., fever, night sweats, weight loss).[34,36] Treatment with chemotherapy alone may be adequate in many cases, although radiation therapy is frequently included. Low-dose chemotherapy has been followed by autologous stem cell transplantation in some NHLs or for recurrent disease. Treatment of B-cell lymphomas with rituximab has proven effective. Rituximab is a commercial monoclonal antibody against antigen CD20, which is expressed on the surface of all B cells, including those that are malignant. Administration of rituximab depletes most B cells and allows the replenishment of normal B cells from the lymphoid stem cell pool. It has also proven useful in a variety of autoimmune diseases, including immune thrombocytopenia purpura, autoimmune anemias, systemic lupus erythematosus, and rheumatoid arthritis.

Radioimmunotherapy, a newer treatment approach, combines radiation therapy with monoclonal antibody therapy and is used to improve rates of complete remission both in indolent forms of lymphoma (follicular and marginal zone) and in aggressive forms, including large B-cell and mantle cell lymphoma. Studies suggest improved complete remission rates and longer disease-free survival in persons with these types of lymphomas.

Individuals with NHL can survive for extended periods.[34,36] A partial remission may be achieved in some cases in which evidence of the disease remains but it does not progress. Survival with nodular lymphoma ranges up to 15 years, but those with diffuse disease generally do not survive as long. Overall,

the survival rates of NHL are less than those for Hodgkin lymphoma. For NHL, the survival rates are 1 year, 77%; 5 years, 59%; and 10 years, 42%. Many investigators believe that more aggressive treatment increases the cure rate. High-grade NHL is seen with increasing frequency in persons with AIDS and has an extremely poor prognosis.

Burkitt Lymphoma

Burkitt lymphoma is a B-cell tumor with unique clinical and epidemiologic features that accounts for 30% of childhood lymphomas worldwide. It is a highly aggressive B-cell non-Hodgkin lymphoma that is the fastest growing human tumor. It occurs in children from east-central Africa and New Guinea and is characterized by a rapidly growing tumor primarily in the jaw and facial bones (Figure 29-12). In the United States, Burkitt lymphoma is rare, usually involves the abdomen, and is characterized by extensive bone marrow invasion and replacement. EBV, found in nasopharyngeal secretions, is associated with Burkitt lymphoma in African children.

PATHOPHYSIOLOGY. EBV is associated with almost all cases (more than 90%) of Burkitt lymphoma. It is suspected that suppression of the immune system by other illnesses (e.g., HIV infection, chronic malaria) increases the individual's susceptibility to EBV. B cells are particularly sensitive because of specific surface receptors for EBV. As a result, the B cell undergoes chromosomal translocations that result in overexpression of the *C-MYC* proto-oncogene and loss of control of cell growth (Figure 29-13). The most common translocation (75% of individuals) is between chromosomes 8 (containing the *C-MYC* gene) and 14 (containing the immunoglobulin heavy-chain genes). Other translocations have been reported between chromosome 8 and chromosomes 2 or 22, which contain genes for immunoglobulin light chains.

CLINICAL MANIFESTATIONS. In non-African Burkitt lymphoma the most common presentation is abdominal swelling. More advanced disease may involve other organs—eye, ovaries, kidneys, glandular tissue (breast, thyroid, tonsil)—and presents with type B symptoms (night sweats, fever, weight loss).

EVALUATION AND TREATMENT. The distribution of tumors and biopsies of enlarged lymph nodes or the bone marrow containing malignant B cells are usually indicative of Burkitt lymphoma. It is one of the most aggressive and quickly growing malignancies. However, the African variety in children has been successfully treated with radiotherapy and cyclophosphamide (60% survival overall; 90% survival with limited disease). The American type is more resistant to treatment. Adjuvant monoclonal antibody therapy with rituximab appears to be a promising agent for improving outcomes with minimal toxic effects.[37]

Lymphoblastic Lymphoma

Lymphoblastic lymphoma (LL) is a relatively rare variant of NHL (2% to 4%) but accounts for almost one third of cases of NHL in children and adolescents, with a male predominance. It is estimated that there will be more than 6000 new cases and more than 1400 deaths in 2012. The vast majority of LL (more than 85%) is of T-cell origin, and the remainder arises from B cells. LL is similar to acute lymphoblastic leukemia and may be considered a variant of that disease.

PATHOPHYSIOLOGY. The disease arises from a clone of relatively immature T cells that becomes malignant in the thymus. As with most lymphoid tumors, LL is frequently associated with translocations, primarily of the chromosomes that encode for the T-cell receptor (chromosomes 7 and 14). These aberrations result in increased expression of a variety of transcription factors and loss of growth control.

CLINICAL MANIFESTATIONS. The first sign of LL is usually a painless lymphadenopathy in the neck. Peripheral lymph nodes in the chest become involved in about 70% of individuals, mostly above the diaphragm. LL is a very aggressive tumor that presents as stage IV in most people. T-cell LL is associated with a unique mediastinal mass (up to 75%) because of the apparent origin of the tumor in the thymus.

The mass results in chest pain and may cause compression of bronchi or the superior vena cava. The tumor may infiltrate the bone marrow in about half of those affected, and suppression of bone marrow hematopoiesis leads to increased susceptibility to infections. Other organs, including the liver, kidney, spleen, and brain, may also be affected. Many individuals express type B symptoms: fever, night sweats, and significant weight loss.

EVALUATION AND TREATMENT. The most common therapeutic approach is combined chemotherapy with multiple drugs. In early disease, the response rate is high with increased survival; the 5-year survival in children is 80% to 90%, and 45% to 55% in adults. Although LL is easily treated, there is a high relapse rate: 40% to 60% of adults.

Conditions That Mimic Lymphomas

Certain other clinical conditions mimic the malignant lymphomas. These conditions include tuberculosis (TB), syphilis, systemic lupus erythematosus, lung cancer, and bone cancer. An important distinction between lymphomas and other conditions is that lymphomas usually involve localized lymphadenopathy. Infectious precursors of malignant lymphomas are characterized by more generalized lymphadenopathy with systemic signs and symptoms.

Plasma Cell Malignancies

The plasma cell is the end-stage cell of the humoral immune response (see Chapter 8). Immunocompetent B cells presented with antigen and stimulated with cytokines from T helper cells will undergo proliferation and differentiation into antibody-producing plasma cells. Antigen-reactive B cells have undergone rearrangement of immunoglobulin heavy-chain variable region genes *(V, D, J)* and express surface IgM or IgD, or both. After stimulation with antigen, the B cells may not undergo any further genetic rearrangement and develop into plasma cells that secrete IgM or selectively rearrange the immunoglobulin heavy-chain genes to irreversibly switch to secreting IgG, IgA, or IgE. During this process some cells may undergo malignant transformation, leading to one of several types of plasma cell malignancies (Figure 29-14). The most common and most aggressive plasma cell tumor is multiple myeloma. Other diseases in this classification include precursors to malignant myeloma (smoldering myeloma, monoclonal gammopathy of undetermined significance [MGUS]), solitary plasmacytoma of the bone, and Waldenström macroglobulinemia.[38] A common characteristic of these tumors is secretion of complete or partial immunoglobulin molecules.

Multiple Myeloma

Multiple myeloma (MM) is a clonal plasma cell cancer characterized by the slow proliferation of malignant cells as tumor cell masses in the bone marrow that usually results in destruction of the bone. Most MMs secrete large amounts of monoclonal proteins that resemble intact immunoglobulins. The reported incidence of myeloma has doubled in the past two decades, possibly as a result of more sensitive testing used for diagnosis. The annual incidence rate in the United States is 5.6 per 100,000, with more than 21,700 new cases and more than 10,700 deaths estimated for 2012.[39] Multiple myeloma occurs in all races, but the incidence in blacks is about twice that of whites. It rarely occurs before the age of 40 years—peak age of incidence is about 70 years. It is slightly more common in men than in women. Neoplastic cells of multiple myeloma reside in the bone marrow and are usually not found in the peripheral blood. Occasionally it may spread to other tissues, especially in very advanced disease.

PATHOPHYSIOLOGY. Many myelomas are aneuploidy, with chromosomal numbers ranging from 44 chromosomes to near tetraploid. Chromosomal translocations (breakpoints) are responsible for development of myeloma in most individuals. The primary translocation involves the immunoglobulin heavy chain on chromosome 14 that relocates to sites containing genes that cell cycle (cyclins) on chromosomes 11(q13), 12(p13), and 6(p21); oncogenes on chromosomes 16(q23), 8(q24), and 20; and fibroblast growth factor receptor on chromosome 4(p16).[9] A progression of further secondary genetic alterations causes development to an aggressive MM (Figure 29-15). The molecular pathogenesis of multiple myeloma also involves proto-oncogene mutations and, more rarely, inactivation of tumor-suppressor

genes. The precise timing and reason for the genetic alteration and accumulation are unknown, but probably occur initially late in B-cell development after exposure to antigen. Investigators are studying various epigenetic alterations in multiple myeloma, for example, miRNAs and global changes in chromatin.[40]

Malignant plasma cells arise from one clone of B cells that produce abnormally large amounts of one class of immunoglobulin (usually IgG, occasionally IgA, and rarely IgD or IgE). The malignant transformation may begin early in B-cell development, possibly before encountering antigen in the secondary lymphoid organs. The myeloma cells return

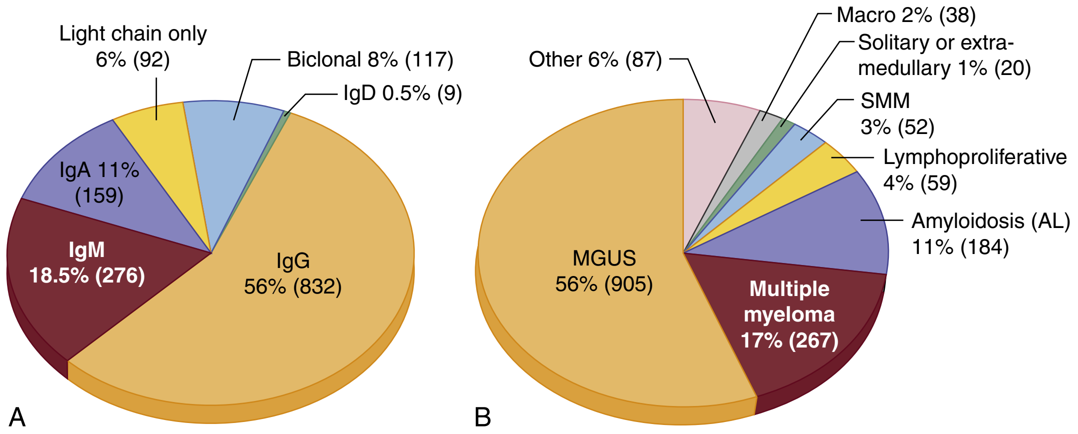

FIGURE 29-14 **Distribution of Monoclonal Gammopathy Types. (From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, Saunders.)

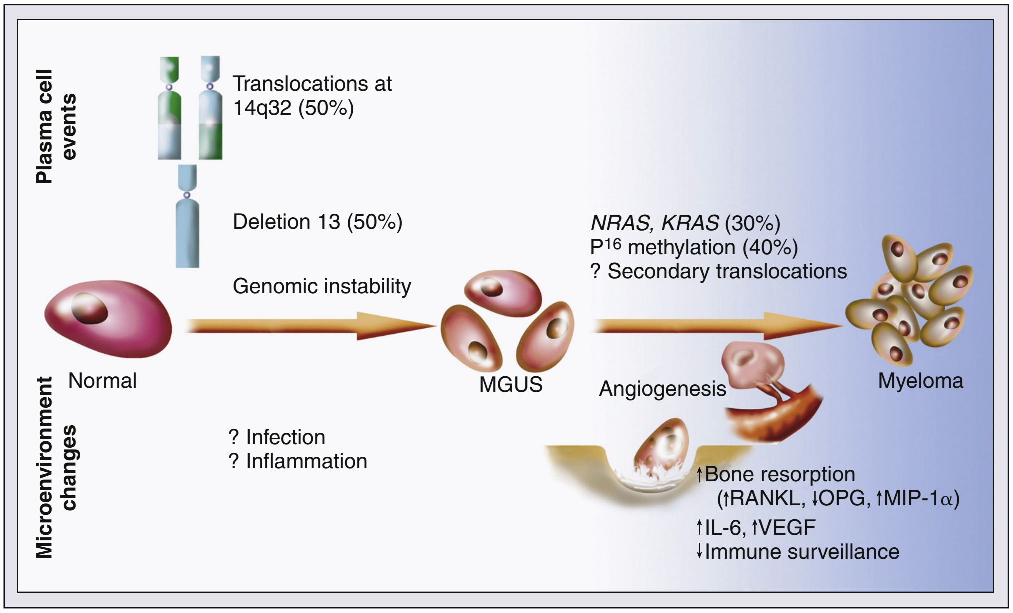

FIGURE 29-15 **Myeloma Cell Proliferation and Disease Progression.** Development of the malignant myeloma results from multiple genetic changes, initially a translocation involving the immunoglobulin heavy-chain genes on chromosome 14 or a deletion in chromosome 13. The intermediate phenotype is frequently genetically unstable, leading to further mutations that result in a myeloma. Interactions between myeloma cells and extracellular matrix proteins further increase adhesion molecule expression, anti-apoptotic pathways, angiogenesis, bone resorption, and cytokine secretion. *IL-6,* Interleukin-6; *KRAS,* V-Ki-ras Z Kirsten rat sarcoma viral oncogene homolog; *MGUS,* monoclonal gammopathy of undetermined significance; *MIP-1α,* macrophage inflammatory protein-1α; *NRAS,* neuroblastoma RAS viral (v-ras) oncogene homolog; *OPG,* osteoprotegerin; *RANKL,* receptor activator of nuclear factor-κB ligand; *VEGF,* vascular endothelial growth factor. (From Abeloff M et al: *Abeloff's clinical oncology,* ed 4, Philadelphia, 2008, Churchill Livingstone.)

either to the bone marrow or to other soft tissue sites. Their return is aided by cell adhesion molecules that help them target favorable sites that promote continued expansion and maturation.

Myeloma cells in the bone marrow directly secrete hepatocyte growth factor and parathyroid hormone–related peptide and adhere to stromal cells, inducing their production of several cytokines (e.g., IL-6, IL-1, TNF-α, TNF-β, IL-11, macrophage inflammatory protein). (Lymphocytes and cytokines are described in Chapter 8.) These factors, particularly IL-6, act as an osteoclast-activating factor and stimulate osteoclasts to reabsorb bone. This process results in bone lesions and hypercalcemia (high calcium levels in the blood) resulting from release of calcium from the breakdown of bone.

The antibody produced by the transformed plasma cell is usually defective, containing truncations, deletions, and other abnormalities, and is frequently referred to as a paraprotein (abnormal protein in the blood). Because of the large number of malignant plasma cells, the abnormal antibody, called the **M protein,** becomes the most prominent protein in the blood in 80% of myeloma clients (Figure 29-16). Suppression of normal plasma cells by the myeloma results in diminished or absent normal antibodies. The excessive amount of M protein also may contribute to many of the clinical manifestations of the disease. The myeloma may produce free immunoglobulin light chain **(Bence Jones protein)** that is present in the blood and urine in approximately 80% of clients and contributes to damage of renal tubular cells.

CLINICAL MANIFESTATIONS. The common presentation of MM is characterized by elevated levels of calcium in the blood (hypercalcemia) (13% of persons), renal failure (19%), anemia (72% of persons), and bone lesions (80% of persons).[41] The hypercalcemia and bone lesions result from infiltration of the bone by malignant plasma cells and stimulation of osteoclasts to reabsorb bone. This process results in the release of calcium (hypercalcemia) and the development of "lytic lesions" (round, "punched-out" regions of bone) (Figure 29-17). Destruction of bone tissue causes pain, the most common presenting symptom, and pathologic fractures. The pain may be felt in a single bone of the entire skeleton, and the bones most commonly involved, in decreasing order of frequency, are the vertebrae, ribs, skull, pelvis, femur, clavicle, and scapula. Spinal cord compression, because of the weakened vertebrae, occurs in about 10% of individuals. The pain is initially aching, intermittent, and aggravated by weight-bearing. As the disease progresses, pain becomes severe and prolonged. It is common for the individual with myeloma to be treated for a slipped disk or arthritis before the correct diagnosis of myeloma is established. The individual may complain of weakness, fatigue, weight loss, and anorexia in addition to pain.

Proteinuria is observed in 90% of individuals. Renal failure may be either acute or chronic and is usually secondary to the hypercalcemia. Bence Jones protein may lead to damage of the proximal tubules. Anemia is usually normocytic and normochromic and results from inhibited erythropoiesis caused by tumor cell infiltration of the bone marrow.

The high concentration of paraprotein in the blood may lead to hyperviscosity syndrome. The increased viscosity interferes with blood circulation to various sites (brain, kidneys, extremities). Hyperviscosity syndrome is observed in up to 20% of individuals with MM. Additional neurologic symptoms (e.g., confusion, headaches, blurred vision) may occur secondary to hypercalcemia or hyperviscosity.

Suppression of the humoral (antibody-mediated) immune response results in repeated infections, primarily pneumonias and pyelonephritis. The most commonly involved organisms are encapsulated bacteria that are particularly sensitive to the effects of antibody: pneumonia caused by *Streptococcus pneumoniae*, *Staphylococcus aureus,* or *Klebsiella pneumoniae* or pyelonephritis caused by *Escherichia coli* or other gram-negative organisms. Cell-mediated (T-cell) function is relatively normal. Overwhelming infection is the leading cause of death from MM.

MM is a progressive disorder and is often preceded by a condition known as **monoclonal gammopathy of undetermined significance (MGUS).** MGUS is diagnosed by the presence of an M protein in the blood or urine without additional evidence of MM.[41] MGUS is present in approximately 1% of the general population and in 3% of individuals older than 70 years. Although MGUS is considered nonpathologic and requires no treatment, about 2% of individuals with MGUS progress to malignant plasma cell disorders. Progression of MM following MGUS advances to asymptomatic MM and finally symptomatic MM. Asymptomatic MM also may be referred to as **smoldering myeloma** and indolent myeloma.[41] Smoldering myeloma is usually characterized by the presence of an M protein and clonal bone marrow plasma cells, but with no indication of end-organ damage.

Most cases of symptomatic plasma cell tumors are multiple myeloma (about 94%). The remaining 6% is divided equally between solitary plasmacytomas and extramedullary plasmacytomas.[38] **Solitary plasmacytoma** is characterized by a solitary tumor of malignant plasma cells that may result in a single lytic bone lesion or may be in the tissues (extramedullary plasmacytoma).[41] Extramedullary plasmacytoma can be found in a variety of soft tissues, but commonly in those of the upper respiratory tract (e.g., tonsils, nasopharynx, sinuses). Additionally, MM is staged to help determine prognosis and appropriate treatment (Table 29-9).

EVALUATION AND TREATMENT. Diagnosis of MM is made by symptoms, radiographic and laboratory studies, and a bone marrow biopsy. Quantitative measurements of immunoglobulins (IgG, IgM, IgA) are usually performed. Typically, one class of immunoglobulin (the M protein produced by the myeloma cell) is greatly increased, whereas the others are suppressed. Serum electrophoretic analysis reveals increased levels of M protein. Because the M protein is monoclonal, each molecule has the same electric change and migrates at about the same site on electrophoresis, resulting in a highly concentrated protein (M spike). Bence Jones protein is observed in the urine or serum by immunoelectrophoresis or in the serum using enzyme-linked immunosorbent assay (ELISA). Usually individuals with Bence Jones protein also have M protein in their blood. However, variants of MM include individuals in which free light chain only is produced and a rare variant that

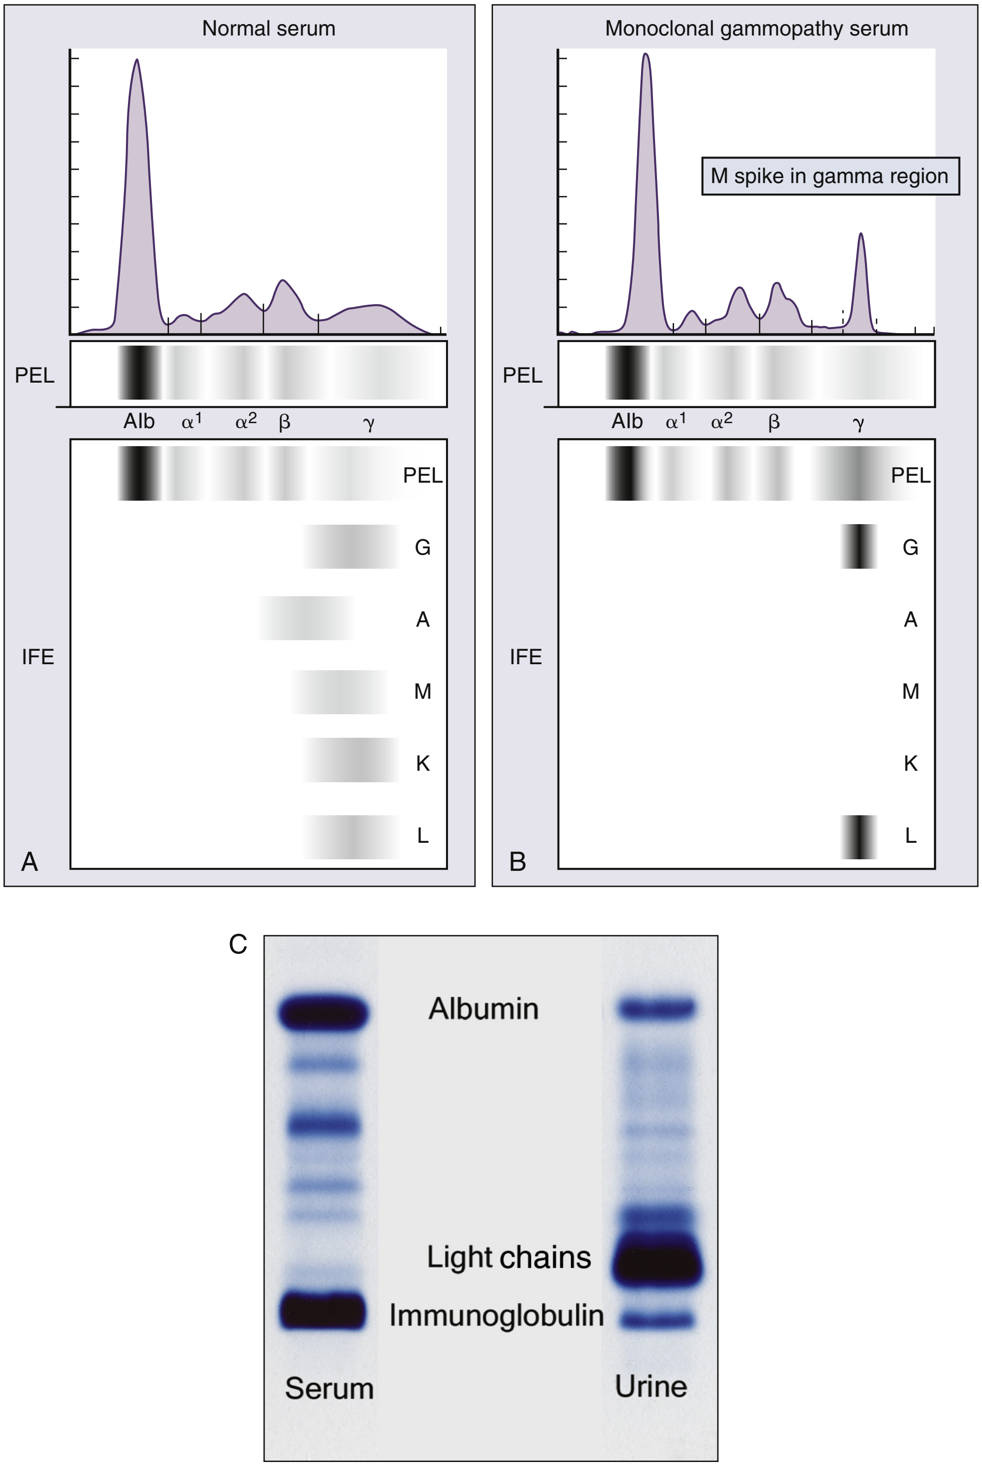

FIGURE 29-16 **M Protein.** Serum protein electrophoresis *(PEL)* is used to screen for M proteins in multiple myeloma. **A,** In normal serum the proteins separate into several regions between albumin *(Alb)* and a broad band in the gamma (γ) region, where most antibodies (gamma globulins) are found. Immunofixation *(IFE)* can identify the locations of IgG *(G),* IgA *(A),* IgM *(M),* and kappa *(K)* and lambda *(L)* light chains. **B,** Serum from an individual with multiple myeloma contains a sharp M protein *(M spike).* The M protein is monoclonal and contains only one heavy chain and one light chain. In this instance the IFE identifies the M protein as an IgG containing a lambda light chain. **C,** Serum and urine protein electrophoretic patterns in a client with multiple myeloma. Serum demonstrates an M protein *(immunoglobulin)* in the gamma region, and the urine has a large amount of the smaller-sized light chains with only a small amount of the intact immunoglobulin. (**A** and **B** from Abeloff M et al: *Abeloff's clinical oncology,* ed 4, Philadelphia, 2008, Churchill Livingstone. **C** from McPherson R, Pincus M: *Henry's clinical diagnosis and management by laboratory methods,* ed 22, Edinburgh, 2012, Saunders.)

(**A** from Abeloff M et al: *Abeloff's clinical oncology,* ed 4, Philadelphia, 2008, Churchill Livingstone. **B** from Kissane JM, editor: *Anderson's pathology,* ed 9, St Louis, 1990, Mosby.)

TABLE 29-9 INTERNATIONAL STAGING SYSTEM FOR MULTIPLE MYELOMA

STAGE	CRITERIA
I	Serum β_2-microglobulin <3.5 mg/L Serum albumin ≥3.5 g/dl
II	Not stage I or III*
III	Serum β_2-microglobulin ≥5.5 mg/L

From Greipp PR et al: *J Clin Oncol* 23(15):3412–3420, 2005.
*There are two categories for stage II: serum β_2-microglobulin <3.5 mg/L but serum albumin <3.5 g/dl; or serum β_2-microglobulin 3.5 to <5.5 mg/L irrespective of the serum albumin level.

produces only free heavy chain, and approximately 1% are nonsecretory so that neither an M protein nor Bence Jones protein is produced. The amount of M protein in the blood may be used as a measure of the extent of the disease or as a measure of response to therapy. The serum level of another protein, free **β_2-microglobulin,** is a useful indicator of prognosis or effectiveness of therapy.

A bone marrow biopsy is performed to confirm the presence of myeloma cells in the marrow (Figure 29-18). Radiographic studies include x-ray, CT scans, and magnetic resonance imaging (MRI) to document the presence of bone lesions and areas of destruction. Diagnosis is based on findings and the degree of involvement. The individual must have all three major criteria (Box 29-4); however, new more sensitive and specific criteria have been proposed but not yet accepted into practice.[42]

Combinations of chemotherapy, radiation therapy, and plasmapheresis (exchange), and marrow transplantation have been the standards of treatment.[38] Conventional combinations of chemotherapeutic agents have included melphalan and prednisone (MP); MP with vincristine, carmustine, and cyclophosphamide; vincristine, doxorubicin, and dexamethasone; and thalidomide and dexamethasone. The drug thalidomide disrupts the stromal marrow–MM cell interaction by modulating cell surface adhesion molecules and inhibiting angiogenesis. In addition, it increases apoptosis and G_1 growth arrest (i.e., the cell cycle gap 1; see Chapter 1) of MM cells.

Dose intensification improves the outcomes in younger clients; however, long-term remissions are obtained in a minority of clients. Thus intensive research measuring the effect of novel new therapies is the objective of ongoing trials. Gene expression profiling (GEP) helps improve the treatment of MM because it identifies prognostic subgroups and defines the molecular pathways associated with these subgroups. Newer agents (e.g., bortezomib, lenalidomide) have broadened the therapeutic regimens for end-stage myeloma. Lenalidomide is related to thalidomide; however, it increases treatment efficacy while avoiding the adverse effects associated with thalidomide. In combination with dexamethasone, lenalidomide is now an approved second-line treatment for MM.

High-dose chemotherapy followed by blood-forming stem cell transplantation (SCT) has become standard treatment for younger individuals (up to 70 years old in some trials).[38,43] Survival is increased with SCT compared with chemotherapy alone. SCT uses the client's own blood-forming stem cells (autologous) or a donor's cells (allogeneic). Survival may be prolonged by performing a second autologous transplant, called *tandem transplant,* within 6 to 12 months from the first transplant.

Radiation with high-energy x-rays is used more for a localized effect rather than systemic. It is most often used to treat areas of the bone that have been damaged and are not responding to chemotherapy. In addition, it may be used to treat sites where tumor has led to collapse of vertebrae and spinal cord compression.

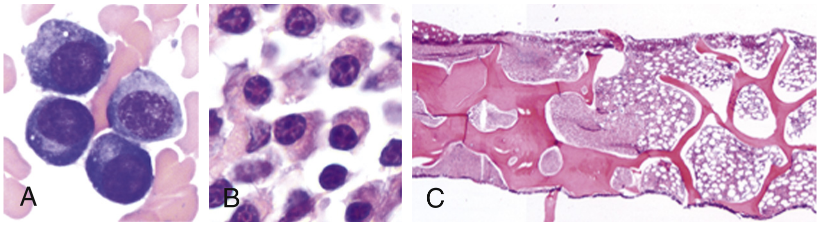

FIGURE 29-18 **Myeloma Cells.** The typical myeloma type has fairly mature-appearing plasma cells with eccentric nuclei on bone marrow aspirate **(A)** and biopsy **(B)**. **C,** Osteosclerotic myeloma in which the left side of the photograph shows bone sclerosis and the marrow cavity replaced by myeloma. (From Hoffman R et al: *Hematology: basic principles and practice,* ed 6, Philadelphia, 2013, Churchill Livingstone.)

BOX 29-4 DIAGNOSTIC CRITERIA FOR MULTIPLE MYELOMA

Major Criteria

Positive biopsy result
More than 30% plasma cells in bone marrow sample
Monoclonal antibody in blood/urine

Minor Criteria

10% to 30% plasma cells in bone marrow sample
Monoclonal antibody present but not enough to be a major criterion
Holes in bone from tumor seen on imaging studies
Normal antibody in blood abnormally low

Additional interventions are used to prevent and treat complications arising from progression of the disease. Drugs that inhibit bone resorption—bisphosphonates—reduce the incidence of skeletal damage, which also reduces hypercalcemia and decreases bone pain. Hydration and diuretics may be used to maintain a high urine output, and antibiotics to treat recurring infections.

The prognosis for persons with MM remains poor. The median survival for all states of MM is 3 years. Individuals with multiple bone lesions, if untreated, rarely survive more than 6 to 12 months. Individuals with inactive (indolent) myeloma, however, can survive for many years. With chemotherapy and aggressive management of complications, median survival may increase to 24 to 30 months, with a 10-year survival rate of 3%.

Waldenström Macroglobulinemia

Waldenström macroglobulinemia (WM), also called **lymphoplasmacytic lymphoma,** is a rare type of slow-growing plasma cell tumor that secretes a monoclonal IgM molecule. Approximately 1500 new cases are diagnosed yearly in the United States; the median age of diagnosis is 63 years of age.[44] WM shares a great deal of similarity with multiple myeloma regarding its plasma cell origin, diagnosis, and treatment. However, the overproduction of the macromolecule IgM leads to certain unique clinical characteristics.

PATHOPHYSIOLOGY. WM arises from plasma cells that have undergone genetic rearrangement of the variable region genes *(V, D, J),* but have not undergone class-switch. Therefore, the principal secretory product of the tumor is IgM. Although no definitive genetic defect has been identified, WM may originate from aberrant B-cell maturation and class-switch.

Most of the pathology is associated with the production of large amounts of IgM, a high-molecular-weight protein (about 900,000 daltons). Excessive production leads to thickening of the blood and abnormally high blood viscosity (hyperviscosity syndrome). The increased viscosity interferes with circulation to various sites (e.g., eyes, brain, kidneys, extremities). IgM paraprotein may also result in cryoglobulins (proteins that precipitate from the blood at lower than body temperature). Hyperviscosity syndrome is observed in up to 20% of individuals with WM.

CLINICAL MANIFESTATIONS. Many clients with WM are asymptomatic. The most common symptoms include weakness and fatigue, bleeding (from gums and nose), weight loss, and bruising. Bleeding may result secondary to formation of complexes among the macroglobulin, clotting factors, and platelets that diminish hemostatic capacity. If hyperviscosity syndrome occurs, the individual may develop neurologic problems (e.g., blurred vision, loss of vision, headaches, dizziness, vertigo). The macromolecules may also precipitate in colder regions of the body (cryoglobulins) leading to Raynaud phenomenon.

Although the malignant plasma cells invade the bone marrow, erosion of the bone is not commonly observed; less than 5% of individuals have lytic bone lesions. The tumor often disseminates to other organs, including the spleen, lymph nodes, and liver. Anemia occurs in about 10% of individuals, secondary to tumor infiltration of the bone marrow. Peripheral hemolysis can also result from production of cold agglutinins.

EVALUATION AND TREATMENT. Diagnosis is made on the basis of high levels of monoclonal IgM in the blood and the identification of malignant cells in bone marrow aspirates. Other hematologic abnormalities may be observed, especially anemia (80% of clients with symptomatic WM) but also thrombocytopenia and leukopenia. Bence Jones protein may be observed in almost half of individuals with WM.

Treatment is similar to that described for multiple myeloma.[45] First-line therapy includes combined chemotherapy with nucleoside analogs, alkylating agents, and monoclonal antibody (e.g., rituximab). Bone marrow stem cell transplantation has also proven effective in some individuals. The current recommendations include treatment with a combination of dexamethasone, rituximab, and cyclophosphamide, with the use of other drugs (e.g., doxorubicin, vincristine, and nucleoside analogs) in individuals with very high levels of M protein.

ALTERATIONS OF SPLENIC FUNCTION

The spleen has been an organ of mystery and perplexity in the study of medicine. Its relationship to other organs and disease processes, particularly the immune and hematologic systems, was not identified until the eighteenth century. The complexities of splenic function are not totally understood, and its mysteries are still being explored. The spleen is a useful organ, but its functions overlap those of other organs so that one is capable of living a normal, healthy life without the spleen. The relationship between asplenia and a higher risk for infection was not recognized until the early 1950s.

In the past, **splenomegaly** (enlargement of the spleen) was associated with various disease states. It is now recognized that splenomegaly is not necessarily pathologic; an enlarged spleen may be present in certain individuals without any evidence of disease. Splenomegaly may be, however, one of the first physical signs of underlying conditions, and its presence should not be ignored. In conditions in which splenomegaly is present, the normal functions of the spleen may become overactive, producing a condition known as **hypersplenism.**

Current criteria indicating the presence of hypersplenism include: (1) cytopenias (anemia, leukopenia, thrombocytopenia, or combinations of these); (2) cellular bone marrow; (3) splenomegaly; and (4) improvement after splenectomy. Some individuals may seek treatment for problems even though they have not met all these clinical criteria; therefore, the relevance and significance of hypersplenism are still uncertain. Primary hypersplenism is recognized when no etiologic factor has been identified; secondary hypersplenism occurs in the presence of another condition.

PATHOPHYSIOLOGY. Splenomegaly without a specific etiology is seen in 7% to 15% of individuals who are being evaluated for primary splenomegaly and is generally a diagnosis of exclusion. Specific conditions causing secondary splenomegaly and resulting hypersplenism are many and are related to all other categories of disease that affect individuals. Secondary splenomegaly may be classified according to the underlying cause. Specific conditions related to these various classifications of splenomegaly are detailed in Box 29-5. Different pathologic processes that produce splenomegaly are described briefly.

Acute inflammatory or infectious processes cause splenomegaly because of an increased demand for defensive activities. Acutely enlarged spleens secondary to infection may become so filled with erythrocytes that their natural rubbery resilience is lost and they become fragile and vulnerable to blunt trauma. Splenic rupture is a complication associated with infectious mononucleosis; rupture occurs mostly in males between the fourth and twenty-first day of acute illness.

Congestive splenomegaly is accompanied by ascites, portal hypertension, and esophageal varices and is most commonly seen in those with hepatic cirrhosis. Splenic hyperplasia develops in disorders that increase splenic workload and is associated most commonly with various types of anemia (hemolytic) and chronic myeloproliferative disorders (i.e., polycythemia vera).

BOX 29-5 DISEASES RELATED TO CLASSIFICATION OF SPLENOMEGALY

Inflammation or Infection

Acute: viral (hepatitis, infectious mononucleosis, cytomegalovirus), bacterial (*Salmonella,* gram negative), parasitic (typhoid)

Subacute or chronic: bacterial (subacute bacterial endocarditis, tuberculosis), parasitic (malaria), fungal (histoplasmosis), Felty syndrome, systemic lupus erythematosus, rheumatoid arthritis, thrombocytopenia

Congestive

Cirrhosis, heart failure, portal vein obstruction (portal hypertension), splenic vein obstruction

Infiltrative

Gaucher disease, amyloidosis, diabetic lipemia

Tumors or Cysts

Malignant: polycythemia vera, chronic or acute leukemias, Hodgkin lymphoma, metastatic solid tumors

Nonmalignant: hamartoma

Cysts: true cysts (lymphangiomas, hemangiomas, epithelial, endothelial); false cysts (hemorrhagic, serous, inflammatory)

Infiltrative splenomegaly is caused by engorgement by the macrophages with indigestible materials associated with various "storage diseases." Tumors and cysts cause actual growth of the spleen. Metastatic tumors in the spleen are rare and may result from primary tumors of the skin, lung, breast, and cervix.

CLINICAL MANIFESTATIONS. Overactivity of the spleen results in hematologic alterations that affect all blood components. Sequestering of red blood cells, granulocytes, and platelets results in a reduction of all circulating blood cells. The spleen may sequester up to 50% of the red blood cell population, thereby upsetting the normal physiologic concentration of red blood cells in the circulation. The rate of splenic pooling is directly related to spleen size and the degree of increased blood flow through it. Sequestering exposes the red blood cells to splenic conditions that accelerate destruction, further contributing to the decreased red blood cell concentration. Anemia is the result of these combined activities. Anemia may be further potentiated by an increase in blood volume, which produces a dilutional effect on the already reduced concentration of red blood cells. The dilutional effect, as well as the removal and destruction of red blood cells, depends primarily on the degree of splenomegaly.

White blood cells and platelets also are affected by sequestering, although not to the same degree as the red blood cell. Again, the size of the spleen is the determining factor in the number of cells sequestered.

EVALUATION AND TREATMENT. Treatment for hypersplenism is splenectomy; however, it is not always the treatment of choice. A splenectomy should be performed when its removal is considered necessary to alleviate the destructive effects on red blood cells. Clinical indicators should determine the need for splenectomy, not necessarily the specific condition. Splenectomy for splenic rupture no longer is considered mandatory in light of

the possibility of overwhelming sepsis after removal. Repair and preservation of the ruptured spleen are now considered before the decision to remove the spleen. Splenectomy also may be performed as treatment for hairy cell leukemia, Felty syndrome, agnogenic myeloid metaplasia, thalassemia major, Gaucher disease, hemodialysis, splenomegaly, splenic venous thrombosis, and thrombotic thrombocytopenic purpura (TTP).

Individuals are able to lead normal lives after splenectomy, but hematologic abnormalities often exist after removal of the spleen. The red blood cells become thinner, broader, and wrinkled as a result of increases in surface area and membrane lipids. The white blood cell count increases dramatically 1 week after removal and then stabilizes to approximately 40% greater than normal. Platelet numbers also rise immediately after surgery and then equilibrate to above-normal levels for the duration of the individual's life. Increased platelet levels have been implicated in ischemic heart disease in males because of increased thrombocytosis and hypercoagulability.

A major postoperative complication following splenectomy is overwhelming post-splenectomy infection (OPSI). Unless treated in time, OPSI may rapidly progress to septic shock and possibly disseminated intravascular coagulation (DIC). Initial statistics indicate a death rate of 50% to 70%, with most deaths occurring within the first 48 hours after hospitalization. Prompt medical attention can reduce the death rate to 10%.

ALTERATIONS OF PLATELETS AND COAGULATION

Hemostasis is dependent on adequate numbers of platelets and levels of coagulation factors. Diminished or excessive levels may lead to defective hemostasis or spontaneous and unnecessary activation of clotting. (Hemostasis is described in Chapter 27.) Diminished hemostasis results in either internal or external hemorrhage. Diffuse hemorrhage into skin tissues that is visible through the skin causes a red-purple discoloration identified as a **purpura.** Purpuric disorders occur when there are not enough normal platelets to plug damaged vessels or prevent leakage from the many minute tears that occur daily in normal capillaries. Disorders of the clotting system tend to result in more serious internal bleeding than platelet defects and usually are caused by a deficiency of one or several clotting factors. Disorders that result in spontaneous clotting can result from genetic disorders of clotting system components or from acquired diseases that activate clotting. These disorders are known collectively as **thromboembolic disease.**

Disorders of Platelets

Quantitative or qualitative abnormalities of platelets can interrupt normal blood coagulation and prevent hemostasis.[46] The quantitative abnormalities are thrombocytopenia, a decrease in the number of circulating platelets, and thrombocythemia, an increase in the number of platelets. Qualitative disorders affect the structure or function of individual platelets and can coexist with the quantitative disorders. Qualitative disorders usually prevent platelet adherence and aggregation, preventing formation of a platelet plug.

Thrombocytopenia

Thrombocytopenia is defined as a platelet count less than 150,000 platelets/µL of blood, although most healthcare providers do not consider the decrease of significance unless the count falls to less than 100,000 platelets/µL of blood.[47] Hemorrhage resulting from minor trauma does not usually occur until the count falls below 50,000/µL. Spontaneous bleeding without apparent trauma can occur with counts between 10,000 and 15,000/µL, resulting in petechiae, ecchymoses, larger purpuric spots, or frank bleeding from mucous membranes. Severe spontaneous bleeding may result if the count is less than 10,000/µL and can be fatal if it occurs in the gastrointestinal tract, respiratory system, or CNS.

Before the diagnosis of thrombocytopenia is made, **pseudothrombocytopenia** must be ruled out. This phenomenon occurs in approximately 1 in 1000 to 1 in 10,000 laboratory samples and is an in vitro artifact that may occur when a blood sample is analyzed by an automated cell counter. Platelets in the sample may become nonspecifically agglutinated by immunoglobulins in the presence of ethylenediaminetetraacetic acid (EDTA), a preservative in banked blood. The agglutinated platelets are not counted, thus giving an apparent, but false, thrombocytopenia. Thrombocytopenia also may be falsely diagnosed because of a dilutional effect observed after massive transfusion of platelet-poor packed cells to treat a hemorrhage. This occurs when more than 10 units of blood have been transfused within a 24-hour period. The hemorrhage that necessitated the transfusion also accelerates the loss of platelets, which further contributes to the pseudothrombocytopenic state. Splenic sequestering of platelets secondary to hypersplenism (congestive) induces an apparent thrombocytopenia, as does hypothermia (less than 25° C [77° F]), which is reversed when temperatures return to normal, suggesting an increased platelet sequestration in response to chilling.

PATHOPHYSIOLOGY. Thrombocytopenia results from decreased platelet production, increased consumption, or both. The condition also may be congenital or acquired and primary or secondary to other acquired or congenital conditions. Thrombocytopenia secondary to congenital conditions occurs in a large number of different diseases, although each is relatively rare. These include thrombocytopenia with absence of radius (TAR) syndrome, Wiskott-Aldrich syndrome (see Chapter 9), various forms of *MYH9* gene mutation (e.g., May-Hegglin syndrome), X-linked thrombocytopenia, and many other examples.

Acquired thrombocytopenia is more common and may occur as a result of decreased platelet production secondary to viral infections (e.g., EBV, rubella, CMV, HIV), drugs (e.g., thiazides, estrogens, quinine-containing medications, chemotherapeutic agents, ethanol), nutritional deficiencies (vitamin B_{12} or folic acid in particular), chronic renal failure, bone marrow hypoplasia (e.g., aplastic anemia), radiation therapy, or bone marrow infiltration by cancer. Most common forms of thrombocytopenia are the result of increased platelet consumption. Examples include heparin-induced thrombocytopenia, idiopathic (immune) thrombocytopenic purpura, and thrombotic thrombocytopenic purpura.

Heparin-Induced Thrombocytopenia. Heparin is a common cause of drug-induced thrombocytopenia. Approximately 4% of individuals treated with unfractionated heparin develop **heparin-induced thrombocytopenia (HIT).** The incidence is lower (about 0.1%) with the use of low-molecular-weight heparin. HIT is an immune-mediated, adverse drug reaction caused by IgG antibodies against the heparin–platelet factor 4 complex leading to platelet activation through platelet FcγIIa receptors (Figure 29-19).[48] The release of additional platelet factor 4 from activated platelets and activation of thrombin lead to increased platelet consumption and a decrease in platelet counts beginning 5 to 10 days after administration of heparin.

CLINICAL MANIFESTATIONS. The hallmark of HIT is thrombocytopenia. A decrease of approximately 50% in the platelet count is seen in more than 95% of individuals. However, 30% or more of those with thrombocytopenia are also at risk for venous or arterial thrombosis.[48] Venous thrombosis is most common and results in deep venous thrombosis and pulmonary emboli. Arterial thromboses affect the large arteries of the lower extremities, causing acute limb ischemia. Arterial thrombosis also may lead to cerebrovascular accidents and myocardial infarctions. Other major arteries (renal, mesenteric, upper limb) also may be affected. Bleeding is uncommon in HIT, even with low platelet counts.

EVALUATION AND TREATMENT. Diagnosis is primarily based on clinical observations.[48] The individual presents with dropping platelet counts after 5 days or longer of heparin treatment. On average, platelet counts may reach $60{,}000/mm^3$. Because most individuals develop this condition after surgery, and the onset of symptoms, including thrombosis, may be delayed until after release from the hospital, other possible causes of thrombocytopenia (e.g., infection, other drug reactions) must be considered.

Tests are available to measure antibodies against heparin–platelet factor 4.[49] The test sensitivity is extremely high (more than 90%), but the specificity is less because of false-positive reactions (e.g., persons receiving dialysis). HIT antibody titers may be measured, but the titers must be evaluated in the context of the clinical presentation. If HIT is not recognized and treated, intravascular aggregation of platelets causes rapid development of arterial and venous thrombosis. Although rare, heparin antibodies have caused anaphylactic shock.

Treatment is the withdrawal of heparin and use of alternative anticoagulants. A switch to low-molecular-weight heparin is not indicated, and warfarin should not be used until the symptoms of HIT have resolved because of an increased risk of initiating skin necrosis. The thrombocytopenia should progressively resolve. The chance of spontaneous blood clots can be diminished using thrombin inhibitors (e.g., lepirudin, argatroban).[48]

Immune Thrombocytopenic Purpura. The most common cause of thrombocytopenia secondary to increased platelet destruction is **immune thrombocytopenic purpura (ITP).** The incidence of ITP is estimated to be 5.8 to 6.6 per 100,000 in the general population. ITP was formerly known as *idiopathic thrombocytopenic purpura;* however, it is widely recognized

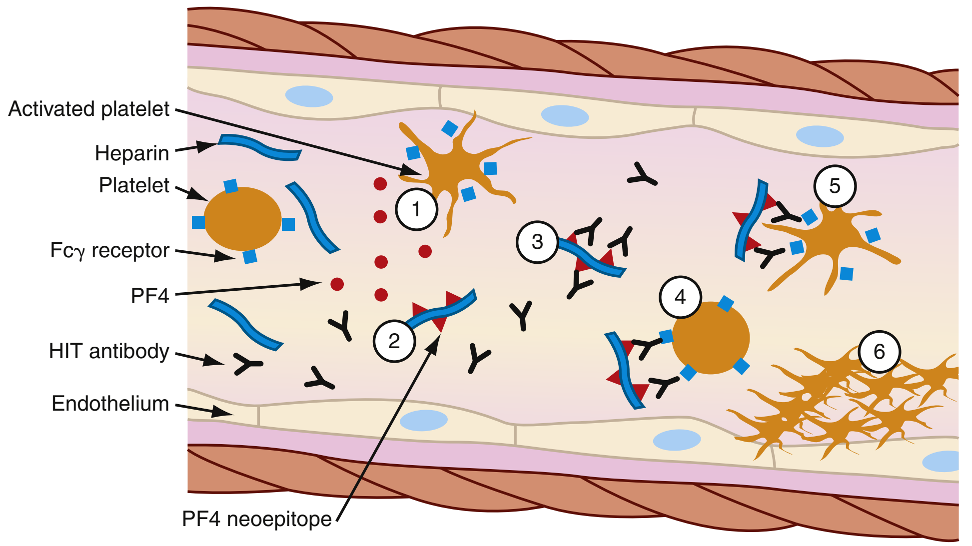

FIGURE 29-19 Pathogenesis of Heparin-Induced Thrombocytopenia (HIT). **(1)** Activated platelets release procoagulant proteins from α-granules, including platelet factor 4 *(PF4).* Administered heparin binds PF4 **(2),** which undergoes a conformational change and expresses a new antigen (neoepitope). Individuals with HIT produce an immunoglobulin G (IgG) antibody that specifically reacts **(3)** with multiple identical neoepitopes on the heparin-PF4 complex. The reaction forms heparin-PF4-IgG immune complexes. Platelets express FcγRIIa receptors (Fcγ receptor) that react **(4)** with the Fc portion of IgG in immune complexes. Cross-linking of Fc receptors **(5)** results in FcγRIIa-dependent platelet activation. The activated platelets mediate a series of events that lead to further activation of the coagulation cascade, resulting in thrombin generation. Further release of PF4 from newly activated platelets leads to a cycle of continuing platelet activation and **(6)** formation of a primary clot. The reaction can be enhanced by the release of platelet-derived microparticles that are rich in surface phosphatidylserine and increase activation of coagulation, and by the binding of heparin-PF4 complexes and HIT-IgG to the vascular endothelium (not shown.)

now as an immune process, hence the change from idiopathic to immune.[50] ITP may be acute or chronic. The acute form is frequently observed in children and typically lasts 1 to 2 months with a complete remission. In some instances it may last for up to 6 months, and some children (7% to 28%) may progress to the chronic condition. Acute ITP is usually secondary to infections (particularly viral) or other conditions that lead to large amounts of antigen in the blood, such as drug allergies or systemic lupus erythematosus (SLE) (see Chapter 9). Under these conditions the antigen usually forms immune complexes with circulating antibody, and it is thought that the immune complexes bind to Fc receptors on platelets, leading to their destruction in the spleen. The acute form of ITP usually resolves as the source of antigen is removed (e.g., the viral infection resolves).

Chronic ITP is associated with autoantibodies against platelet-specific antigens. This form is more commonly observed in adults, with highest prevalence in women between 20 and 40 years old, although it can develop at most any age. The chronic form tends to get progressively worse.

The autoantibodies are generally of the IgG class, although IgA and IgM antibodies also have been identified. They react against one or more of several platelet glycoproteins (e.g., GPIIb-IIIa, GPIb-IX, GPIa-IIa) (see Chapter 27).[51] The antibody-coated platelets are removed from the circulation by mononuclear phagocytes in the spleen through the Fc receptor.

CLINICAL MANIFESTATIONS. Initial manifestations are usually minor bleeding problems (development of petechiae and purpura) over the course of several days that progress to major hemorrhage from mucosal sites (epistaxis, hematuria, menorrhagia, bleeding gums). Rarely will an individual present with intracranial bleeding or internal bleeding at other sites.

During pregnancy, an individual with ITP may have a newborn that is also thrombocytopenic. In most individuals the antiplatelet antibody is an IgG that readily crosses the placenta (see Chapters 8 and 9). If the fetal platelets express the same antigen as the mother, the maternal antibody will coat the platelets, potentially resulting in thrombocytopenia in utero. A variant of neonatal thrombocytopenia (neonatal alloimmune thrombocytopenia) occurs when the mother does not have ITP, but makes IgG antibodies against an antigen inherited from the father and found on fetal platelets but not on maternal platelets.[52] Alloimmune neonatal thrombocytopenia occurs in 1 of 2000 pregnancies. The most common antibody in this condition is against the human platelet antigen-a (HPA-a) antigen on the GPIIIa protein. Neonatal thrombocytopenia, either secondary to maternal autoimmune thrombocytopenia or as alloimmune thrombocytopenia, may occur to various degrees. The most severe form results in fetal platelet counts below 20,000/mm^3 with a high associated risk of intracranial hemorrhage.

EVALUATION AND TREATMENT. Diagnosis of ITP is based on a history of bleeding and associated symptoms, such as weight loss, fever, and headache. Physical examination includes notations on the types of bleeding, location, and severity. Evidence of infections (bacterial, HIV, and other viral), medication history, family history, and evidence of thrombosis are also assessed. Other diagnostic tests include complete blood count (CBC) and peripheral blood smear. Unlike some other forms of thrombocytopenia, splenectomy is rarely observed. Testing for antiplatelet antibodies is usually not helpful. Although most cases of ITP are associated with elevated levels of IgG on platelets, other forms of thrombocytopenia also have a high incidence of platelet-associated antibodies; thus the specificity is low (50% to 65%).[53] In addition, some cases of ITP will not present with elevated platelet-associated antibodies; the sensitivity is 75% to 94%, so that a negative test does not completely rule out ITP.

The acute form of ITP usually resolves without major clinical consequences. As with most autoimmune diseases, the course of the chronic form is variable, with multiple remissions and exacerbations. For many individuals the platelet count may remain adequate enough to avoid clinically serious bleeding. However, the presence of spontaneous bleeding suggests more severe disease and requires immediate attention. Treatment is initiated when platelet counts are less than 30,000/μL or less than 50,000/μL with evidence of bleeding from mucous membranes or when the individual is at high risk to develop bleeding.

Treatment is palliative, not curative, focusing on prevention of platelet destruction. Initial therapy for ITP is infusion of glucocorticoids (e.g., prednisone), which suppresses the production of antiplatelet antibodies and prevents sequestering and further destruction of platelets. If platelet counts do not increase appropriately, other medications, such as prednisone, may be tried. Treatment with intravenous immunoglobulin (IVIG) is used to prevent major bleeding. The response rate is 80%, but the effects are transient, lasting only days or a few weeks. Anti-(Rh_o)D (RhoGAM), which is a preparation of antibody against the D antigen of the Rh blood group, has been used with limited success to treat individuals who are Rh-positive.

Newer treatments include romiplostim (trade name Nplate) and eltrombopag (trade name Promacta in the United States, Revolade in the European Union). Both drugs are thrombopoiesis–stimulating Fc-peptide fusion proteins (peptibody). Romiplostim is administered subcutaneously and eltrombopag is taken orally. These drugs increase platelet counts and decrease bleeding. Romiplostim is often used as a second-line treatment after IVIG or in individuals who experience relapse post-splenectomy.

If all other therapies are ineffective, splenectomy is considered to remove the primary site of platelet destruction.[54] The response rate (resolution of the thrombocytopenia) is 60% to 70%; however, the procedure is not without risk. Approximately 10% to 20% of individuals who undergo splenectomy suffer a relapse and require further treatment. It is thought that other reticuloendothelial organs, particularly the liver, can become major sites for platelet destruction. If splenectomy is unsuccessful and life-threatening thrombocytopenia persists, more aggressive immunosuppressive medications (e.g., azathioprine, cyclophosphamide) may be used. Because of potential major complications, these medications are reserved for individuals who are severely thrombocytopenic and refractive to other therapies.

Thrombotic Thrombocytopenic Purpura. **Thrombotic thrombocytopenic purpura (TTP)** is characterized by thrombotic microangiopathy in which platelets aggregate and cause occlusion of arterioles and capillaries within the microcirculation.[55] Aggregation may lead to increased platelet consumption and organ ischemia. TTP is relatively uncommon, occurring in about 5 per 1 million individuals per year. The incidence is increasing, which appears to be an actual increase in the number of affected individuals rather than a result of improved recognition. There are two forms of TTP: familial or acquired idiopathic. The familial form is the more rare and is usually chronic, relapsing, and seen in children. The child experiences predictable recurring episodes at approximately 3-week intervals and is responsive to treatment. Acquired TTP is more common, as well as more acute and severe. It occurs mostly in females in their thirties and is rarely observed in infants or older adults.

Platelet aggregation and microthrombi formation are found throughout the entire vascular system, causing damage to multiple organs. Organs most susceptible to damage are the kidney, brain, and heart. Other organs often affected are the pancreas, spleen, and adrenal glands. The thrombi are primarily composed of platelets with minimal fibrin and red cells, differentiating them from thrombi secondary to intravascular coagulation. Most cases of TTP are related to a dysfunction of the plasma metalloprotease ADAMTS13. This enzyme is responsible for digesting large precursor molecules of von Willebrand factor (vWF) produced by endothelial cells into smaller molecules. Defects in ADAMTS13 result in expression of large-molecular-weight vWF on the endothelial cell surface and the formation of large aggregates of platelets. The aggregates may break off and form occlusions in smaller vessels. Most individuals with TTP (about 80%) have less than 5% of normal plasma ADAMTS13 levels. TTP also is commonly associated with an IgG autoantibody against ADAMTS13 that is able to neutralize the enzyme's activity and accelerate its clearance from the plasma.

CLINICAL MANIFESTATIONS. The rare familial **chronic relapsing TTP** observed in children is usually recognized and successfully treated. The acquired **acute idiopathic TTP** is much more common and more severe.[55] Early diagnosis and treatment is important because the disease may be fatal within 90 days of onset. TTP is clinically related to and must be distinguished from other thrombotic microangiopathic conditions, including hemolytic uremic syndrome, malignant hypertension, preeclampsia, or the pregnancy-induced HELLP (**h**emolysis, **e**levated **l**iver enzymes, **l**ow **p**latelet count) syndrome. Hemolytic uremic syndrome (HUS) shares many of the clinical characteristics of TTP; however, HUS often follows a hemorrhagic, diarrheal illness.

EVALUATION AND TREATMENT. Acute idiopathic TTP is characterized by a "pathognomonic pentad" of symptoms. However, only 20% to 30% of people present with the classic pentad. These include extreme thrombocytopenia (less than 20,000 platelets/μL), intravascular hemolytic anemia, ischemic signs and symptoms most often involving the CNS (about 65% present with memory disturbances, behavioral irregularities, headaches, or coma), kidney failure (affecting about 65% of individuals), and fever (present in about 33%).[55] It is not mandatory that all five be present to begin treatment. A routine blood smear usually reveals fragmented red cells *(schizocytes)* produced by shear forces when red cells are in contact with the fibrin mesh in clots that form in the vessels. As a result of tissue injury, serum levels of lactate dehydrogenase (LDH) may be very high, and low-density lipoprotein (LDL) levels may be elevated. Tests for antibody on red cells are negative, excluding immune hemolytic anemia.

Untreated acute TTP has a death rate of 90%, which can be reduced to 10% to 20% with prompt treatment. Plasma exchange with fresh frozen plasma replenishes functional ADAMTS13 and is the treatment of choice, achieving a response rate of 70% to 85%. Additionally, steroids (glucocorticoids) are administered. In the absence of major organ damage, this approach may lead to complete recovery with no long-term complications. The anti-CD20 monocolonal antibody rituximab has shown some activity in people who are refractory to plasma exchange.[56] Relapses do occur at a rate of 13% to 36%, and recurrences have been reported, some as long as 9 years after the initial treatment. Individuals who do not respond to conventional treatment may be candidates for splenectomy; however, postoperative hemorrhage remains a dangerous complication. Immunosuppressive (azathioprine) therapy has been successful in some individuals.

Thrombocythemia

Thrombocythemia (also called **thrombocytosis**) is defined as a platelet count greater than 400,000/μL of blood.[57] Thrombocythemia may be primary or secondary (reactive) and is usually asymptomatic until the count exceeds 1 million/mm^3 of blood. Then intravascular clot formation (thrombosis), hemorrhage, or other abnormalities can occur.

PATHOPHYSIOLOGY. Secondary thrombocythemia may occur after splenectomy because platelets that normally would be stored in the spleen remain in circulating blood. The increase in the number of platelets may be gradual, with thrombocythemia not occurring for up to 3 weeks after splenectomy. Reactive thrombocythemia may occur during some inflammatory conditions, such as rheumatoid arthritis and cancers. In these conditions, excessive production of some cytokines (e.g., IL-6, IL-11) may induce increased production of thrombopoietin in the liver, resulting in increased megakaryocyte proliferation. Reactive thrombocythemia may also occur during a variety of physiologic conditions, such as after exercise. Because of the relatively self-resolving nature of secondary thrombocythemia, the remaining discussion will focus on the more severe primary form.

Essential (primary) thrombocythemia (ET) is a chronic myeloproliferative disorder characterized by excessive platelet production resulting from a defect in bone marrow megakaryocyte progenitor cells.[58] The overall incidence of ET is 0.8 per 100,000 in the United Kingdom, 2.53 in the United States, and 0.59 in Denmark. It is more common in middle-age individuals, with the majority of cases occurring between ages 50 and 60 years. There is no known gender preference. There also is a rare hereditary type of ET called *familial essential thrombocythemia (FET)* that is inherited in an autosomal dominant pattern.

The thrombocythemia is secondary to increased plasma thrombopoietin levels resulting from defects in the thrombopoietin receptor. The defective receptor cannot adequately bind and remove thrombopoietin from the blood, thus circulating levels remain high. Along with increased platelet levels, there may be a concomitant increase in red blood cells (RBCs), indicating a myeloproliferative disorder; however, the increase in red cells is not to the extent seen in polycythemia vera (see Chapter 28). The bone marrow of affected individuals with ET is characterized by hyperplasia of megakaryocytes. The platelets of affected individuals appear to have a normal survival time, compatible with a defect in production rather than an increase in platelet life span.

RBCs in ET tend to aggregate and contribute to the blockage of flow in the microvasculature and altered interactions between platelets and the vascular endothelium.[59] Increased adherence of erythrocytes to the endothelium appears to result from a mutation in an erythrocyte Janus kinase 2 (JAK2) that is responsible for phosphorylation of the erythrocyte receptor for endothelial laminin.[60,61] The frequency of JAK2 mutations in ET is about 30%. Increased platelet aggregation arises from several mutations that result in altered platelet membrane glycoproteins, particularly resulting in increased expression of GPIV, and increased secretion of thromboxane.

CLINICAL MANIFESTATIONS. Clinical manifestations vary significantly among individuals. Those with ET are at risk for large-vessel arterial or venous thrombosis, although the most common complication is **microvasculature thrombosis** leading to ischemia in the fingers, toes, or cerebrovascular regions.[59] The primary presenting symptoms of microvasculature thrombosis are erythromyalgia, headache, and paresthesias. **Erythromyalgia** is characterized by unilateral or bilateral warm, congested, red hands and feet with painful burning sensations, particularly in the forefoot sole and one or more toes. The lower extremities are affected more often, and only one side may be involved. The pain is initiated by standing, exercise, or warmth and relieved by elevation and cooling. In extreme situations, acrocyanosis and gangrene may result.

Arterial thrombosis is more common than venous thrombosis and may involve the coronary and renal arteries. The carotid, mesenteric, and subclavian arteries also may be affected. Myocardial ischemia and infarction have occurred without clear evidence of coronary artery disease. Deep venous thrombosis of the lower extremities and pulmonary embolism are the major sites for venous involvement. Intra-abdominal venous thrombosis of the portal and hepatic veins also is common. People older than 60 years of age or those with prior history of thrombotic events have as much as a 25% chance of developing a cerebral, cardiac, or peripheral arterial thrombus. Conversion to acute leukemia is found in less than 10%.[62]

Microvascular thrombosis in the CNS is usually associated with headache and dizziness, with paresthesias, transient ischemic attacks, strokes, visual disturbances, and seizures also being reported. Major thrombotic events, not directly related to the platelet count, occur in about 20% to 30% of individuals with ET. Prior history of thrombotic events, advanced age, and duration of thrombocytosis are predictors of future thrombotic complications. Individuals older than age 60 are at greatest risk.

Although thrombosis is the most common symptom, hemorrhage can also occur. Sites for bleeding include the gastrointestinal (GI) tract, skin, mucous membranes, urinary tract, gums, tooth sockets (after extraction), joints, eyes, and brain. GI bleeding may be mistaken for a duodenal ulcer. Hemorrhage is not severe, and generally occurs in the presence of very high platelet counts, and occasionally requires transfusion. Important is recognition that bleeding and clotting may exist simultaneously and individuals will not necessarily be "bleeders" or "clotters."

EVALUATION AND TREATMENT. Initial diagnosis is not difficult; as many as two thirds of affected individuals are diagnosed from a routine complete blood count (CBC). Secondary thrombocytosis may present as a moderate rise in the platelet count that resolves with treatment or resolution of the underlying condition. The World Health Organization (WHO) criteria for the diagnosis of ET require the following four conditions be met: (1) sustained platelet count of at least 450,000/μL; (2) bone marrow biopsy showing proliferation of enlarged mature megakaryocytes and no increase of granulocyte or erythocyte precursors; (3) failure to meet the criteria of polycythemia vera, myelofibrosis, CML, or other myelodysplastic syndrome; and (4) the presence of JAK2 617F or another clonal marker or evidence of reactive thrombocytosis.[63]

After diagnosis, these individuals may recall events related to thrombosis or hemorrhage. Manifestations of ET may be mistaken for CML; therefore, differentiation of the two is important because treatment varies significantly. Identification of the Philadelphia chromosome is recommended in all cases of ET.

Treatment of ET is directed toward preventing thrombosis or hemorrhage.[64] The importance of reducing the platelet count remains a significant treatment issue. Historically, treatment of ET relied on the use of alkylating agents (busulfan) or radiophosphorus (^{32}P) to suppress platelet production. Hydroxyurea, a nonalkylating myelosuppressive agent, has been the drug of choice to suppress platelet production: however, long-term use may cause progression to other myelodysplastic disorders, particularly AML or myelofibrosis.[64] Conversion to myelofibrosis occurs approximately 8% of the time and conversion to AML occurs approximately 3.5% of the time when treated with hydroxyurea as a single cytotoxic agent, but increases to 14% when more than one cytotoxic agent is used.

Interferon (IFN) also may be used and has a response rate of 80%. IFN may not be effective for everyone because it has many side effects and 20% of individuals may be intolerant. Anagrelide is now considered to be the drug of choice. Anagrelide specifically interferes with platelet maturation rather than production, thus not affecting erythropoiesis or leukopoiesis.

Aspirin also is used in the treatment of ET; however, its action is not to reduce the platelet count but to prevent adherence of platelets to each other and prevent thrombus formation. Early studies with aspirin found hemorrhage to be a major contraindication for its use; however, in lower doses (80 to 160 mg/daily) it effectively alleviates erythromyalgia and transient neurologic manifestations.

Prognosis and survival of individuals with ET have been somewhat difficult to establish. ET is not necessarily considered life threatening, but in those older than age 60 and who have a history of previous incidences of thrombosis, complications are more common and have a higher risk of mortality.

Alterations of Platelet Function

Qualitative alterations in platelet function occur with an increased bleeding time in the presence of a normal platelet count. Associated clinical manifestations include spontaneous petechiae and purpura, as well as bleeding from the GI tract, genitourinary tract, pulmonary mucosa, and gums. Congenital alterations in platelet function (thrombocytopathies) are quite rare and may be categorized into several types of disorders: (1) platelet–vessel wall adhesion, (2) platelet-platelet interactions, (3) platelet granules and secretion, (4) arachidonic acid pathways, and (5) membrane phospholipid regulation (coagulation protein–platelet interactions).[65]

Disorders of platelet–vascular wall adhesion result from aberrations of the platelet membrane glycoprotein GPIb-IX-V complex (Bernard-Soulier syndrome) or the collagen receptor GPVI, or deficiencies of vWF. The GPIb protein is the most commonly mutated in individuals with Bernard-Soulier syndrome. Lack of these proteins prevents platelets from adhering to collagen, resulting in impaired hemostasis and clinical hemorrhage.

Disorders of platelet-platelet interactions result in failure of platelets to aggregate in response to adenosine diphosphate (ADP), collagen, epinephrine, or thrombin because of a deficiency in the glycoprotein (αIIbβ3) that acts as a receptor for fibrinogen, vWF, and fibronectin (Glanzmann thrombasthenia). Lack of this protein results in a failure to build "fibrinogen bridges" between platelets (see Figure 27-20). Defects also can occur in platelet receptors for platelet activators. These include mutations in the receptors for thromboxane or ADP.

Disorders of platelet granules and secretion and arachidonic pathways are characterized by initial normal platelet aggregation with collagen or ADP; however, there is failure of subsequent processes, specifically secretion of prostaglandins and release of granules. Defective α-granule numbers or release (gray platelet syndrome) results from mutations in several aspects of granule function, including biosynthesis or loading of proteins normally found in these granules. Defects in dense granules include Hermansky-Pudlak syndrome, Chédiak-Higashi syndrome, and delta-storage pool disease. These usually result from mutations in proteins involved in formation of dense granules or their movement to the plasma membrane. Defects in the thromboxane pathway prevent the release of this mediator.

Externalization of plasma membrane phosphatidylserine (PS) is necessary for effective platelet function. In Scott syndrome, the enzyme responsible for PS efflux is defective; thus platelets are unable to support the activation of factor X and prothrombin. The reverse of Scott syndrome is Stormorken syndrome, in which platelets constitutively externalize PS.

Acquired disorders of platelet function are more common than the congenital disorders and may be categorized into three principal causes: (1) drug effects, (2) systemic inflammatory conditions, and (3) hematologic conditions.

Multiple drugs are known to affect platelet function in several ways: inhibition of platelet membrane receptors, inhibition of prostaglandin pathways, and inhibition of phosphodiesterase activity. Aspirin is the most commonly used drug that affects platelets and the only drug specifically used for its platelet effects. It irreversibly inhibits cyclooxygenase function for several days after administration. Nonsteroidal anti-inflammatory drugs also affect cyclooxygenase, although in a reversible fashion.

Systemic disorders that affect platelet function are chronic renal disease, liver disease, cardiopulmonary bypass surgery, severe deficiencies of iron or folate, and the presence of antiplatelet antibodies associated with autoimmune disorders. Hematologic disorders that cause platelet dysfunction are chronic myeloproliferative disorders, multiple myeloma, leukemias, myelodysplastic syndromes, and dysproteinemias.

Disorders of Coagulation

Disorders of coagulation usually are caused by defects or deficiencies of one or more of the clotting factors. (Normal function of the clotting factors is described in Chapter 27.) Qualitative or quantitative abnormalities of clotting factors interfere with or prevent the enzymatic reactions that transform circulating clotting proteins into a stable fibrin clot (see Figure 27-22).

Some clotting factor defects are inherited and usually involve a single factor, such as hemophilias and von Willebrand disease, caused by deficiencies of specific clotting factors (see Chapter 30). Other coagulation defects are acquired and tend to result from deficient synthesis of clotting factors by the liver. Causes include liver disease and dietary deficiency of vitamin K.

Other coagulation disorders are attributed to pathologic conditions that trigger coagulation inappropriately. For example, any cardiovascular abnormality that alters normal blood flow by acceleration, deceleration, or obstruction can result in spontaneous coagulation within the vessels. Coagulation is also stimulated by the presence of tissue factor, which is released by damaged or dead tissues. **Vasculitis,** or inflammation of the blood vessels, as well as vessel damage, activates platelets, which in turn activates the coagulation cascade. In extensive or prolonged vasculitis, blood clot formation can suppress mechanisms that normally control clot formation and breakdown, leading to clogging of the vessels. In each of these acquired conditions, normal hemostatic function proves detrimental to the body by consuming coagulation factors excessively or by overwhelming the normal control of clot formation and breakdown (fibrinolysis).

Impaired Hemostasis

Impaired hemostasis, or the inability to promote coagulation and the development of a stable fibrin clot, is commonly associated with liver disorders, either from the lack of vitamin K or from specific diseases of the liver.

Vitamin K Deficiency. Vitamin K, a fat-soluble vitamin, is necessary for synthesis and regulation of prothrombin, procoagulant factors (VII, IX, X), and anticoagulant regulators (proteins C and S) within the liver.[66] The primary

dietary source of vitamin K is green, leafy vegetables. Vitamin K also is synthesized by intestinal flora, but its contribution to the overall supply of vitamin K is uncertain. The most common cause of vitamin K deficiency is the use of parenteral nutrition in combination with broad-spectrum antibiotics that destroy normal gut flora. Rarely is a deficiency caused by lack of dietary intake; however, bulimia can suppress vitamin K–dependent activity. Clinical manifestations of vitamin K deficiency are caused by a reduction of vitamin K–dependent proteins. The severity of manifestations is related to the degree of deficiency and ranges from laboratory abnormalities to significant hemorrhage.

Parenteral administration of vitamin K is the treatment of choice and usually results in correction of the deficiency. Improvement of clotting tests is usually noted within 8 to 12 hours. Fresh frozen plasma may be administered but usually is reserved for individuals with life-threatening hemorrhages or who require emergency surgery.

Liver Disease. Individuals who have liver disease (e.g., acute or chronic hepatocellular diseases, cirrhosis, vitamin K deficiency) or have undergone major liver surgery present with a broad range of hemostasis derangements that may be characterized by defects in the clotting or fibrinolytic systems or platelet function.[66] The hepatic parenchymal cells produce most of the factors involved in hemostasis. Thus damage to the liver frequently results in diminished production of factors involved in clotting, usually in proportion to the degree of hepatic parenchymal cell damage. For instance, factor VII is most sensitive to liver damage because of its rapid turnover. Factor IX levels are less affected and do not decline until liver destruction is well advanced. The liver is also a major site for production of plasminogen and α_2-antiplasmin of the fibrinolytic system, as well as thrombopoietin and the metalloprotease ADAMTS13. Diminished levels of thrombopoietin may lead to thrombocytopenia from decreased platelet production. Decreased production of ADAMTS13 results in increased levels of large precursor molecules of vWF, which leads to the formation of large aggregates of platelets.

In conditions of severe liver disease (e.g., cirrhosis) circulating levels of most clotting factors are significantly depressed. Concurrently, production of clotting system regulators (e.g., antithrombin, protein C, protein S) and of fibrinogen is diminished. The fibrinolytic system is commonly active because of decreased levels of plasmin inhibitor and unaffected levels of fibrinolytic activators (e.g., tissue plasminogen activator [tPA], urokinase-like plasminogen activator [uPA]). The affected individuals also are thrombocytopenic because of diminished thrombopoietin and ADAMTS13, as well as increased platelet sequestration in the spleen, which is frequently enlarged in cirrhosis and is associated with portal hypertension. Thus the individuals with cirrhosis may appear to have a condition similar to disseminated intravascular coagulation (DIC) (see next section).

Treatment of hemostatic alterations in liver disease must be comprehensive to cover all aspects related to platelet, clotting, and fibrinolytic dysfunctions. Fresh frozen plasma administration is the treatment of choice, but not all individuals tolerate the volume needed to adequately replace all deficient factors. Alternative modalities include the addition of exchange transfusions and platelet concentration to plasma administration.

Consumptive Thrombohemorrhagic Disorders

Consumptive thrombohemorrhagic disorders are a heterogeneous group of conditions that demonstrate the entire range of hemorrhagic and thrombotic pathologic conditions. Symptoms range from subtle to devastating and generally are considered to be intermediary disease processes that complicate many primary disease states. These disorders also are characterized by confusion and controversy regarding diagnosis, treatment, and management. No single definition can cover all possible varieties of these disorders; however, DIC is the most common term used in the clinical setting to describe a pathologic condition associated with hemorrhage and thrombosis.

Disseminated Intravascular Coagulation. **Disseminated intravascular coagulation (DIC)** is an acquired clinical syndrome characterized by widespread activation of coagulation, resulting in the formation of fibrin clots in medium and small vessels throughout the body. Disseminated clotting may lead to blockage of blood flow to organs, resulting in multiple organ failure. The magnitude of clotting may result in consumption of platelets and clotting factors, leading to severe bleeding. The Subcommittee on DIC of the International Society on Thrombosis and Hemostasis defined DIC as "an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction."[67,68]

The clinical course of DIC largely is determined by the intensity of the stimulus, host response, and comorbidities and ranges from an acute, severe, life-threatening process that is characterized by massive hemorrhage and thrombosis to a chronic low-grade condition. The chronic condition is characterized by subacute hemorrhage and diffuse microcirculatory thrombosis. DIC may be localized to one specific organ or generalized, involving multiple organs.

Because of the complexity and wide variations in manifestations of DIC, diagnosis has been confusing and difficult. Minimally acceptable diagnostic criteria have been established and include a systemic thrombohemorrhagic disorder with laboratory evidence of (1) clotting activation, (2) fibrinolytic activation, (3) coagulation inhibitor consumption, and (4) biochemical evidence of end-organ damage or failure.

DIC is secondary to a wide variety of well-defined clinical conditions, specifically those capable of activating the clotting cascade (Box 29-6). These include: (1) arterial hypotension, frequently accompanying shock; (2) hypoxemia; (3) acidemia; and (4) stasis of capillary blood flow.

Sepsis is the most common condition associated with DIC. Gram-negative microorganisms, as well as some gram-positive microorganisms, fungi, protozoa (malaria), and viruses (influenza, herpes), are capable of precipitating DIC by causing damage to the vascular endothelium. Gram-negative endotoxins are the primary cause of endothelial damage; DIC may occur in up

BOX 29-6 MAJOR ETIOLOGIES IDENTIFIED AS ANTECEDENTS TO THE INITIATION AND DEVELOPMENT OF DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

- Malignancy: acute leukemias, metastatic solid malignancies
- Infections: bacterial (gram-negative endotoxin, gram-positive mucopolysaccharides), viral (hepatitis, varicella, cytomegalovirus), fungal, parasitic
- Pregnancy complications: eclampsia/preeclampsia, placental abruption, amniotic fluid embolism
- Severe trauma: head injury, burns, crush injuries, tissue necrosis
- Liver disease: obstructive jaundice, acute liver failure
- Intravascular hemolysis: transfusion reactions, drug-induced hemolysis
- Medical devices: aortic balloon, prosthetic devices
- Hypoxia and low blood flow states: arterial hypotension secondary to shock, cardiopulmonary arrest

Data from Bick RL et al: *Hematology: clinical and laboratory practice,* St Louis, 1993, Mosby.

to 50% of individuals with gram-negative sepsis. DIC occurs in approximately 10% to 20% of individuals with metastatic cancer or acute leukemia. Direct tissue damage (e.g., ischemia and necrosis, surgical manipulation, crushing injury) also results in release of tissue factor (TF) by the endothelium. Severe trauma, especially to the brain, can induce DIC. DIC occurs in about two thirds of individuals with a systemic inflammatory response to trauma. Some complications of pregnancy also are associated with DIC; incidences range from 50% for women with placental abruptions to less than 10% for women with severe preeclampsia. Other causes of DIC have been identified, most notably blood transfusion. Transfused blood dilutes the clotting factors, as well as circulating naturally occurring antithrombins. In hemolytic transfusion reactions, the endothelium is damaged by complement-mediated reactions.

PATHOPHYSIOLOGY. The coagulation system is designed to function at local areas of vascular damage, resulting in cessation of bleeding and activation of repair to the vessels. DIC results from abnormally widespread and ongoing activation of clotting (Figure 29-20). A variety of conditions are associated with DIC (see Box 29-6), primarily by activating the extrinsic clotting cascade. The common pathway for DIC appears to be excessive and widespread exposure of TF. This may occur by several mechanisms. Widespread damage to the vascular endothelium results in exposure of subendothelial TF. Several types of cells, either after stimulation by cytokines or constitutively, express TF on their surfaces. Endothelial cells and monocytes do not normally express surface TF unless stimulated by inflammatory cytokines (particularly IL-6 and TNF-α).[69] Many tumors express surface TF or produce cytokines that stimulate TF expression by endothelium or monocytes, or both.[70] These cytokines are abundantly produced during many of the conditions listed in Box 29-6. Endotoxin, in particular, triggers the release of multiple cytokines that play a significant role in the development and maintenance of DIC. Proinflammatory cytokines (TNF-α, interleukins [IL-1, IL-6, IL-8], and platelet activating factor [PAF]) are responsible for the clinical signs and symptoms associated with sepsis. They also contribute to the development of DIC by activating endothelial cells, causing release of TF and vWF, increasing plasminogen activator inhibitor-1 (PAI-1) synthesis and tissue factor activity, and decreasing thrombomodulin expression, thereby promoting development of thrombi. TF also may be released directly into the bloodstream from circulating white blood cells (monocyte/endotoxin interaction).

TF binds clotting factor VII, which leads to conversion of prothrombin to thrombin and formation of fibrin clots (see Figure 27-22). This pathway appears to be the primary route by which DIC is initiated; inhibition of TF or factor VIIa completely prevents the generation of thrombi by gram-negative bacterial endotoxin in animal models of DIC.

Not only is the clotting system extensively activated in DIC, but also the predominant natural anticoagulants (tissue factor inhibitor, antithrombin III [AT III], protein C) are greatly diminished (see Figure 27-18). During DIC the activation of clotting is prolonged by the increased rate of consumption because of persistent thrombin production, as well as decreased synthesis, of these inhibitors and protein S and by cytokine-mediated decreased expression of thrombomodulin on the endothelial cell surface. Hepatic dysfunction in sepsis results in decreased antithrombin synthesis and extravascular leakage of this protease inhibitor because of capillary leakage. Additionally, antithrombin is degraded by elastase released by activated neutrophils, and clotting is initiated concurrently with loss of regulation of the extent of thrombosis; thus the amount of thrombin produced during DIC exceeds the ability of the body's naturally occurring anticoagulants to regulate it.

The rate of fibrinolysis is also diminished in DIC. The primary component of fibrinolysis is plasmin, which exists in the circulation as an inactive precursor, plasminogen (see Figure 27-25). Plasminogen is activated to plasmin that digests fibrin clots, thus controlling the extent of fibrin deposition in the vessels. During DIC the activity of plasmin is diminished by increased production of its natural inhibitor, PAI-1. Although some fibrinolytic activity remains, the level is inadequate to control the systemic deposition of fibrin. The slow breakdown of fibrin by plasmin produces fibrin degradation products (FDPs) that are released into the blood. These are potent anticoagulants that are normally removed from blood by fibronectin and macrophages. FDPs, along with thrombin, induce further cytokine release from monocytes, contributing to endothelial damage and TF release. During DIC the presence of fibrin degradation products is prolonged, probably because of diminished production of fibronectin. Fibronectin is a glycoprotein with adhesive properties that mediate removal of particulate matter (e.g., fibrin clumps). Low levels of fibronectin suggest a poor prognosis.

Although thrombosis is generalized and widespread, individuals with DIC are paradoxically at risk for hemorrhage. Hemorrhage is secondary to the abnormally high consumption of clotting factors and platelets, as well as the anticoagulant properties of FDPs, which interfere with polymerization of fibrin monomers. Both thrombin and FDPs have a high affinity for platelets and cause platelet activation and aggregation—an event that occurs early in the development of DIC—which facilitates

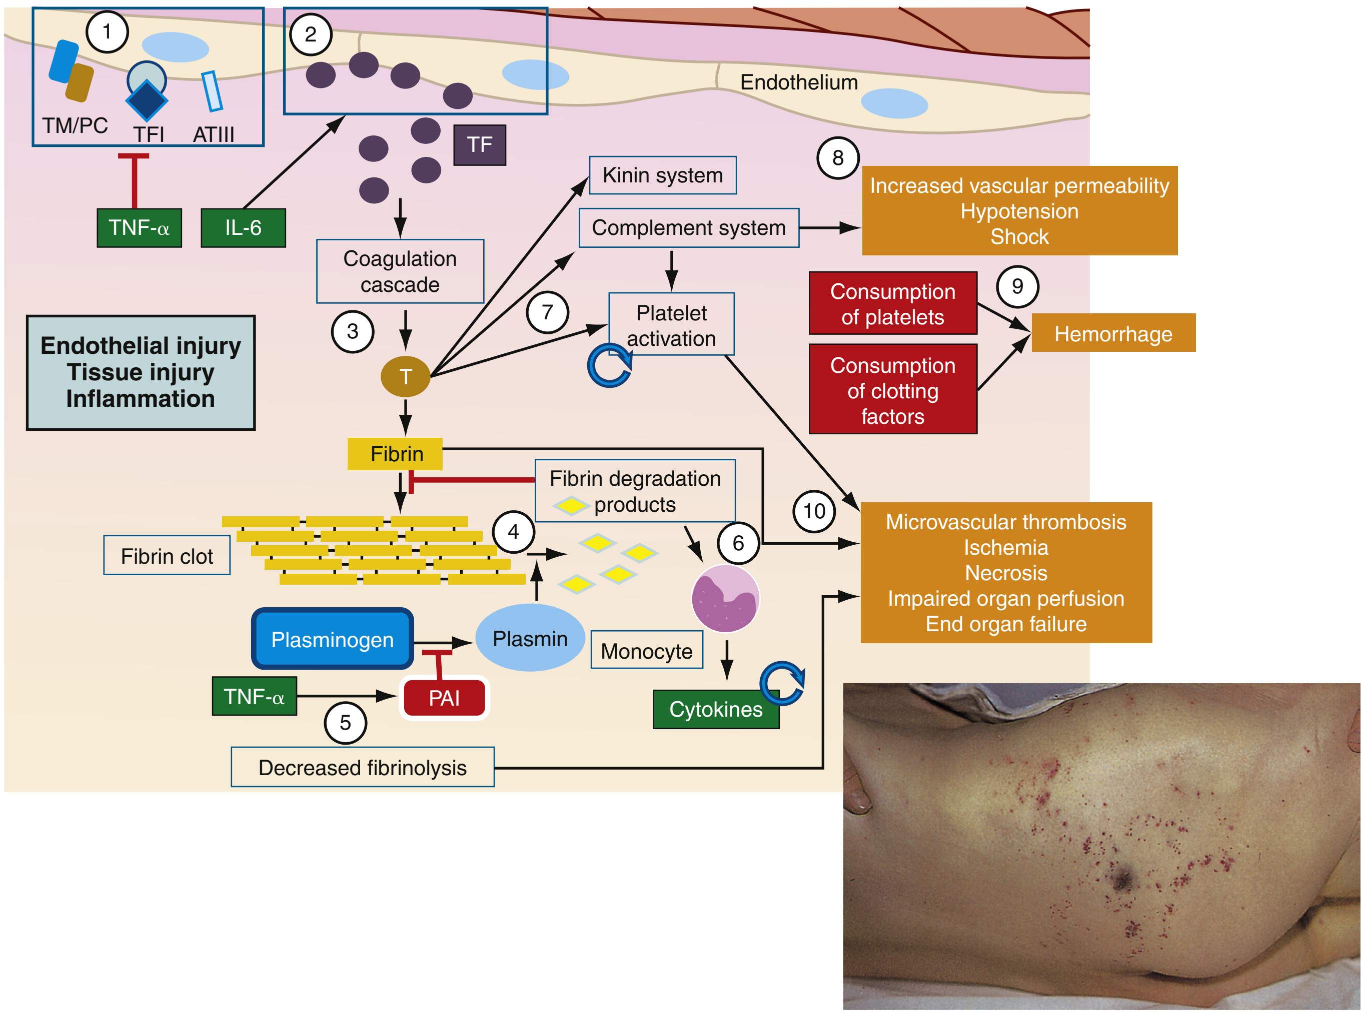

FIGURE 29-20 Pathophysiology of Disseminated Intravascular Coagulation (DIC). DIC is initiated by a variety of factors (endothelial injury, tissue injury, inflammation, and others), most of which either directly or indirectly result in release of large amounts of tissue factor. Many cytokines create a procoagulant environment by concurrently **(1)** suppressing normal control of homeostasis and **(2)** inducing tissue factor release by endothelium or monocytes. Tissue factor initiates the coagulation cascade **(3)** leading to the activation of thrombin, production of fibrin, and polymerization into a fibrin clot. Fibrinolysis normally digests clots **(4)** through the activity of plasmin, resulting in the production of various fibrin degradation products. However, during DIC, factors, such as TNF-α, induce **(5)** inhibitors of plasmin generation, thus leading to diminished fibrinolysis. Fibrin split products possess several biologic activities that affect DIC, including **(6)** the induction of further cytokine release by monocytes. Enzymatically active products of the coagulation cascade, including thrombin, activate **(7)** other inflammatory systems, including platelets and the kinin and complement systems. Activation of platelets and monocytes continues the procoagulant cycle (indicated by circular arrows) by inducing additional tissue factor and cytokines. Mediators produced from the kinin and complement system **(8)** affect vascular endothelium, leading to increased vascular permeability that contributes to hypotension and potential shock. The uncontrolled consumption of platelets and clotting factors **(9)** compromises the normal hemostatic mechanisms, resulting in potential systemic hemorrhages. Excess activation of the coagulation cascade and platelets, with decreased fibrinolysis, leads to systemic microvascular thrombosis **(10)** and blockage of the vessels with progressive ischemia. Uncontrolled DIC will eventually lead to multiple end-organ failure. For further details of these mechanisms see Chapters 7 and 27. *AT III,* Antithrombin III; *IL-6,* interleukin-6; *PAI,* plasminogen activator inhibitor; *T,* thrombin; *TF,* tissue factor; *TFI,* tissue factor inhibitor; *TM/PC,* thrombomodulin/protein C complex; *TNF-α,* tumor necrosis factor-alpha. microcirculatory coagulation and obstruction in the initial phase. However, platelet consumption exceeds production, resulting in a thrombocytopenia that increases bleeding (Box 29-7).

Activation of clotting also leads to activation of other inflammatory pathways, including the kallikrein-kinin and complement systems (see Chapter 7). Factor XIIa, generated in DIC, converts prekallikrein to kallikrein, ultimately resulting in conversion to circulating kinins. Activation of these systems contributes to increased vascular permeability, hypotension, and shock. Activated complement components also induce platelet destruction, further contributing initially to the thrombosis and later to the thrombocytopenia.

BOX 29-7 CLINICAL MANIFESTATIONS ASSOCIATED WITH DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Integumentary System
Widespread hemorrhage and vascular lesions
Oozing from puncture sites, incisions, mucous membranes
Acrocyanosis (irregularly shaped cyanotic patches)
Gangrene

Central Nervous System
Subarachnoid hemorrhage
Altered state of consciousness (slight confusion to convulsions and coma)

Gastrointestinal System
Occult bleeding to massive gastrointestinal bleeding
Abdominal distention
Malaise
Weakness

Pulmonary System
Pulmonary infarctions
ARDS
Cyanosis
Tachypnea
Hypoxemia

Renal System
Hematuria
Oliguria
Renal failure

ARDS, Acute respiratory distress syndrome.

The deposition of fibrin clots in the circulation interferes with blood flow, causing widespread organ hypoperfusion.

This condition may lead to ischemia, infarction, and necrosis, further potentiating and complicating the existing DIC process by causing further release of TF and eventually organ failure.

In addition to initiation of clotting by TF, DIC may be precipitated by direct proteolytic activation of factor X. This has been described as "thrombin mimicry" and is the result of activated factor X directly converting fibrinogen to fibrin. The proteases that activate factor X may come from snake venom, some tumor cells, or the pancreas and liver, where they are released during episodes of pancreatitis and various stages of liver disease. Direct proteolytic activity appears to be independent of any type of damage to the endothelium or tissue.

Vascular obstruction results from circulatory deposition of thrombin and clot formation that impedes blood flow, causing widespread organ hypoperfusion that can lead to tissue ischemia, infarction, and necrosis. The resulting tissue damage further potentiates and complicates the existing DIC process. Because organ perfusion is drastically impaired, manifestations of multisystem organ dysfunction and failure ultimately result. Multisystem organ dysfunction and failure are discussed in Chapter 48. Whatever initiates the process of DIC, the cycle of thrombosis and hemorrhage persists until the underlying cause of the DIC is removed or appropriate therapeutic interventions are used.

CLINICAL MANIFESTATIONS. Clinical signs and symptoms of DIC present a wide spectrum of possibilities, depending on the underlying disease process that initiates DIC and whether the DIC is acute or chronic (see Box 29-7). Most symptoms are the result of either hemorrhage or thrombosis. Acute DIC presents with rapid development of hemorrhaging, such as oozing from venipuncture sites, arterial lines, and surgical wounds, or development of ecchymotic lesions (purpura, petechiae) and hematomas. Other sites of bleeding include the eyes (sclera and conjunctiva), the nose (epistaxis), and the gums. Most individuals with DIC demonstrate bleeding at three or more unrelated sites, and any combination may be observed. Shock of variable intensity, out of proportion to the amount of apparent blood loss, also may be observed. Hemorrhaging into closed compartments of the body also can occur and may precede the development of shock.

DIC has been conceptualized as a systemic hemorrhagic disorder because bleeding, sometimes very extensive, is usually the initial observation. Symptoms of thrombosis are not always as evident, even though it is often the first pathologic alteration to occur and ultimately determines the degree of morbidity and risk for death. A large amount of microvascular and macrovascular occlusion may occur that is not clinically obvious. Several organ systems are susceptible to microvascular thrombosis that affects their function; these include the cardiovascular, pulmonary, central nervous, renal, and hepatic systems. Quick and accurate clinical diagnosis is critical to preventing further progression of DIC that may lead to multisystem organ dysfunction or failure. Indicators of multisystem failure include changes in level of consciousness, behavior, and mentation; confusion; seizure activity; oliguria; hematuria; hypoxia; hypotension; hemoptysis; chest pain; and tachycardia. Symmetric cyanosis of the fingers and toes ("blue finger/toe syndrome") and, in some instances, of the nose and breasts may be present. Symmetric parts are often affected and are indicative of microvascular thrombosis. This may progress to infarction and gangrene, requiring amputation. Jaundice also may be present and is believed to result from red blood cell destruction rather than hepatic dysfunction.

Individuals with chronic or low-grade DIC do not present with overt manifestations of hemorrhaging and thrombosis but instead have subacute bleeding and diffuse thrombosis and are described as having a **compensated DIC,** or non-overt DIC. The major characteristic of this state is an increased turnover and decreased survival time of the components of hemostasis: platelets and clotting factors. On occasion diffuse or localized thrombosis develops, but this is infrequent.

EVALUATION AND TREATMENT. No single laboratory test can be used to effectively diagnosis DIC. Diagnosis is based primarily on clinical symptoms and confirmed by a combination of laboratory tests. The individual must present with a clinical condition that is known to be associated with DIC. The most commonly used combination of laboratory tests usually confirms thrombocytopenia or a rapidly decreasing platelet count

BOX 29-8 LABORATORY DIAGNOSTIC CRITERIA FOR DISSEMINATED INTRAVASCULAR COAGULATION (DIC)*

Group I Tests (Indicators of Procoagulant Activation)
1. Elevated prothrombin fragment 1+2
2. Elevated fibrinopeptide A
3. Elevated fibrinopeptide B
4. Elevated thrombin-antithrombin (TAT) complex
5. Elevated D-dimer

Group II Tests (Indicators of Fibrinolytic Activity)
1. Elevated D-dimer
2. Elevated fibrin degradation products (FDPs)
3. Elevated plasmin
4. Elevated plasmin-antiplasmin (PAP) complex

Group III Tests (Indicators of Inhibitor Consumption)
1. Decreased antithrombin III
2. Decreased α_2-antiplasmin
3. Decreased heparin cofactor II
4. Decreased protein C or S
5. Elevated TAT complex
6. Elevated PAP complex

Group IV Tests (Indicators of End-Organ Damage/Failure)
1. Elevated lactic dehydrogenase (LDH)
2. Elevated creatinine
3. Decreased pH
4. Decreased Pa_{O_2}

Data from Bick RL: *Semin Thromb Hemost* 24(1):3, 1998.
*Satisfactory criteria for laboratory diagnosis of DIC require one abnormality in each of groups I through III and at least two abnormalities in group IV.

on repeated testing, prolongation of clotting times, the presence of fibrin degradation products, and decreased levels of coagulation inhibitors. The relationships among these criteria are summarized in Box 29-8. Platelet counts less than 100,000/mm^3 or a progressive decrease in platelet counts is very sensitive for DIC, although not greatly specific. These changes usually indicate consumption of platelets.

The standard coagulation tests (e.g., prothrombin time [PT], activated partial thromboplastin time [aPTT]) also have a high degree of sensitivity, but they are not highly specific for DIC. As a result of consumption of circulating clotting factors, these tests are usually abnormal, ranging from shortened to prolonged times. However, conditions other than DIC may prolong clotting times. Assays of specific clotting factors do not contribute meaningful diagnostic information.

Detection of various fibrin degradation products is more specific for DIC; of these tests the detection of D-dimers is the most widely used, reliable, and specific test.[71] A **D-dimer** is a molecule produced by plasmin degradation of cross-linked fibrin in clots. D-dimers in the blood can be quantified using enzyme-linked immunosorbent assay (ELISA) tests that include commercially available and highly specific monoclonal antibody against the D-dimer. Agglutination tests for other fibrin degradation products are available. Levels of fibrin degradation products, in general, are elevated in the plasma in 95% to 100% of cases; however, they are less specific and only document the presence of plasmin and its action of fibrin, whereas detection of D-dimers measures a specific DIC-related product.

ELISAs for markers of thrombin activity are sometimes used. Normal conversion of prothrombin to thrombin produces an inactive prothrombin fragment 1.2 (PF1+2).[71] This fragment is released from the prothrombin molecule, generating an intermediate factor, prethrombin 2. Once generated, prethrombin 2 can be split to produce thrombin that can then proteolyze fibrinogen, liberating fibrinopeptide A (FPA), or can combine with its major antagonist, antithrombin, and form a stable inactive enzyme-inhibitor complex, the thrombin-antithrombin (TAT) complex. Assays of these factors (PF1+2, FPA, TAT) are now generally available to quantify their blood levels, providing evidence of excessive factor Xa (PF1+2) and thrombin (FPA) generation.

Levels of coagulation inhibitors (e.g., AT III, protein C) can be measured by assays that rely on function or by ELISAs that quantify the amount of the specific inhibitor. AT III levels can provide key information for diagnosing and monitoring therapy of DIC. Initial levels of functional AT III are low in DIC because thrombin is irreversibly complexed with activated clotting factors and AT III.

Treatment of DIC is directed toward (1) eliminating the underlying pathology, (2) controlling ongoing thrombosis, and (3) maintaining organ function. Elimination of the underlying pathology is the initial intervention in the treatment phase in order to eliminate the trigger for activation of clotting. Once the stimulus is gone, production of coagulation factors in the liver leads to restoration of normal plasma levels within 24 to 48 hours.

Control of thrombosis is more difficult to attain. Heparin has been used for this; however, its use is controversial because its mechanism of action is binding to and activating AT III, which is deficient in many types of DIC. Currently heparin is indicated only in certain situations related to DIC. For instance, heparin seems to be effective in DIC caused by a retained dead fetus or associated with acute promyelocytic leukemia. Organ function is compromised by microthrombi, and there is a risk of losing an extremity because of vascular occlusion; thus heparin is also indicated in these conditions. Heparin's usefulness, however, for DIC that is precipitated by septic shock has not been established and so is contraindicated in that instance; heparin is also contraindicated when there is evidence of postoperative bleeding, peptic ulcer, or CNS bleeding.

Replacement therapy (interventions based on restoring the balance of coagulation factors, deficient coagulation factors, platelets, and other coagulation elements) is gaining recognition as an effective treatment modality. Components used in replacement therapy include platelets, fresh frozen plasma, and cryoprecipitate. Platelets are given for thrombocytopenia, plasma provides volume and replaces clotting factors, and cryoprecipitate replaces fibrinogen. Their use is not without controversy, however, because of the possible risk of adding components that will increase the rate of thrombosis. Clinical

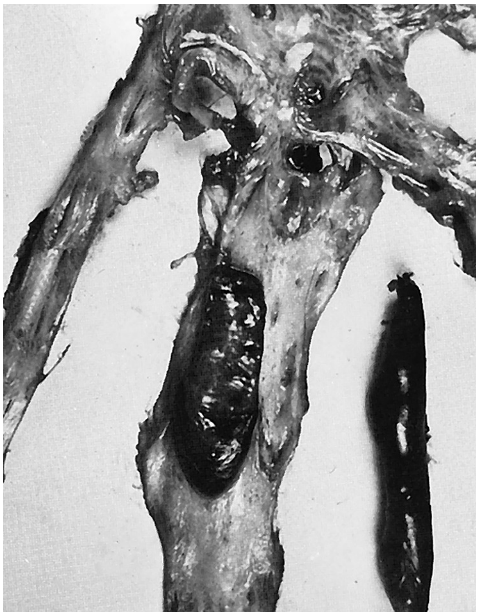

FIGURE 29-21 Thrombus. Thrombus arising in valve pocket at upper end of superficial femoral vein. Postmortem clot on the right is shown for comparison. (From McLachlin J, Paterson JC: *Surg Gynecol Obstet* 93:1, 1951.)

judgment is the key factor in determining whether replacement is to be used as a treatment modality.

Several clinical trials are evaluating replacement of anticoagulants (i.e., AT III, protein C). Replacement of AT III appears to be effective in DIC caused by sepsis. Low levels of AT III correlate with sepsis-initiated DIC, which makes a case for its use. AT III is an α_2-globulin that inactivates thrombin, factor Xa, factor IXa, and other activated components of the clotting system. Heparin augments AT III, but the increased benefit of a combination of heparin with AT III replacement has not been established. Antifibrinolytic drugs also are used in treatment but are limited to instances of life-threatening bleeding that have not been controlled by blood component replacement therapy.

Maintenance of organ function is achieved by fluid replacement to sustain adequate circulating blood volume and to maintain optimal tissue and organ perfusion. Fluids may be required to restore blood pressure, cardiac output, and urine output to normal parameters.

Thromboembolic Disease

Certain conditions within the blood vessels predispose an individual to develop clots spontaneously.[72] A stationary clot attached to the vessel wall is called a **thrombus** (Figure 29-21). A thrombus is composed of fibrin and blood cells and can develop in either the arterial or the venous system. **Arterial thrombi** form under conditions of high blood flow and are composed mostly of platelet aggregates held together by fibrin strands. **Venous thrombi** form in conditions of low flow and are composed mostly of red cells with larger amounts of fibrin and few platelets.

A thrombus may eventually grow large enough to reduce or obstruct blood flow to tissues or organs, such as the heart, brain, or lungs, depriving them of essential nutrients critical to survival. A thrombus also has the potential of detaching from the vessel wall and circulating within the bloodstream (referred to as an **embolus**). The embolus may become lodged in smaller blood vessels, blocking blood flow into the local tissue or organ and leading to ischemia. Whether episodes of thromboembolism are life threatening depends on the site of vessel occlusion.

Therapy consists of removal or lysis of the clot and supportive measures. Anticoagulant therapy is effective in treating or preventing venous thrombosis; it is not as useful in treating or preventing arterial thrombosis. Parenteral heparin is the major anticoagulant used to treat thromboembolism. Oral coumarin drugs also are widely used, particularly for individuals not hospitalized. More aggressive therapy may be indicated for such conditions as pulmonary embolism, coronary thrombosis, or thrombophlebitis. Streptokinase and urokinase activate the fibrinolytic system and are administered to accelerate the lysis of known thrombi. Thrombolytic therapy has limited uses and is prescribed with a high degree of caution because it can cause hemorrhagic complications.

The risk for developing spontaneous thrombi is related to several factors, referred to as the **Virchow triad:** (1) injury to the blood vessel endothelium, (2) abnormalities of blood flow, and (3) hypercoagulability of the blood.

Vascular endothelial injury can result from atherosclerosis (plaque deposits on arterial walls). Atherosclerosis initiates platelet adhesion and aggregation, promoting the development of atherosclerotic plaques that enlarge, causing further damage and occlusion. Other causes of vessel endothelial injury may be related to hemodynamic alterations associated with hypertension and turbulent blood flow. Injury also is caused by radiation injury, exogenous chemical agents (toxins from cigarette smoke), endogenous agents (cholesterol), bacterial toxins or endotoxins, or immunologic mechanisms. Whatever the precipitating cause of endothelial injury, it is a potent thrombogenic agent.

Sites of turbulent blood flow in the arteries and stasis of blood flow in the veins are at risk for thrombus formation. In areas of turbulence, platelets and endothelial cells may be activated, leading to thrombosis. In sites of stasis, platelets may remain in contact with the endothelium for prolonged times, and clotting factors that would normally be diluted with fresh-flowing blood are not diluted and may become activated. The most common clinical conditions that predispose to venous stasis and subsequent thromboembolic phenomena are major surgery (e.g., orthopedic surgery), acute myocardial infarction, congestive heart failure, limb paralysis, spinal injury, malignancy, advanced age, the postpartum period, and bed rest longer than 1 week. Turbulence and stasis occur with ulcerated atherosclerotic plaques (myocardial infarction), hyperviscosity (polycythemia), and conditions with deformed red cells (sickle cell anemia).

Hypercoagulability, or **thrombophilia,** is the condition in which an individual is at risk for thrombosis. Hypercoagulability is differentiated according to whether it results from primary (hereditary) or secondary (acquired) causes. Primary causes

BOX 29-9 CLINICAL CONDITIONS ASSOCIATED WITH HIGH RISK FOR THROMBOSIS OR THROMBOEMBOLISM

ARTERIAL	VENOUS
Atherosclerosis	General surgery
Cigarette smoking	Orthopedic surgery
Hypertension	Arthroscopy
Diabetes mellitus	Trauma
High LDL cholesterol	Malignancy
Hypertriglyceridemia	Immobility
Positive family history	Sepsis
Left ventricular failure	Congestive heart failure
Oral contraceptives	Nephrotic syndrome
Estrogens	Obesity
High lipoprotein A	Varicose veins
Polycythemia	Postphlebotic syndrome
Hyperviscosity syndrome	Oral contraceptives
Leukostasis syndrome	Estrogens
Thrombocythemia	Thrombocythemia

LDL, Low-density lipoprotein.

include defects in proteins involved in hemostasis. Secondary causes include a variety of clinical disorders or conditions (Box 29-9). It is unclear why the incidence of thrombosis formation in hypercoagulable states associated with various disease states and conditions is not more than anticipated.

Hereditary Thrombophilias. A large number of inherited conditions have been identified that increase the risk of developing thrombosis (Box 29-10).[73] Most are autosomal dominant; thus individuals who are homozygous for the mutation are at greatest risk for thrombosis. These include mutations in coagulation proteins, fibrinolytic proteins, platelet receptors, and other factors. The particular mutations that have been most strongly linked as risk factors for venous thrombosis or for arterial thrombosis leading to coronary artery disease or stroke include those that affect fibrinogen, prothrombin (G20210A variant), factor V (factor V Leiden) of the coagulation system, PAI-1 of the fibrinolytic system, the platelet receptor GPIIIa, and methylenetetrahydrofolate reductase (MTHFR), as well as mutations that result in excessive levels of homocysteine (hyperhomocysteinemia). Other inherited thrombophilias are risk factors primarily for venous thrombosis.[74,75] These include deficiencies in protein C, protein S, and AT III.[76]

Factor V Leiden results from a single nucleotide mutation of guanine to adenine at nucleotide 1691 (G1691A). Activated factor V (Va) is usually inactivated by protein C, but this single mutation results in a change in amino acid 506 from arginine to glutamine. The change alters the site where protein C would cleave factor Va and confers partial resistance, resulting in prolonged high levels of Va and prolongation of clot formation.[77] Although this mutation increases the risk for thrombosis, most individuals with factor V Leiden do not have clinically relevant thrombotic events. It is the most common hereditary thrombophilia and is found in about 30% of individuals presenting with deep venous thrombosis (DVT) or pulmonary embolism. It is primarily observed in individuals of European ancestry and in about 5% of whites in the United States and Europe.

BOX 29-10 HEREDITARY AND ACQUIRED THROMBOPHILIC DISORDERS

Inherited Disorders (Primary)

Activated protein C resistance
- Factor V Leiden mutation
- Factor V Cambridge mutation
- Factor V Hong Kong
- Factor V HR2 mutation
- Prothrombin 20210A mutation

Factor XII deficiency (Hageman trait)
Dysfibrinogenemia
Hyperhomocysteinemia
Platelet defects
- Wien-Penzing defect
- Sticky platelet syndrome

Inherited and Acquired Disorders

Antithrombin deficiency
Heparin cofactor II deficiency
Protein C deficiency
Protein S deficiency
Plasminogen deficiency
Other fibrinolytic system defects

Acquired Disorders (Secondary)

Antiphospholipid antibodies
- Anticardiolipin antibodies
- Lupus anticoagulant
- Subgroup phospholipid antibodies

Myeloproliferative syndromes
Trousseau syndrome

From Bick RL: *Hematol Oncol Clin North Am* 17(1):115–147, 2003.

The second most common inherited thrombophilia is a mutation in the prothrombin gene, resulting in a replacement of guanine at nucleotide 20210 with an adenine (G20210A variant).[74] This mutation is observed in about 2% to 5% of individuals of European ancestry, but is found in 5% to 10% of individuals presenting with venous thrombosis. The G20210A variant leads to overproduction of prothrombin and prolongation of clot formation.

MTHFR mutation leads to alterations in the metabolism of the amino acid homocysteine into methionine and abnormally elevated levels of that amino acid in the blood (hyperhomocysteinemia).[78] Acquired hyperhomocysteinemia may result from deficiencies in vitamins B_6 or B_{12}, endocrine diseases (e.g., diabetes mellitus, hypothyroidism), pernicious anemia, inflammatory bowel disease, renal failure, and therapy with some drugs. Individuals with homocysteine levels above the 95th percentile are 2.5 times more likely to experience an episode of DVT.

More than 100 different known mutations lead to defects of proteins C, protein S, and AT III and increase the risk of venous thrombosis. Mutations may lead to either quantitative (low levels of protein) or qualitative (production of defective protein) changes.

FIGURE 29-22 **Arterial Thrombosis Associated with Antiphospholipid Antibodies.** A 12-year-old girl with systemic lupus erythematosus and antiphospholipid antibodies with painful cutaneous vasculitis of the right foot. Arterial thrombosis documented by angiography resulted in cyanosis of the large toe. Symptoms resolved with treatment with heparin and corticosteroids. (From Kliegman R et al: *Nelson textbook of pediatrics,* ed 18, Philadelphia, 2007, Saunders.)

Tests to diagnose inherited thrombophilias include prothrombin time, partial thromboplastin time, and levels of protein C, protein S, and AT III. More elaborate tests to detect precise mutations in factor V, prothrombin, or MTHFR may be indicated.

Acquired Hypercoagulability. Deficiencies in proteins S and C and AT III may be acquired and contribute to a hypercoagulable state.[77] Conditions associated with an acquired protein deficiency include DIC, liver disease, infection, DVT, acute respiratory distress syndrome, l-asparaginase therapy, HUS, and TTP. The postoperative state also predisposes an individual to protein C or S deficiency; however, its role in contributing to DVT remains unclear.

Acquired hypercoagulable states include the antiphospholipid syndrome (APS), an autoimmune syndrome characterized by autoantibodies against plasma membrane phospholipids and phospholipid-binding proteins. As with most autoimmune diseases, the predominantly affected individual is female and of reproductive age. Those with APS are at risk for arterial and venous thrombosis and a variety of obstetric complications, including pregnancy loss and preeclampsia or eclampsia (Figure 29-22).[79] In severe cases the person may die from recurrent major thrombus formation.[80] The pathophysiology is related to autoantibodies directly reacting with platelets or endothelial cells (increasing the risk for thrombosis) or the placental surface (resulting in damage to the placenta). The predominant diagnostic tests measure prolongation of laboratory blood coagulation tests related to an antibody inhibitor (lupus anticoagulant) and specific ELISAs for antibodies against phospholipids (e.g., anticardiolipin antibody) or proteins that bind to phospholipids (e.g., β_2-glycoprotein I).[81,82] Highly effective therapy (i.e., unfractionated or low-molecular-weight heparin with low-dose aspirin) is available to prevent the obstetric complications.[83]

SUMMARY REVIEW

Alterations of Leukocyte Function

1. Quantitative alterations of leukocytes (too many or too few) can be caused by bone marrow dysfunction or premature destruction of cells in the circulation. Many quantitative changes in leukocytes occur in response to invasion by microorganisms.
2. Leukocytosis is a condition in which the leukocyte count is higher than normal and is usually a response to stress and invasion of microorganisms.
3. Leukopenia is a condition in which the leukocyte count is lower than normal and is caused by pathologic conditions such as malignancies and hematologic disorders.
4. Granulocytosis (particularly as a result of an increase in neutrophils) occurs in response to infection. The marrow releases immature cells, causing a shift-to-the-left, when responding to an infection that has created a demand for neutrophils that exceeds the supply in the circulation.
5. Eosinophilia results most commonly from parasitic invasion and ingestion or inhalation of toxic foreign particles.
6. Basophilia is seen in hypersensitivity reactions because of the high content of histamine and subsequent release.
7. Monocytosis occurs during the late or recuperative phase of infection when macrophages (mature monocytes) phagocytose surviving microorganisms and debris.
8. Granulocytopenia, a significant decrease in the number of neutrophils, can be a life-threatening condition if sepsis occurs; it is often caused by chemotherapeutic agents, severe infection, and radiation.
9. Infectious mononucleosis is an acute infection of B lymphocytes most commonly associated with EBV, a type of herpesvirus. Transmission of EBV is by personal contact, commonly through saliva, thus its nickname, the kissing disease.
10. Two of the earliest manifestations of mononucleosis are sore throat and fever caused by inflammation at the primary site of viral entry.
11. Most cases of EBV mononucleosis include fever lasting 7 to 10 days, sore throat, and enlargement and tenderness of the cervical lymph nodes. It is self-limiting, and treatment consists of rest and relief of symptoms.
12. The common pathologic feature of all forms of leukemia is an uncontrolled proliferation of leukocytes and overcrowding of the bone marrow, causing a decreased production and function of the other blood cell lines.

SUMMARY REVIEW—cont'd

13. All leukemias are classified by the cell type involved, lymphocytic or myelogenous, and are differentiated by onset, acute or chronic. Thus there are four major types of leukemia: ALL, CLL, AML, and CML.
14. Although the exact cause of leukemia is unknown, it is considered a clonal disorder. A higher incidence of acute leukemias and CLL is reported in certain families, suggesting a possible genetic predisposition.
15. The most common genetic abnormality in adult ALL is the Philadelphia chromosome.
16. In approximately one third of clients with AML, there is a mutation in the receptor tyrosine kinase FLT3.
17. In leukemia, blasts (precursor cells) "crowd out" the marrow and cause cellular proliferation of the other cell lines to cease.
18. The major clinical manifestations of leukemia include fatigue caused by anemia, bleeding caused by thrombocytopenia, fever secondary to infection, anorexia, and weight loss.
19. Chemotherapy is the treatment of choice for leukemia. Acute leukemias are associated with an increasing survival rate of 80% to 90%, with long-term survival of 30% to 40%. Chronic leukemias are associated with a longer life expectancy than are acute leukemias.
20. Chronic leukemias progress differently than acute leukemias, advancing slowly and without warning. The presence of the Philadelphia chromosome is a diagnostic marker for CML.

Alterations of Lymphoid Function

1. The number of lymphocytes is decreased (lymphocytopenia) in most acute infections and in some immunodeficiency syndromes.
2. Lymphocytosis occurs in viral infections (IM and infectious hepatitis, in particular), leukemia, lymphomas, and some chronic infections.
3. Lymphomas are tumors of primary lymphoid tissue (thymus, bone marrow) or secondary lymphoid tissue (lymph nodes, spleen, tonsils, intestinal lymphoid tissue). The two major types of malignant lymphomas are Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).
4. Reed-Sternberg (RS) cells in lymph nodes are classically associated with HL. The RS cell is derived from a malignant B cell that usually becomes binucleate.
5. A virus might be involved in the pathogenesis of HL. Some familial clustering suggests an unknown genetic mechanism.
6. An enlarged painless mass or swelling, most commonly in the neck, is an initial sign of HL. Local symptoms are produced by lymphadenopathy, usually caused by pressure or obstruction.
7. Treatment of HL includes radiation therapy and chemotherapy. A cure is possible regardless of the stage of HL; however, individuals treated with chemotherapy who relapse in less than 2 years have a poor prognosis.
8. The cause of lymph node enlargement and cancerous transformation in NHL is unknown. Immunosuppressed persons have a higher incidence of NHL, suggesting an immune mechanism.
9. Generally, with NHL, the swelling of lymph nodes is painless, and the nodes enlarge and transform over months or years.
10. Individuals with NHL can survive for long periods. Treatment is chemotherapy.
11. Burkitt lymphoma involves the jaw and facial bones and occurs in children from east-central Africa and New Guinea.
12. Multiple myeloma (MM) is a neoplasm of B cells (immature plasma cells) and mature plasma cells. It is characterized by multiple malignant tumors of plasma cells scattered throughout the skeletal system and occasionally in soft tissue.
13. Myeloma cells usually secrete monoclonal protein (M protein) that is an abnormal antibody molecule. The myeloma cell may also secrete free antibody light chain that is excreted in the urine (Bence Jones protein).
14. The exact cause of MM is unknown, but genetic factors and chronic stimulation of the mononuclear phagocyte system by bacteria, viral agents, and chemicals have been suggested.
15. The major clinical manifestations for MM include recurrent infections caused by suppression of the humoral immune response and renal disease as a result of Bence Jones proteinuria.
16. Chemotherapy is the treatment of choice for MM. Treatment with tandem transplant or thalidomide, or both, is showing promise as an effective therapeutic agent in producing long-term remissions.
17. Waldenström macroglobulinemia is a rare type of slow-growing plasma cell tumor that secretes a monoclonal IgM molecule.

Alterations of Splenic Function

1. Splenomegaly (enlargement of the spleen) may be considered normal in certain individuals, but its presence should not be ignored.
2. Splenomegaly results from (a) acute inflammatory or infectious processes, (b) congestive disorders, (c) infiltrative processes, and (d) tumors or cysts.
3. Splenomegaly causes hypersplenism (overactivity of the spleen). Hypersplenism results in blood cell sequestration, causing destruction of red blood cells and the development of anemia.

Alterations of Platelets and Coagulation

1. Thrombocytopenia is characterized by a platelet count less than 100,000 platelets/μL of blood; a count less than 50,000/μL increases the potential for hemorrhage associated with minor trauma.

SUMMARY REVIEW—cont'd

2. Thrombocytopenia exists in primary or secondary forms and is commonly associated with autoimmune diseases and viral infections; bacterial sepsis with DIC also results in thrombocytopenia.
3. Heparin-induced thrombocytopenia develops in approximately 4% of individuals receiving unfractionated heparin.
4. Immune thrombocytopenic purpura (ITP) is a major cause of platelet destruction, often affecting females, and results in hemorrhaging that ranges from petechiae to bleeding from mucosal sites.
5. Thrombotic thrombycytopenic purpura (TTP) causes platelet aggregation leading to microcirculatory occlusion.
6. Thrombocythemia is characterized by a platelet count more than 400,000 platelets/μL of blood and is symptomatic when the count exceeds 1 million/μL, which increases the risk for intravascular clotting (thrombosis).
7. Thrombocythemia is caused by accelerated platelet production in the bone marrow.
8. Qualitative alterations in normal platelet adherence or aggregation prevent platelet plug formation and may result in prolonged bleeding times.
9. Prolonged bleeding can result from alterations in platelet function, including adhesion between platelets and the vessel wall, platelet-platelet adhesion, platelet granule secretion, arachidonic acid pathway activity, and membrane phospholipid regulation.
10. Disorders of coagulation are usually caused by defects or deficiencies of clotting factors.
11. Coagulation is impaired when there is a deficiency of vitamin K because of insufficient production of prothrombin and synthesis of clotting factors II, VII, IX, and X, often associated with liver diseases.
12. DIC is a complex syndrome that results from a variety of clinical conditions that release tissue factor, causing an increase in fibrin and thrombin activity in the blood and producing augmented clot formation and accelerated fibrinolysis. Sepsis is often associated with DIC.
13. DIC is characterized by a cycle of intravascular clotting followed by active bleeding caused by the initial consumption of coagulation factors and platelets and diffuse fibrinolysis.
14. Diagnosis of DIC is based on dysfunctional coagulation activity. Treatment is complex, nonstandardized, and focused on removing the primary cause, restoring hemostasis, and preventing further organ damage.
15. Thromboembolic disease results from a fixed (thrombus) or moving (embolus) clot that blocks flow within a vessel, denying nutrients to tissues distal to the occlusion; death can result when clots obstruct blood flow to the heart, brain, or lungs.
16. Hypercoagulability is the result of deficient anticoagulation proteins. Secondary causes are conditions that promote venous stasis.
17. The term Virchow triad refers to three factors that can cause thrombus formation: (a) vessel wall injury, (b) blood flow abnormalities, and (c) altered blood constituents leading to hypercoagulability.
18. Autoantibodies against phospholipids result in a state of acquired hypercoagulability, an increased risk for venous or arterial thrombosis, and a higher incidence of pregnancy complications.

CHAPTER OUTLINE

This chapter briefly explains fetal and neonatal hematopoiesis and postnatal changes in blood as a foundation for understanding the pathophysiology of specific blood disorders in childhood. Among the diseases that affect erythrocytes are acquired disorders, such as iron deficiency anemia, hemolytic disease of the newborn, and anemia of infectious disease; and inherited disorders, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency, hereditary spherocytosis, sickle cell disease, and the thalassemias. Disorders of coagulation and platelets include inherited hemorrhagic diseases, such as the hemophilias, and antibody-mediated hemorrhagic diseases, which include idiopathic thrombocytopenic purpura, autoimmune neonatal thrombocytopenias, and autoimmune vascular purpuras. Finally, leukocyte disorders, such as leukemia and the lymphomas (non-Hodgkin lymphoma as well as Hodgkin disease), are discussed.

FETAL AND NEONATAL HEMATOPOIESIS

As the developing embryo becomes too large for oxygenation of tissues by simple diffusion, the production of erythrocytes begins within the vessels of the yolk sac. Shortly after 2 weeks of gestation, circulating erythrocytes play a major role in delivering oxygen to the tissues. At approximately the eighth week of gestation, the site of erythrocyte production shifts from the vessels to the liver sinusoids, and the production of leukocytes and platelets begins in the liver and spleen. Erythropoiesis in the liver and, to a lesser extent, in the spleen and lymph nodes, reaches a peak at approximately 4 months. Hepatic blood formation declines steadily thereafter but does not disappear entirely during the remainder of gestation. By the fifth month of gestation, hematopoiesis begins to occur in the bone marrow and increases rapidly until hematopoietic (red) marrow fills the

entire bone marrow space. By the time of delivery, the marrow is the only significant site of hematopoiesis.

In neonates and young infants, hematopoietic marrow progressively fills the bony cavities of the entire axial skeleton (skull, vertebrae, ribs, sternum), the long bones of the limbs, and many intramembranous bones. (These structures are described in Chapter 45.) Fatty (yellow) marrow gradually replaces hematopoietic marrow in some bones. During childhood, hematopoietic tissue retreats centrally to the vertebrae, ribs, sternum, pelvis, scapulae, skull, and proximal ends of the femur and humerus.

In diseases characterized by hemolysis, erythrocyte production can increase as much as eight times the normal because erythropoietin causes hematopoietic marrow to increase in volume. Initially, hematopoietic marrow expands from the ends of the long bones toward the middle of the shafts, replacing fatty marrow. Next, blood cell production begins to occur outside the marrow cavities, especially in the liver and spleen. Extramedullary hematopoiesis is more likely to occur in children than in adults because the bony cavities of children already are filled with red marrow (Figure 30-1). This is why hemolytic disease causes especially pronounced enlargement of the spleen and liver in children.

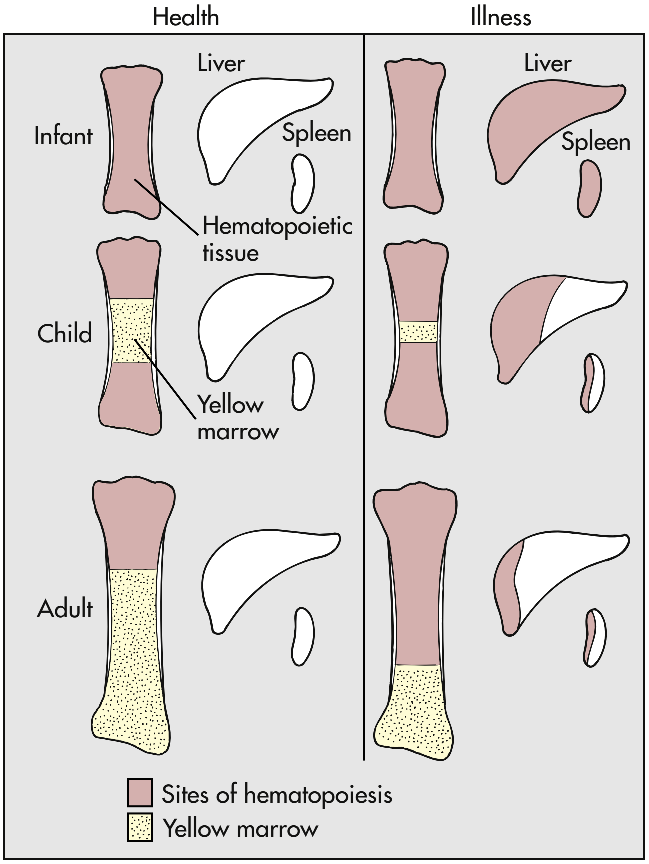

FIGURE 30-1 Sites of Hematopoiesis in Health and Illness. With normal maturation, red marrow is partly replaced by yellow marrow in the shafts of the long bones. In adults, red marrow is largely restricted to the proximal ends of the femur and humerus. In response to hemolysis, red marrow replaces yellow marrow in the long bones. In infants, whose long bones already are filled with red marrow, additional hematopoiesis takes place in the liver and spleen. In children and adults, red marrow can replace yellow marrow in response to hemolysis, necessitating less hematopoiesis in the liver and spleen.

The erythrocytes undergo striking changes during gestation, particularly during the first two trimesters, at which time they nearly double in numbers and in hemoglobin content. A proportionate increase in hematocrit also occurs. By the end of gestation the erythrocyte count has more than tripled but the size of each erythrocyte has decreased.

A biochemically distinct type of hemoglobin is synthesized during fetal life. The three **embryonic hemoglobins (Gower 1, Gower 2, and Portland)** and the **fetal hemoglobin (HbF)** are composed of two α- and two γ-chains of polypeptides, whereas the adult hemoglobins (HbA and HbA_2) are composed of two α-chains and two β-chains. (The structure of an adult hemoglobin molecule is illustrated in Figure 27-15, and types of hemoglobin are defined in Table 27-5.) Some unknown regulatory mechanism promotes γ-chain synthesis and inhibits β- and δ-chain synthesis in utero. This results in production of embryonic or fetal hemoglobin. After birth, γ-chain synthesis is inhibited, whereas β- and δ-chain synthesis is facilitated, resulting in production of adult hemoglobins.

Fetal hemoglobin has greater affinity for oxygen than does adult hemoglobin because it interacts less readily with an enzyme (2,3-diphosphoglycerate [DPG]) that inhibits hemoglobin-oxygen binding. The decreased inhibitory effects of 2,3-DPG enable fetal blood to transport oxygen despite the relative lack of oxygen in the uterine environment. The increased affinity for oxygen enables Hb F to bind with maternal oxygen in the placental circulation.

During the first trimester nearly all of the hemoglobin in the fetus is embryonic, but some Hb A can be detected. Therefore, it is possible to identify as early as 16 to 20 weeks of gestation some disorders of adult hemoglobin, such as sickle cell anemia and thalassemia major. In the 6-month fetus, Hb F constitutes 90% of the total. This percentage then begins to decline. At birth, neonatal hemoglobin consists of 70% Hb F, 29% Hb A, and 1% Hb A_2. Between 6 and 12 months of age, normal adult hemoglobin percentages are established (see Chapter 27).

POSTNATAL CHANGES IN THE BLOOD

Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood. Table 30-1 lists normal ranges during infancy and childhood. The immediate rise in values is the result of accelerated hematopoiesis during fetal life, increased numbers of cells that result from the trauma of birth, and cutting of the umbilical cord. These events surrounding the birth also are accompanied by the presence of large numbers of immature erythrocytes and leukocytes (particularly granulocytes) in peripheral blood (see Chapter 27). As the infant develops over the first 2 to 3 months of life, the numbers of these immature blood cells decrease.

Average blood volume in the full-term neonate is 85 ml/kg of body weight. The premature infant has a slightly larger blood volume of 90 ml/kg of body weight, with the mean increasing to 150 mg/kg during the first few days after birth. In full-term and premature infants, blood volume decreases during the first few

TABLE 30-1 HEMATOLOGIC VALUES DURING INFANCY AND CHILDHOOD

	HEMOGLOBIN (g/dl)		HEMATOCRIT (%)		RETICULOCYTES (%)	MCV (fl)	LEUKOCYTES (WBC/mm³)		NEUTROPHILS (%)		LYMPHOCYTES (%)	EOSINOPHILS (%)	MONOCYTES (%)

months. Thereafter the average blood volume is 75 to 77 ml/kg, which is similar to that of older children and adults.

Erythrocytes

The hypoxic intrauterine environment stimulates erythropoietin production in the fetus. This accelerates fetal erythropoiesis, producing polycythemia (excessive proliferation of erythrocyte precursors) of the newborn. After birth the oxygen from the lungs saturates arterial blood, and the amount of oxygen delivered to the tissues increases. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of erythropoietin and the rate of blood cell formation decrease. The very active rate of fetal erythropoiesis is reflected by the large numbers of immature erythrocytes (reticulocytes) in the peripheral blood of full-term neonates. After birth the number of reticulocytes decreases about 50% every 12 hours, so it is rare to find an elevated reticulocyte count after the first week of life. A decrease in extramedullary hematopoiesis also occurs at this time. In the peripheral blood the erythrocyte count drops for 6 to 8 weeks after birth. During this period of rapid growth the rate of erythrocyte destruction is greater than that in later childhood and adulthood. In full-term infants, normal erythrocyte life span is 60 to 80 days; in premature infants it may be as short as 20 to 30 days; and in children and adolescents, it is the same as that in adults—120 days. (Mechanisms of hemolysis are described in Chapter 27.)

In the premature infant the postnatal fall in hemoglobin and hematocrit values is more marked than in the full-term infant. In the preschool and school-age child, there is a gradual rise in hemoglobin, hematocrit, and red blood cell (RBC) count. Values in males and females first begin to diverge in adolescence. In the female the gradual hemoglobin increase continues into early puberty, at which time it stabilizes. In the male the hemoglobin increase keeps pace with growth and maturation and eventually surpasses that of the female. This higher value of hemoglobin in the mature male is related to androgen secretion.

Metabolic processes within the erythrocytes of neonates differ significantly from those of erythrocytes in the normal adult. The relatively young population of erythrocytes in the newborn consumes greater quantities of glucose than do erythrocytes in adults. Several enzymes that regulate glucose consumption are increased in the erythrocytes of neonates, with a subsequent increase in the rate of glycolysis.

Leukocytes and Platelets

The lymphocytes of children tend to have more cytoplasm and less compact nuclear chromatin than do the lymphocytes of adults. The significance of these differences is unknown. One possible explanation is that children tend to have more frequent viral infections, which are associated with atypical lymphocytes. Even minor infections, in which the child fails to exhibit clinical manifestations of illness, or administration of immunizations may result in lymphocyte changes.[1]

The lymphocyte count is high at birth and continues to rise in some healthy infants during the first year of life. Then a steady decline occurs throughout childhood and adolescence until lower adult values are reached. It is unknown whether these developmental variations are physiologic or are a pathologic response to frequent viral infections and immunizations in children.

At birth the neutrophil count is very high and rises further during the early days of life.[2] After 2 weeks neutrophil counts fall to within or below normal adult ranges. By approximately 4 years of age the neutrophil count is the same as that of an adult. White children have slightly higher counts than black children.[3]

Eosinophil count is high in the first year of life and is higher in children than in teenagers or adults.[4] Monocyte counts are high in the first year of life and then decrease to adult levels. No relationship between age and basophil count has been found. Platelet counts in full-term neonates are comparable to platelet counts in adults and remain so throughout infancy and childhood.[5]

TABLE 30-2 ANEMIAS OF CHILDHOOD

CAUSE	ANEMIC CONDITION
Deficient Erythropoiesis or Hemoglobin Synthesis	
Decreased stem cell population in marrow (congenital or acquired pure red cell aplasia)	Normocytic-normochromic anemia
Decreased erythropoiesis despite normal stem cell population in marrow (infection, inflammation, cancer, chronic renal disease, congenital dyserythropoiesis)	Normocytic-normochromic anemia
Deficiency of a factor or nutrient needed for erythropoiesis	
Cobalamin (vitamin B_{12}), folate	Megaloblastic anemia
Iron	Microcytic-hypochromic anemia
Increased or Premature Hemolysis	
Alloimmune disease (maternal-fetal Rh, ABO, or minor blood group incompatibility)	Hemolytic disease of the newborn (HDN)
Autoimmune disease (idiopathic autoimmune hemolytic anemia, symptomatic systemic lupus erythematosus, lymphoma, drug-induced autoimmune processes)	Autoimmune hemolytic anemia
Inherited defects of plasma membrane structure (spherocytosis, elliptocytosis, stomatocytosis) or cellular size or both (pyknocytosis)	Hemolytic anemia
Infection (bacterial sepsis, congenital syphilis, malaria, cytomegalovirus infection, rubella, toxoplasmosis, disseminated herpes)	Hemolytic anemia
Intrinsic and inherited enzymatic defects (deficiencies of glucose-6-phosphate dehydrogenase [G6PD], pyruvate kinase, 5′-nucleotidase, glucose phosphate isomerase)	Hemolytic anemia
Inherited defects of hemoglobin synthesis	Sickle cell anemia Thalassemia
Disseminated intravascular coagulation (see Chapter 29)	Hemolytic anemia
Galactosemia	Hemolytic anemia
Prolonged or recurrent respiratory or metabolic acidosis	Hemolytic anemia
Blood vessel disorders (cavernous hemangioma, large vessel thrombus, renal artery stenosis, severe coarctation of the aorta) (see Chapter 33)	Hemolytic anemia

DISORDERS OF ERYTHROCYTES

Anemia is the most common blood disorder in children. Like anemia in adults, the anemias of childhood are caused by ineffective erythropoiesis or premature destruction of erythrocytes. The most common cause of insufficient erythropoiesis is iron deficiency, which may result from insufficient dietary intake or chronic loss of iron caused by bleeding. The hemolytic anemias of childhood may be divided into two large categories. The first category consists of disorders that result from premature destruction caused by intrinsic abnormalities of the erythrocytes, and the second category consists of disorders that result from damaging extraerythrocytic factors. The hemolytic anemias are inherited, congenital, or both.

The most dramatic form of acquired congenital hemolytic anemia is **hemolytic disease of the newborn (HDN),** also termed **erythroblastosis fetalis.** HDN is an alloimmune disorder in which maternal blood and fetal blood are antigenically incompatible, causing the mother's immune system to produce antibodies against fetal erythrocytes. Fetal erythrocytes that have been bound to maternal antibodies are recognized as foreign or defective by the fetal mononuclear phagocyte system and are removed from the circulation by phagocytosis, usually in the fetal spleen. (For a complete discussion of HDN, see p. 1059.) Other acquired hemolytic anemias—some of which begin in utero—include those caused by infections or the presence of toxins.

The inherited forms of hemolytic anemia result from intrinsic defects of the child's erythrocytes, any of which can lead to erythrocyte destruction by the mononuclear phagocyte system. Structural defects include abnormal red blood cell size and abnormalities of plasma membrane structure (spherocytosis). Intracellular defects include enzyme deficiencies, the most common of which is G6PD deficiency, and defects of hemoglobin synthesis, which manifest as sickle cell disease or thalassemia, depending on which component of hemoglobin is defective. These and other causes of childhood anemia, some more common than others, are listed in Table 30-2.

Acquired Disorders

Iron Deficiency Anemia

Iron deficiency anemia is the most common blood disorder of infancy and childhood, with the highest incidence occurring between 6 months and 2 years of age. Incidence is not related to gender or race, but socioeconomic factors are important because they affect nutrition, for example, the risk of iron deficiency anemia in children of single, homeless women.[6] However, greater use of iron-fortified products has decreased the prevalence of anemia in low-income infants.[7] Iron deficiency anemia is a common disorder in children because of their extremely high need for iron for normal growth to occur.

Between 4 years of age and the onset of puberty, dietary iron deficiency is uncommon. During adolescence, however, it is relatively common, especially in menstruating females. Rapid growth, together with the average adolescent's dietary habits, causes iron depletion. (Mechanisms of iron depletion are described in Chapter 27.)

PATHOPHYSIOLOGY. Although inadequate intake of iron is the most common cause of iron deficiency anemia during the first few years of life and during adolescence, blood loss is the most common cause in childhood. Chronic iron deficiency anemia from occult (hidden) blood loss may be caused by a gastrointestinal lesion, parasitic infestation, or hemorrhagic disease. Infants and young children who develop severe iron deficiency anemia have chronic intestinal blood loss induced by exposure to a heat-labile protein in cow's milk. Such exposure causes an inflammatory gastrointestinal reaction that damages the mucosa and results in diffuse microhemorrhage.

The amount of iron available for hemoglobin synthesis in the infant depends on maternal iron stores present at birth, rate of growth, the amount of dietary iron absorbed, and physiologic or pathologic loss of iron. During the period of inactive erythropoiesis immediately after birth, iron from erythrocytes that die at the end of their normal life span is stored, as hemosiderin, in bone marrow and liver tissue. This creates an iron reserve that can be used in lieu of dietary intake. The greatest stores are present 4 to 8 weeks after birth. Until erythropoiesis resumes, these iron stores are mobilized. In the premature infant, resumption of erythropoiesis depletes iron stores within 6 to 12 weeks; in the full-term infant, depletion takes longer—about 16 to 20 weeks. Once iron stores have been used, the infant depends on dietary iron.

The amount of dietary iron available for erythropoiesis depends on which foods are consumed. Iron-fortified cereals, green and yellow vegetables, fruits, and milk are common in the average 6-month-old infant's diet and provide iron in the amount of 0.9 to 1.5 mg/kg/day, amounts that satisfy the normal average daily requirement. Iron-fortified formulas are available commercially, and although the amount of iron in breast milk is low, it is easily absorbed.

CLINICAL MANIFESTATIONS. The symptoms of mild anemia—lethargy and listlessness—usually are not present or inconsequential in infants and young children, who are unable to describe these symptoms. Therefore, parents usually do not notice any change in the child's behavior or appearance until moderate anemia has developed. General irritability, decreased activity tolerance, weakness, and lack of interest in play are nonspecific indications of anemia. In mild to moderate iron deficiency anemia (hemoglobin of 6 to 10 g/dl), compensatory mechanisms of tissue oxygenation, such as increased amounts of 2,3-DPG within erythrocytes and a shift of the oxyhemoglobin dissociation curve, may be so effective that few clinical manifestations are apparent. When the hemoglobin falls below 5 g/dl, however, pallor, tachycardia, and systolic murmurs often occur.

Splenomegaly is evident in 10% to 15% of children with iron deficiency anemia, and if the condition is long-standing, the sutures of the skull may be widened. Chronic anemia also may result in decreased physical growth and developmental delays. Some children exhibit pica, a behavior in which nonfood substances are eaten. Weight is not necessarily an indicator of iron deficiency anemia because children may be obese, underweight, or of normal weight.

Iron deficiency anemia may affect neurologic and intellectual function. Decreased iron in the blood may affect attention span, alertness, and learning ability, even when anemia is not severe.

EVALUATION AND TREATMENT. The most definitive test for differentiating iron deficiency from other microcytic anemias is the absence of iron stores in the bone marrow. However, measurement of serum ferritin iron concentration, transferrin saturation, iron-binding capacity, and serum transferrin receptors often is an adequate diagnostic tool and often prevents proceeding to actual bone marrow evaluation. Evaluation and treatment of iron deficiency anemia in children are similar to evaluation and treatment in adults (see Chapter 27). Oral administration of simple ferrous salts usually is satisfactory, and additional vitamin C helps promote absorption.[8] Administration of supplementary trace metals or other vitamins is not necessary. Iron in a liquid form should be administered through a straw because it can stain teeth. If malabsorption is the cause of the anemia (or if oral administration has not been successful), iron dextran is given intravenously. Iron therapy is continued for at least 2 months after erythrocyte indexes have returned to normal in order to replenish iron stores.[9]

Dietary modification is required to prevent recurrences of iron deficiency anemia. Intake of iron-rich foods is increased, and the intake of cow's milk may be restricted, with the exact amount depending on the child's age (from 16 to 32 ounces). Limiting milk intake makes the child hungrier for other iron-rich foods and prevents gastrointestinal blood loss in children whose anemia is aggravated or caused by inflammatory reactions to proteins in cow's milk.

Hemolytic Disease of the Newborn

HDN can occur only if antigens on fetal erythrocytes differ from antigens on maternal erythrocytes. The antigenic properties of erythrocytes are determined genetically: they may be type A, B, or O and may or may not include Rh antigen D. Erythrocytes that express Rh antigen D are Rh-positive; those that do not are Rh-negative. The frequency of Rh negativity is higher in whites (15%) than in blacks (5%), and is rare in Asians. Maternal-fetal incompatibility exists if mother and fetus differ in ABO blood type or if the fetus is Rh-positive and the mother is Rh-negative. (The antigenic properties of erythrocytes are described in Chapter 9.)

ABO incompatibility occurs in about 20% to 25% of all pregnancies, but only 1 in 10 cases of ABO incompatibility results in HDN. Rh incompatibility occurs in less than 10% of pregnancies and rarely causes HDN in the first incompatible fetus. Even after five or more pregnancies, only 5% of women have babies with hemolytic disease. Usually erythrocytes from the first incompatible fetus cause the mother's immune system to produce antibodies that affect the fetuses of subsequent incompatible pregnancies. Only one in three cases of HDN is caused by Rh incompatibility; most cases are caused by ABO incompatibility.

PATHOPHYSIOLOGY. If the mother and fetus have antigenically incompatible erythrocytes, HDN will result if the mother's blood contains preformed antibodies against fetal erythrocytes or produces them on exposure to fetal erythrocytes, if sufficient amounts of antibody (usually immunoglobulin G [IgG]) cross the placenta and enter fetal blood, and if IgG binds with

sufficient numbers of fetal erythrocytes to cause widespread antibody-mediated hemolysis or splenic removal. (Antibody-mediated red blood cell destruction is discussed in Chapter 9.)

IgM antibodies are formed against the ABO antigen that a person does not express, the A antigen if the mother is blood type O or B, or the B antigen if the mother is type O or A. These antibodies are produced early in life against gastrointestinal bacteria that make antigens similar to A and B. IgM antibodies do not cross the placenta or cause HDN. Occasionally a mother with blood type O may have also produced IgG against the A or B antigen. If the fetus is blood group A or B, the ABO incompatibility can cause HDN in the first pregnancy. HDN is usually not severe because A and B antigens are expressed on most cells, including the placenta, and much of the IgG against A or B is absorbed before encountering fetal blood cells.

Anti-Rh antibodies, on the other hand, are formed *only* in response to the presence of incompatible (Rh-positive) erythrocytes in the blood of an Rh-negative mother. Sources of exposure include fetal blood that is mixed with the mother's blood at the time of delivery or transfused blood.

The first Rh-incompatible pregnancy usually presents no difficulties because very few fetal erythrocytes cross the placental barrier during gestation. However, when the placenta detaches at birth, large numbers of fetal erythrocytes usually enter the mother's bloodstream. If the mother is Rh-negative and the fetus is Rh-positive, the mother produces anti-Rh antibodies. The capacity of the mother's immune system to produce anti-Rh antibodies depends on many factors, including her genetic capacity to make antibodies against the Rh antigen D, the amount of fetal-to-maternal bleeding, and the occurrence of any bleeding earlier in the pregnancy. Anti-Rh antibodies persist in the bloodstream for a very long time, and if the next offspring is Rh-positive, the mother's anti-Rh antibodies can enter the fetus's bloodstream and destroy the erythrocytes. Antibodies against Rh antigen D are of the IgG class and easily cross the placenta.

IgG-coated fetal erythrocytes are destroyed through extravascular hemolysis, primarily by mononuclear phagocytes in the spleen. As hemolysis progresses, the fetus becomes anemic. Erythropoiesis accelerates, particularly in the liver and spleen, and immature nucleated cells (erythroblasts) are released into the bloodstream, hence the name *erythroblastosis fetalis* (Figure 30-2). The degree of anemia depends on the length of time the antibody has been in the fetal circulation, antibody concentration, and the ability of the fetus to compensate for increased hemolysis. Unconjugated (indirect) bilirubin, which is formed during breakdown of hemoglobin, is transported across the placental barrier into the maternal circulation and is excreted by the mother. **Hyperbilirubinemia** occurs in the neonate after birth because excretion of lipid-soluble unconjugated bilirubin through the placenta no longer is possible.

The pathophysiologic effects of HDN are more severe in Rh incompatibility than in ABO incompatibility. ABO incompatibility may resolve after birth without life-threatening complications. Maternal-fetal incompatibility in which a mother with type O blood has a child with type A or B blood usually is so mild that it does not require treatment.

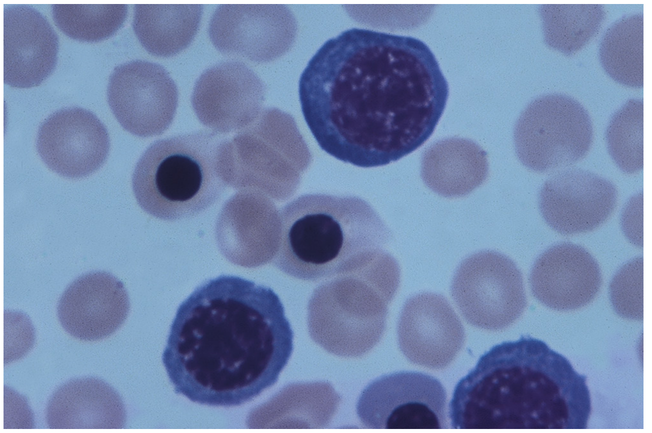

FIGURE 30-2 Rh Incompatibility in Hemolytic Disease of the Newborn. This micrograph shows immature red blood cells not normally found in blood. Large purple cells are erythroblasts; nucleated red blood cells are normoblasts. Normal red blood cells also are shown (× 500). (Copyright Ed Reschke.)

Rh incompatibility is more likely than ABO incompatibility to cause severe or even life-threatening anemia, death in utero, or damage to the central nervous system (CNS). Severe anemia alone can cause death as a result of cardiovascular complications (see Chapter 28). Extensive hemolysis also results in increased levels of unconjugated bilirubin in the circulation. If bilirubin levels exceed the liver's ability to conjugate and excrete bilirubin, some of it is deposited in the brain, causing cellular damage and eventually death, if exchange transfusions are not administered.

Fetuses that do not survive anemia in utero usually are stillborn, exhibiting gross edema throughout the entire body, a condition called **hydrops fetalis.** Death can occur as early as 17 weeks of gestation and results in spontaneous abortion.

CLINICAL MANIFESTATIONS. Neonates with mild HDN may appear healthy or slightly pale, with slight enlargement of the liver and spleen. Pronounced pallor, splenomegaly, and hepatomegaly indicate severe anemia, which predisposes the neonate to cardiovascular failure and shock. Life-threatening Rh incompatibility is rare today, largely because of maternal testing and the routine use of Rh immune globulin.

Because maternal antibodies remain in the neonatal circulation after birth, erythrocyte destruction can continue. This causes hyperbilirubinemia and **icterus neonatorum (neonatal jaundice)** that occurs shortly after birth. Without replacement transfusions, in which the child receives Rh-negative erythrocytes, the bilirubin is deposited in the brain, causing a condition termed **kernicterus.** Kernicterus produces cerebral damage and usually causes death **(icterus gravis neonatorum).** Infants who do not die may have significant developmental delay, cerebral palsy, or high-frequency deafness.

EVALUATION AND TREATMENT. Routine evaluation for HDN includes the Coombs test. The indirect Coombs test measures antibody in the mother's circulation and indicates whether the fetus is at risk for HDN. The direct Coombs test measures antibody already bound to the surfaces of fetal erythrocytes and is used primarily to confirm the diagnosis of antibody-mediated HDN. Determining prior history of fetal hemolytic disease, as well as diagnostic tests, may help predict the severity of the

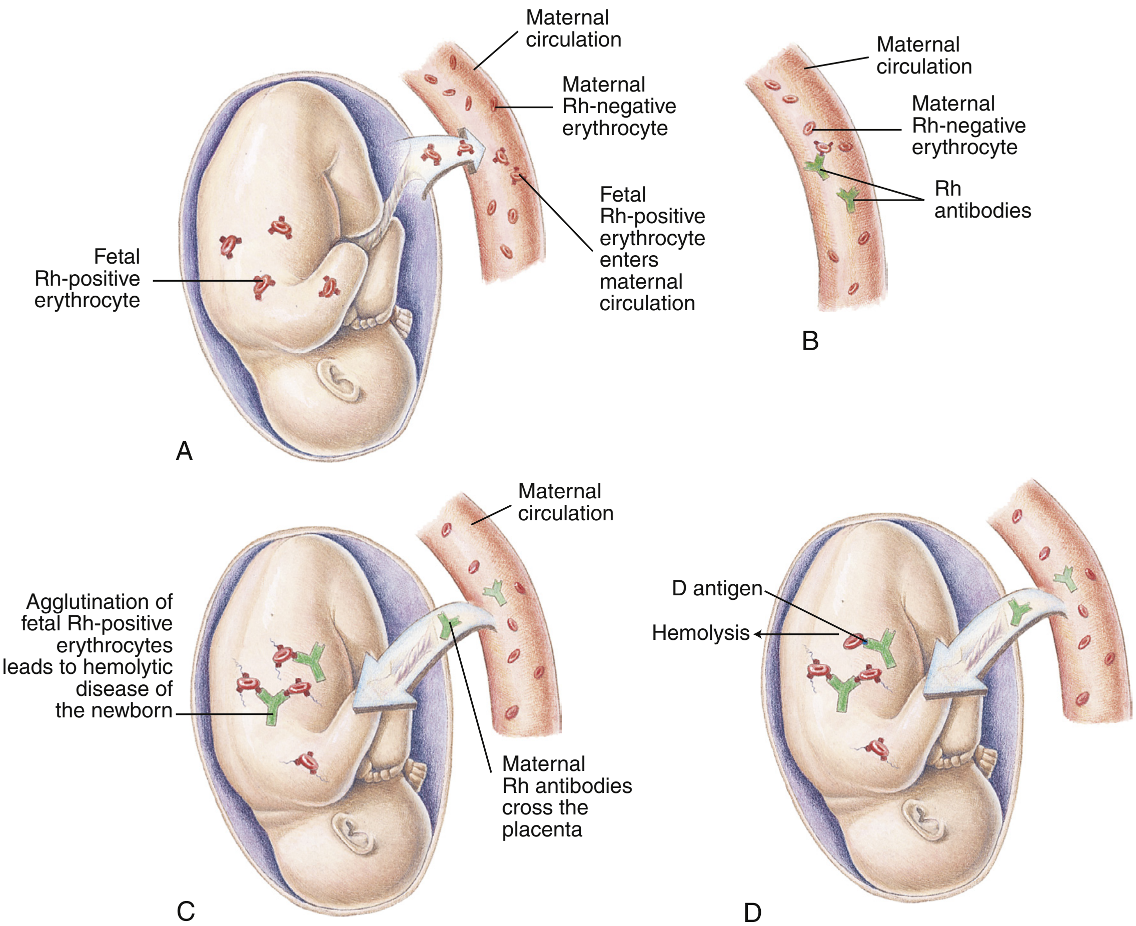

FIGURE 30-3 Hemolytic Disease of the Newborn (HDN). **A**, Before or during delivery, Rh-positive erythrocytes from the fetus enter the blood of an Rh-negative woman through a tear in the placenta. **B**, The mother is sensitized to the Rh antigen and produces Rh antibodies. Because this usually happens after delivery, there is no effect on the fetus in the first pregnancy. **C**, During a subsequent pregnancy with an Rh-positive fetus, Rh-positive erythrocytes cross the placenta, enter the maternal circulation, and **(D)** stimulate the mother to produce antibodies against the Rh antigen. The Rh antibodies from the mother cross the placenta, using agglutination and hemolysis of fetal erythrocytes, and HDN develops. (Modified from Seeley RR, Stephens TD, Tate P: *Anatomy and physiology,* ed 3, St Louis, 1995, Mosby.)

disorder. Diagnostic measures include maternal antibody titers, fetal blood sampling, amniotic fluid spectrophotometry, and ultrasound fetal assessment.[10]

The key to treatment of HDN resulting from Rh incompatibility lies in prevention (immunoprophylaxis). Rh immune globulin (RhoGAM), a preparation of antibody against Rh antigen D administered within 72 hours of exposure to Rh-positive erythrocytes, ensures that the mother will not produce antibody against the D antigen, and the next Rh-positive baby will be protected (Figure 30-3). The injected antibodies remain in the mother's bloodstream long enough to prevent her immune system from producing its own anti-Rh antibodies but not long enough to affect subsequent offspring. The mother must be given Rh immune globulin injections after the birth of each Rh-positive baby and after a miscarriage. The mother must be especially careful not to receive a transfusion containing Rh-positive blood, because this would stimulate production of anti-Rh antibodies. In many hospitals Rh immune globulin is given prophylactically at 28 weeks to all pregnant Rh-negative women with Rh-positive partners. Various international recommendations suggest that antenatal anti-D prophylaxis should be administered to unsensitized Rh(D)-negative women as a complement to postpartum prophylaxis.[11]

If antigenic incompatibility of the mother's erythrocytes is not discovered in time to administer Rh immune globulin and a child is born with HDN, treatment consists of exchange transfusions in which the neonate's blood is replaced with new Rh-positive blood that is not contaminated with anti-Rh antibodies. This treatment is instituted during the first 24 hours of extrauterine life to prevent kernicterus. Phototherapy also is used to reduce the toxic effects of unconjugated bilirubin.

Jaundice and indirect hyperbilirubinemia are reduced when the infant is exposed to high-intensity light in the visible spectrum from 420 to 470 nm. Bilirubin in the skin absorbs light energy, which, by photoisomerization, converts the toxic unconjugated bilirubin into conjugated isomers that are excreted in the bile. Phototherapy also causes autosensitization that results in oxidation reactions. Breakdown products from the oxidation reactions are excreted by the liver and kidney without need for conjugation. The therapeutic effect of phototherapy depends on the light energy emitted in the effective

wavelengths, the distance between the infant and the light source, and the amount of skin exposed; the rate of hemolysis and the infant's ability to excrete bilirubin also are factors in determining the effectiveness of phototherapy in lowering serum bilirubin levels.

Anemia of Infectious Disease

Infections of the newborn, often initially acquired by the mother and transmitted to the fetus, may result in a hemolytic anemia with clinical manifestations similar to those of HDN. Congenital syphilis, toxoplasmosis, cytomegalic inclusion disease, rubella, coxsackievirus B infection, herpesvirus infection, and bacterial sepsis can cause hemolytic anemia in the neonate.

The exact mechanism of anemia caused by congenital infections is unclear. In some instances it is related to direct injury of erythrocyte membranes or erythrocyte precursors by the infectious microorganism. In other instances it results from traumatic destruction of erythrocytes during their passage through inflamed capillaries.

Anemia in Critically ILL Children

Anemia is a common occurrence in critically ill children (see Chapter 49). The causes are numerous and include decreased erythropoietin activity, poor iron use by the body, and blood loss from diverse conditions and consequences of treatment. A topic of discussion is anemia has been shown to worsen patient outcomes presumably because of decreased oxygen delivery. Controversial is whether transfusion of blood products, particularly packed RBCs, improve outcomes because of problems related to blood storage. New research is ongoing and needed to understand these problems, the development of new blood transfusion strategies, and blood substitutes.[11a]

Inherited Disorders

A number of inherited and intrinsic erythrocyte defects are known to cause increased hemolysis (see Table 30-2). These defects may be associated with enzymatic abnormalities that disrupt metabolic processes and prevent normal biochemical balance within the cell, with alterations of hemoglobin structure or synthesis, or with plasma membrane defects accompanied by changes in erythrocyte size or shape.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an inherited, X-linked recessive disorder, most fully expressed in homozygous males, although partial expression and a carrier state are possible in heterozygous females. (X-linked inheritance is discussed in Chapter 4.) The deficiency is present in 10% of blacks and tends to occur in Sephardic Jews, Greeks, Iranians, Chinese, Filipinos, and Indonesians, with a frequency ranging from 5% to 40%.

PATHOPHYSIOLOGY. G6PD is an enzyme that normally enables erythrocytes to maintain metabolic processes despite injury, such as the presence of certain drugs (sulfonamides, antimalarial agents, salicylates, or naphthaquinolones); ingestion of fava beans (a dietary staple in some Mediterranean areas); hypoxemia; infection; fever; or acidosis. Therefore, G6PD deficiency is usually asymptomatic unless one of these events occurs. Erythrocyte damage in affected children begins after intense or prolonged exposure to one of these substances or conditions, and it will cease when they are removed. In black males the G6PD defect becomes more pronounced as the erythrocyte ages and in other populations the defect is profound even in young erythrocytes. By ingesting a substance with oxidant properties, such as a salicylate (aspirin), a pregnant woman may cause an episode of hemolysis in a fetus with G6PD deficiency.

In the absence of G6PD, oxidative stressors damage hemoglobin and the plasma membranes of erythrocytes and possibly interfere with the activities of other enzymes within the cell. Hemoglobin is oxidized progressively to methemoglobin, sulfmethemoglobin, and denatured globin-glutathione complexes. Eventually, exposure to oxidating substances results in the precipitation of insoluble hemoglobin inclusions, called *Heinz bodies*, within the cell. Plasma damage and the presence of Heinz bodies cause hemolysis, primarily in the spleen.

CLINICAL MANIFESTATIONS. In Asian and Mediterranean infants, G6PD deficiency is likely to be associated with icterus neonatorum. The most common clinical manifestation of G6PD deficiency is acute hemolytic anemia, usually after infections or the ingestion of certain oxidative drugs. The fava bean produces a severe hemolytic reaction in infants with G6PD deficiency.

Hemolytic episodes are characterized by pallor, icterus, dark urine, back pain, and, in severe cases, shock, cardiovascular collapse, and death. Between hemolytic episodes, the child does not have anemia and erythrocyte survival is normal.

EVALUATION AND TREATMENT. Reduced G6PD activity in erythrocytes is required for diagnosis. Immediately after a hemolytic episode, reticulocytes and young erythrocytes are evident. Because young erythrocytes have significantly higher enzyme activity than do older cells, laboratory evaluation should be performed shortly after a crisis so that a low level of enzyme activity can be demonstrated. G6PD activity that is within the low normal range in the presence of a high reticulocyte count suggests G6PD deficiency. G6PD deficiency also can be detected by electrophoretic analysis.

Prevention of hemolysis is the most important therapeutic measure. Males from high-risk groups (Greeks, southern Italians, Sephardic Jews, Filipinos, Chinese, Africans, Thais) should be tested for the defect before being given drugs known to be oxidative. When hemolysis occurs supportive treatment may include blood transfusions and oral iron therapy. Spontaneous recovery generally follows treatment.

Hereditary Spherocytosis

Hereditary spherocytosis (HS), also known as *congenital hemolytic anemia* or *congenital acholuric jaundice,* is the most common of the hemolytic disorders in which there is no hemoglobin abnormality.

PATHOPHYSIOLOGY. Transmitted as an autosomal dominant trait, HS represents approximately new mutations in about 25% of cases. The defect is believed to be caused by an undefined abnormality in the erythrocyte membrane. Affected cells are overly permeable to sodium and acquire a particular characteristic structure (Figure 30-4). An increased concentration of

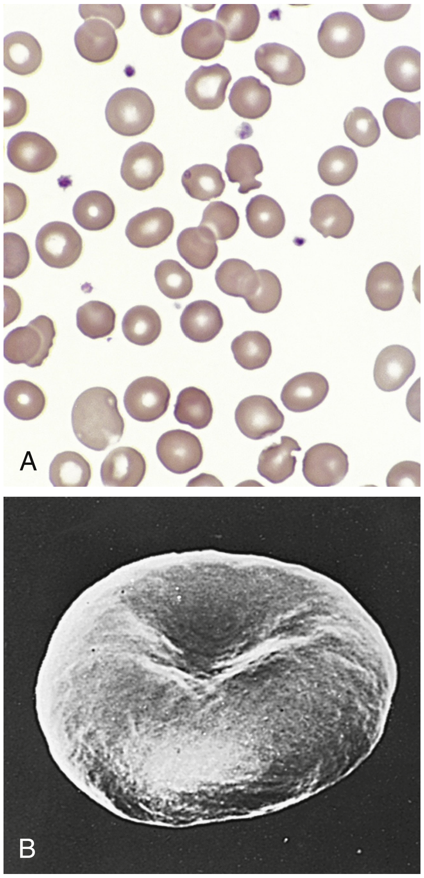

FIGURE 30-4 The Microspherocyte. **A**, Blood smear from individual with hereditary spherocytosis (Wright stain). **B**, Scanning electron micrograph. (**A** from Hoffbrand AV, Pettit JE, Vyas P: *Color atlas of clinical hematology,* ed 4, Philadelphia, 2009, Mosby. **B** courtesy Dr. M. Bessis. intracellular sodium is believed to lead to increased use of adenosine triphosphate (ATP) to drive the so-called cation pump. Early aging or destruction of erythrocytes is believed to result from metabolic overwork and loss of erythrocyte membrane.

The spleen is intimately involved in the hemolytic process. The spherocyte is relatively rigid and passes with difficulty through the small openings between the splenic cords and sinuses. Circulation of blood to the spleen creates repeated circulation through a metabolic environment that results in sequestration and destruction of spherocytes.

CLINICAL MANIFESTATIONS. The presenting signs of HS are anemia, jaundice, and splenomegaly. Anemia may be mild or absent in some cases depending on physiologic compensation. If this is the case the reticulocyte count will be elevated. Splenomegaly is usually mild. HS can present at any age, from the neonatal period until older adulthood. More severe types of HS present during the newborn period when the infant develops signs of hemolytic anemia and hyperbilirubinemia.[12] These children therefore may have life-threatening anemia with clinical symptoms ranging from difficulty feeding, circumoral pallor, tachycardia, nasal flaring, diaphoresis, and lethargy. They also are at increased risk for gallstones because of the presence of extra bile pigment. Infection (specifically parvovirus),[13] fever, and stress stimulate the spleen to destroy more red blood cells than usual, leading to a worsening anemia in an already baseline anemic child.

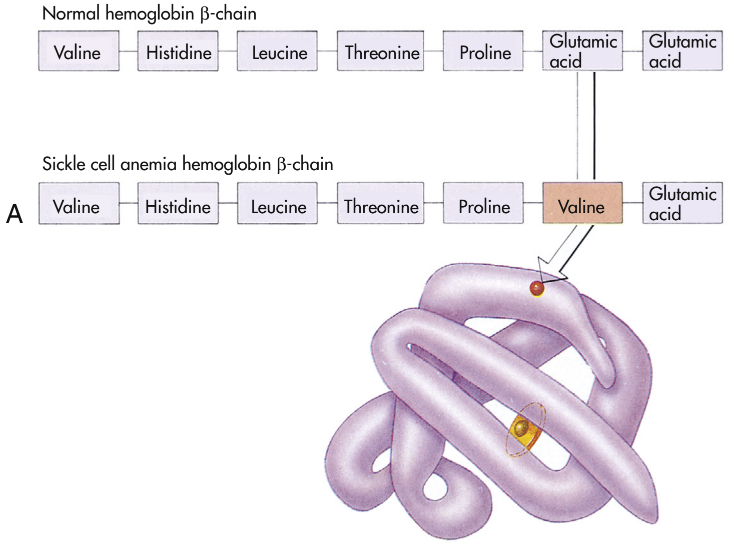
EVALUATION AND TREATMENT. It is important to ascertain family history of spherocytosis. Laboratory findings include spherocytes in the peripheral blood smear, elevated reticulocyte count (with or without anemia), indirect hyperbilirubinemia, and a positive osmotic fragility test. An osmotic fragility test is performed by placing red blood cells in a saline solution for 24 hours. Spherocytes do not tolerate saline solutions, thus causing them to burst more readily than normal red blood cells. Treatment of HS is based on disease severity. Although some children with HS will have severe anemia, blood transfusions are rarely required. Treatment before the age of 5 years consists of daily folic acid supplementation to increase production of healthy red blood cells. In the past, splenectomy was the first line of treatment. Currently, however, splenectomy is only recommended for those children more than 5 years of age with severe disease or those who develop symptomatic gallstones. Partial splenectomy, in which only a portion of the spleen is removed, is being performed on children with HS in an attempt to decrease the risk of postsplenectomy complications.[14]

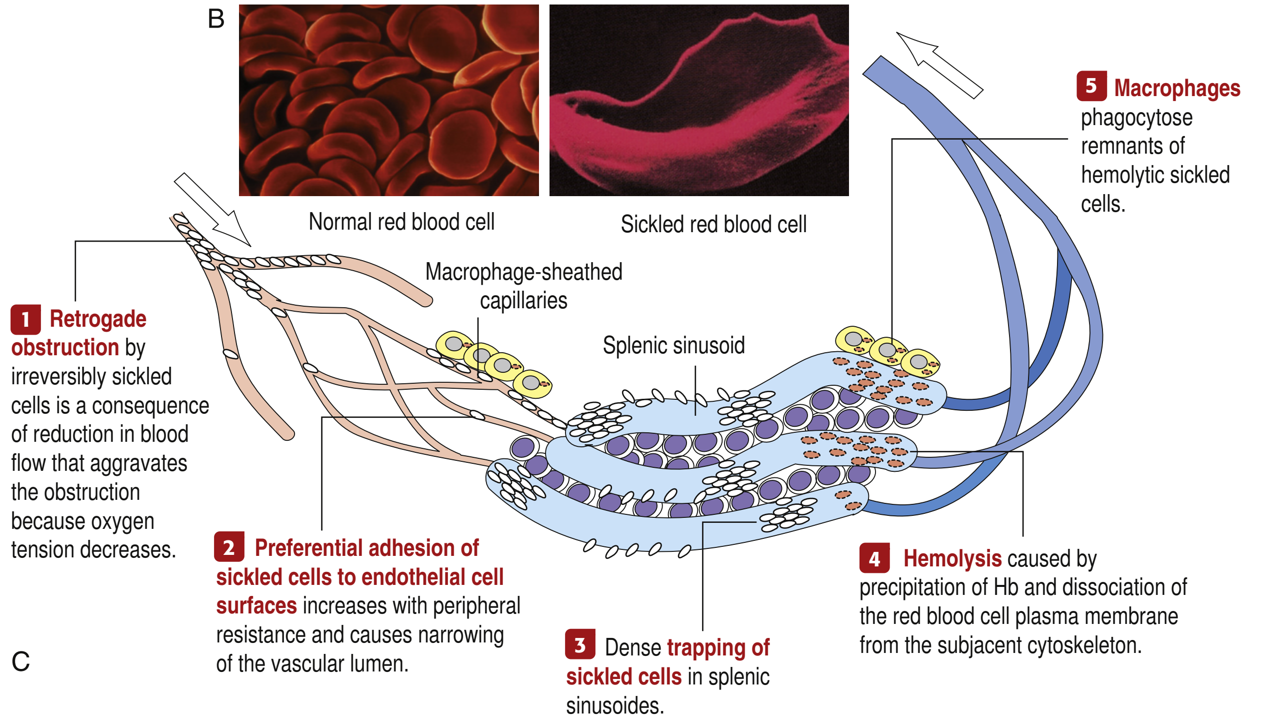
Sickle Cell Disease

Sickle cell disease (SCD) is a group of disorders characterized by the presence of an abnormal form of hemoglobin—**hemoglobin S (HbS)**—within the erythrocytes. Hb S is formed by a genetic mutation in which one amino acid (valine) replaces another (glutamic acid) (Figure 30-5, *A*). Hb S, also known as sickle hemoglobin, reacts to deoxygenation and dehydration by solidifying and stretching the erythrocyte into an elongated sickle shape. This change causes a variety of pathologic consequences, including hemolytic anemia.

SCD is an inherited autosomal recessive disorder that is expressed as sickle cell anemia, sickle cell–thalassemia disease, or sickle cell–Hb C disease, depending on mode of inheritance (Table 30-3). (See Chapter 4 for a discussion of genetic inheritance of disease.) **Sickle cell anemia,** a homozygous form, is the most severe. **Sickle cell–thalassemia disease** and **sickle cell–Hb C disease** are heterozygous forms in which the child simultaneously inherits another type of abnormal hemoglobin from one parent. **Sickle cell trait,** in which the child inherits Hb S from one parent and normal hemoglobin (Hb A) from the other, is a heterozygous carrier state that rarely has clinical manifestations. All forms of SCD are lifelong conditions. Bone marrow or stem cell transplants can cure sickle cell anemia. However, they are currently not an option for most children because it is often difficult to find well-matched stem cell donors.

SCD tends to occur in people with origins in equatorial countries, particularly central Africa, the Near East, the Mediterranean, and parts of India. In the United States, about 1 out of 500 black children and 1:36,000 Hispanic-American born have sickle cell anemia. Most infants with SCD born in the United States are now identified by routine neonatal screening. Sickle cell trait occurs among about 1:12 blacks and 1:100 Hispanic-Americans. It is estimated that 2.5 million Americans are heterozygous carriers for the sickle cell trait.[15] The sickle cell





Sickle cell anemia is determined by the substitution of normal hemoglobin (Hb A) by hemoglobin S (Hb S) caused by a point mutation (replacement of the nucleotide triplet CTC coding glutamic acid at the mRNA level [GAG] by the CAC triplet [GUG] coding for valine) that modifies the physicochemical properties of the β-globin chain of hemoglobin. All hemoglobin is abnormal in homozygous individuals for the mutant gene, and red blood cells show a sickling deformity and hemolytic anemia in the presence or absence of normal oxygen tension. Heterozygous individuals contain a mixture of Hb A and Hb S, and sickling and anemia are observed when the tension of oxygen decreases.

Irreversibly sickled red blood cells are trapped within the splenic sinusoids and are destroyed by adjacent macrophages. Hemolysis may also occur in the macrophage-sheathed capillaries of the red pulp.

FIGURE 30-5 **Sickle Cell Hemoglobin. A,** Sickle cell hemoglobin is produced by a recessive allele of the gene encoding the β-chain of the protein hemoglobin. It represents a single amino acid change—from glutamic acid to valine at the sixth position on the chain. In this model of a hemoglobin molecule, the position of the mutation can be seen near the end of the upper arm. **B,** Color-enhanced electron micrograph shows normal erythrocytes. **C,** Illustration of the characteristic shape of a red blood cell containing the abnormal hemoglobin. (**A** from Raven PH, Johnson GB: *Biology,* ed 3, St Louis, 1992, Mosby. **B** copyright Dennis Kunkel Microscopy, Inc. **C** from Miale JB: *Laboratory medicine: hematology,* ed 6, St Louis, 1982, Mosby.)

TABLE 30-3 INHERITANCE OF SICKLE CELL DISEASE*

HEMOGLOBIN (Hb) INHERITED FROM FIRST PARENT	HEMOGLOBIN INHERITED FROM SECOND PARENT	FORM OF SICKLE CELL DISEASE IN CHILD
Hb S (an abnormal Hb)	Hb S	Sickle cell anemia: homozygous inheritance in which the child's Hb is mostly Hb S, with the remainder fetal hemoglobin (Hb F)
Hb S	Defective or insufficient α- or β-chains of Hb A (alpha- or beta-thalassemia)	Sickle cell: thalassemia disease (heterozygous inheritance of Hb S and alpha- or beta-thalassemia)
Hb S	Hb C or D (both abnormal Hb)	Sickle cell: Hb C (or D) disease (heterozygous inheritance of Hb S and either Hb C or Hb D)
Hb S	Normal Hb (mostly Hb A)	Sickle cell trait, the carrier state (heterozygous inheritance of Hb S and normal Hb)

*See Chapter 27 for a description of normal fetal and adult hemoglobins.

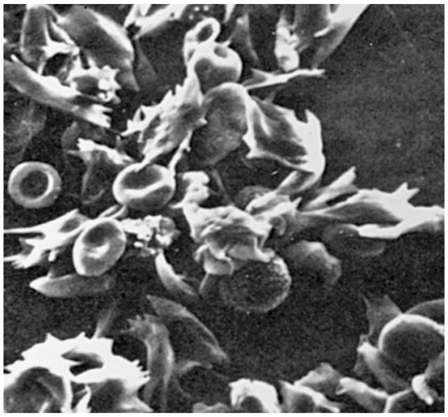


FIGURE 30-6 **Normal and Sickle-Shaped Blood Cells.** Scanning electron micrograph of normal and sickle-shaped red blood cells. The irregularly shaped cells are the sickle cells; the circular cells are the normal blood cells. (From Raven PH, Johnson GB: *Biology,* ed 3, St Louis, 1992, Mosby.)

trait may provide protection against lethal forms of malaria, a genetic advantage to carriers who reside in endemic regions for malaria (Mediterranean and African zones) but no advantage to carriers living in the United States.

PATHOPHYSIOLOGY. Deoxygenation is probably the most important variable in determining the occurrence of sickling. The degree of deoxygenation required to produce sickling varies with the percentage of Hb S in the cells. Sickle trait cells will sickle at oxygen tensions of about 15 mmHg, whereas those from an individual with SCD will begin to sickle at about 40 mmHg. Hb S that is not bound with oxygen forms aggregates of semisolid gel that become stacked within the erythrocyte, stretching it into an elongated crescent (see Figure 30-5, *C;* Figure 30-6). Sickled erythrocytes are stiff and cannot change shape as easily as normal cells when they pass through the microcirculation. (The reversible deformability of erythrocytes is described in Chapter 27.) As a result, sickled erythrocytes tend to plug the blood vessels, causing vascular occlusion, pain, and organ infarction. Sickled cells undergo hemolysis in the spleen or become sequestered there, causing blood pooling and infarction of splenic vessels. The anemia that follows triggers erythropoiesis in the marrow and, in extreme cases, in the liver.[16]

Most sickled erythrocytes regain a normal shape after reoxygenation and rehydration. Irreversible sickling is not caused by irreversible hemoglobin changes but rather by irreversible plasma membrane damage caused by sickling. The precise nature of the permanent membrane injury is not known, but it is known that while in the sickled state, the plasma membrane loses some of its capacity for active transport, permitting an influx of calcium ions. (Membrane transport and the effects of calcium influx are described in Chapters 1 and 2.) In people with sickle cell anemia, in which the erythrocytes contain a high percentage of Hb S (75% to 95%), up to 30% of the erythrocytes can become irreversibly sickled. Occasionally, irreversible sickling occurs in SCD but not in children with sickle cell trait.

Sickling is an occasional, intermittent phenomenon that can be triggered or sustained by one or more of the following stressors: decreased oxygen tension (Po_2) of the blood (i.e., hypoxemia), increased hydrogen ion concentration in the blood (decreased pH), increased plasma osmolality, decreased plasma volume, and low temperature (Figure 30-7).

The same decrease in Po_2 will cause the most sickling in persons with sickle cell anemia (high concentrations of Hb S), the

second most in children with sickle cell thalassemia, the third most in those with sickle cell–Hb C disease, and the least or none in those with sickle cell trait. The duration of the Po_2 decrease also is important, because sickling tends to occur only after the inciting stimulus has been present for some time.

The level of Po_2 in the microcirculation also affects sickling because hemoglobin releases the oxygen it is carrying to tissues. The Po_2 normally is lower in the microcirculation. The added reduction in Po_2 caused by persistent hypoxemia—induced by stressors—eventually results in sickling in the microcirculation of all cells that contain Hb S in that site (not throughout the body). Sickling within the microcirculation decreases blood flow as sickled cells clog the vessels. Reduced blood flow causes hypoxemia to worsen and perpetuates sickling. Finally, decreased blood pH reduces hemoglobin's affinity for oxygen. As less oxygen is taken up by hemoglobin in the lungs, Po_2 drops, promoting additional sickling.

Polymerization of sickle hemoglobin is central to the disorder. **Polymerization** stiffens the sickled erythrocyte, changing it from a flexible, beneficial cell to an inflexible one that starves and damages tissues.

Increased osmolality of the plasma (increased concentration of solutes; see Chapters 1 and 3) draws water out of the erythrocytes. This promotes sickling by raising the relative Hb S content in erythrocytes. Decreased plasma volume, which occurs in states of dehydration, causes the blood to become viscous (thick and sticky). Increased viscosity of the blood is the final common pathway leading to many pathologic effects. Viscous blood flows slowly and promotes vascular obstruction by increasing opportunities for sickling while decreasing opportunities for reoxygenation in the lungs. This is an example of positive feedback in a vicious cycle of events. Low temperatures precipitate sickle crisis, presumably because of vasoconstriction.[17]

Once sickling begins, it tends to continue until Po_2 returns to normal; then it ceases spontaneously. The extent, severity, and clinical manifestations of sickling depend to a great extent on the percentage of hemoglobin that is Hb S. That is why homozygous inheritance of Hb S produces the severest form of SCD—sickle cell anemia. Heterozygous inheritance of SCD results in less sickling because the individual's erythrocytes contain other forms of abnormal hemoglobin that although defective, do not contribute to sickling to any great degree. Heterozygous inheritance (sickle cell trait), in which abnormal hemoglobin is inherited from one parent and normal hemoglobin from the other, rarely results in sickling because normal Hb F and Hb A do not contribute to sickling at all. Anemia persists because Hb F does not live 120 days.

CLINICAL MANIFESTATIONS. Clinical manifestations of SCD may first be seen at 6 to 12 months of age as fetal hemoglobin is replaced by Hb S. Two characteristics of SCD determine presentation: the first is its nature to be a chronic disease with acute exacerbations; the second is that it is a condition affecting RBCs that supply oxygen to all cells of the body. Therefore, SCD can affect any part of the body. When sickling occurs, the general manifestations of hemolytic anemia—pallor, fatigue, jaundice, and irritability—sometimes are accompanied by acute manifestations called *crises*. Extensive sickling can precipitate four types of crises: (1) vaso-occlusive (or thrombotic) crisis, (2) aplastic crisis, (3) sequestration crisis, or rarely (4) hyperhemolytic crisis. Sites of specific dysfunction are shown in Figure 30-8.

Vaso-occlusive crisis (thrombotic crisis) begins with sickling in the microcirculation. As blood flow is obstructed by tangled masses of rigid, sickled cells, vasospasm occurs and a "log jam" effect brings all blood flow through the vessel to a halt. Unless the process is reversed, thrombosis and infarction (death caused by lack of oxygen) of local tissue follow. Vaso-occlusive crisis is extremely painful and may last for days or even weeks, with an average duration of 4 to 6 days. The frequency of this type of crisis is variable and unpredictable.

Vaso-occlusive crises may develop spontaneously or be precipitated by infection, exposure to cold, dehydration, low Po_2, acidosis (low pH), or localized hypoxemia. Symmetric, painful swelling of the hands and feet (hand-foot syndrome) caused by infarction in the small vessels of the extremities often is the initial manifestation of SCD in infancy. In older children and adults the large joints and surrounding tissue become painful and swollen. Priapism (persistent erection of the penis) may occur if penile veins become obstructed. Severe abdominal pains often are caused by infarction in abdominal structures. Strokes resulting from cerebral occlusion may leave the child with paralysis (usually hemiplegia) or other CNS deficits.

Aplastic crisis, a transient cessation in red blood cell production resulting in acute anemia, occurs as a result of a viral infection, almost always infection with parvovirus B19, which is the virus responsible for the common childhood infection known as fifth disease. The virus causes temporary shutdown of RBC production in the bone marrow. However, hemolysis, the destruction of RBCs, continues. The outcome is a severe drop in hemoglobin with an extremely low reticulocyte count.

In **sequestration crisis** large amounts of blood become pooled in the liver and spleen. This type of crisis is seen only in young children. Because the spleen can hold as much as one fifth of the blood supply at one time, mortality rates up to 50% have been reported, with death caused by cardiovascular collapse. If blood volume and pressure are maintained by hydration and blood transfusion, much of the sequestered blood eventually returns to circulation. Removal of the spleen is the treatment for recurrent sequestration crises and may be performed after the child reaches 5 years of age.[18]

Hyperhemolytic crisis, an accelerated rate of RBC destruction, is unusual but may occur in association with certain drugs or infections. It is characterized by anemia, jaundice, and reticulocytosis. The concomitant presence of G6PD deficiency (see p.1062) contributes to hyperhemolytic episodes, especially when combined with infections.

Acute chest syndrome is the presence of a new pulmonary infiltrate (not atelectasis), involving at least one complete lung segment and chest pain, a temperature of more than 38.5° C (101.3° F) increased respiratory rate (tachypnea), wheezing, or cough. Sickled RBCs attach to the endothelium of the injured, underventilated, and inflamed lung and, as they fail to be reoxygenated, will eventually undergo additional inflammation and lung infarction. The prognosis is poor, and infarction is a

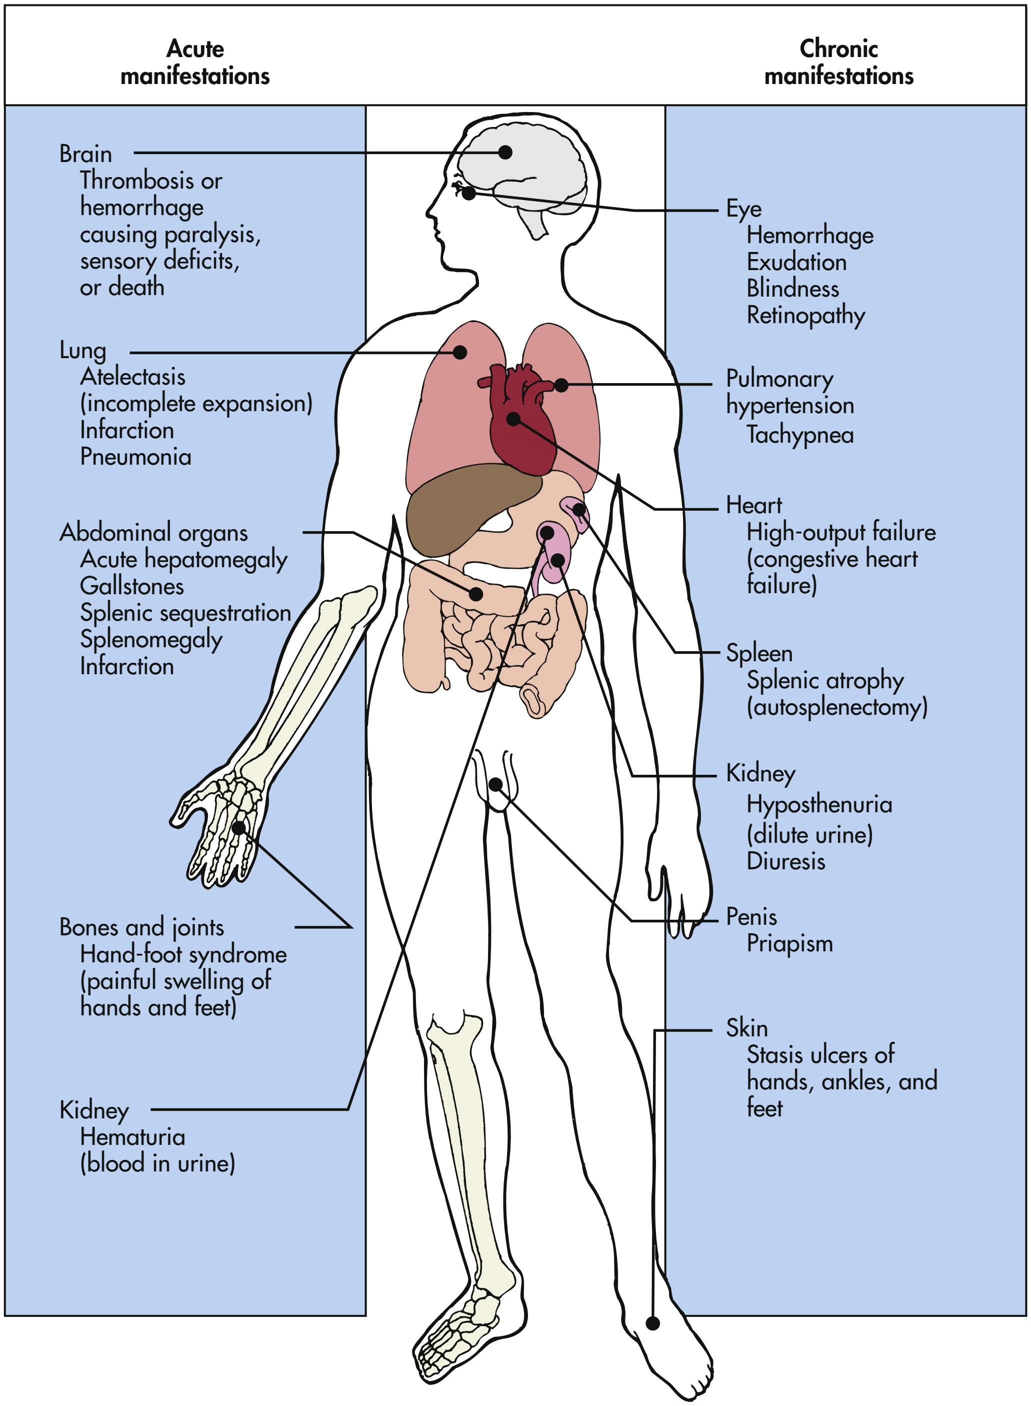

FIGURE 30-8 Clinical Manifestations of Sickle Cell Disease.

leading cause of morbidity. Acute chest syndrome is the cause of death in approximately 25% of all deaths in people with SCD.[19]

Infection is the most common cause of death resulting from SCD. Sepsis and meningitis develop in as many as 10% of children with sickle cell anemia during the first 5 years of life, with a mortality rate of 25%. Survival time is unpredictable, and many young adults die in their 20s.

Glomerular disease, characterized by damage to the glomeruli allowing protein and often red blood cells to leak into the urine, is caused by sickling of red blood cells in the kidneys. Extensive damage to the glomeruli results in nephropathy that may progress to renal failure. The earliest manifestation of SCD in the kidney is hyposthenuria, or the inability of the tubules of the kidneys to concentrate urine. Very low urine specific gravity occurs and in young children this often results in bed-wetting. Proteinuria also is an early manifestation of sickle nephropathy.

Cholecystitis, inflammation of the gallbladder that occurs when a gallstone blocks the cystic duct, can be caused by hemolysis resulting in an increase of bilirubin, which in turn causes the formation of gallstones in the gallbladder. The presence of

gallstones can cause right upper quadrant pain, nausea, vomiting, and an elevated white blood cell count and alkaline phosphatase. Cholecystectomy may be required.

Sickle cell–Hb C disease is usually milder than sickle cell anemia. The peripheral blood smear reveals many target cells resulting from the presence of Hb C. The main clinical problems are related to vaso-occlusive crises and are believed to result from higher hematocrit values and viscosity. In older children, sickle cell retinopathy, renal necrosis, and aseptic necrosis of the femoral heads occur along with obstructive crises.

Sickle cell–thalassemia has the mildest clinical manifestations of all the SCDs. Even though most of the child's hemoglobin is Hb S (60% to 90%), normal hemoglobins (Hb A and Hb F) also are present. The normal hemoglobins, particularly Hb F, inhibit sickling. In addition, the erythrocytes tend to be small (microcytic) and to contain relatively little hemoglobin (hypochromic). Their small size makes them less likely than normal-size cells to clog the microcirculation, even when in a sickled state.

The sickle cell trait does not affect life expectancy or interfere with daily activities. However, on rare occasions, severe hypoxia caused by shock, vigorous exercising at high elevations, flying at high altitudes in unpressurized aircraft, or undergoing anesthesia is associated with vaso-occlusive episodes in individuals with sickle cell trait. These cells form an ivy shape instead of a sickle shape.

EVALUATION AND TREATMENT. The parents' hematologic history and clinical manifestations may suggest that a child has SCD, but hematologic tests are necessary for diagnosis. If the sickle solubility test confirms the presence of Hb S in peripheral blood, hemoglobin electrophoresis provides information about the amount of Hb S in erythrocytes. Prenatal diagnosis can be made by chorionic villus sampling as early as 8 to 10 weeks of gestation or amniotic fluid analysis at 15 weeks of gestation. Newborn screening for SCD should be performed according to state law.

Treatment advances since the late 1980s have significantly decreased morbidity and mortality in children with SCD. Aggressive management of fever, early diagnosis of *acute chest syndrome* (hypoxia, anemia, progressive multilobar pneumonia, fat emboli), red blood cell transfusions, and proper pain management can improve quality of life and prognosis for these children. Treatment of SCD consists of supportive care aimed at preventing consequences of anemia and avoiding crises. Crises can be prevented by avoiding fever, infection, acidosis, dehydration, constricting clothes, and exposure to cold. Immediate correction of acidosis and dehydration with appropriate intravenous fluids is imperative. In addition to routine childhood immunizations, children with SCD should receive an annual influenza vaccine and also pneumococcal and meningococcal vaccine series to prevent infection (Box 30-1). Infections require aggressive antibiotic therapy. Oxygen is not needed unless the child becomes hypoxic. Pain associated with SCD is very complex, requiring accurate assessment and multimodal management.[20]

Protocols to implement individual-controlled analgesia in the emergency department shorten the time of initiation of narcotic therapy and are preferred by individuals.[21] Hydroxyurea increases Hb F synthesis in individuals with sickle cell anemia and increases hemoglobin and mean corpuscular volume while decreasing reticulocytes and bilirubin. It is safe and well tolerated and has been used successfully in children for more than 10 years.[22] To avoid increased acidosis, acetaminophen is preferable to salicylates for antipyretic therapy. Blood transfusion, including hypertransfusion therapy (e.g., packed RBCs to raise the hematocrit to a level of 35% for a period of time), can be effective but must be weighed against the risks of hemosiderosis and iron and splenic overload. Oral maintenance therapy with folic acid is needed to meet the increased demands of chronic hemolytic anemia. Laparoscopic splenectomy has been demonstrated to be safe and effective in children with recurrent sequestration crises and is associated with minimal complications, zero mortality, and a short hospital stay. Partial splenectomy has been recently evaluated and appears to be successful in children (Box 30-2). The most definitive approach to the treatment of SCD requires a permanent alteration in the hemoglobin phenotype. This can be accomplished through stem cell transplantation, although well-matched donors are difficult to identify.

Genetic counseling and psychologic support are important for the child and family. Recently, a genetic technique called **preimplantation genetic diagnosis** has been performed on parents

BOX 30-1 PNEUMOCOCCAL VACCINE FOR SICKLE CELL DISEASE

A systematic review was conducted to determine the efficacy of pneumococcal vaccines in preventing morbidity and mortality in patients with sickle cell disease. Two authors searched the Cochrane Cystic Fibrosis and Genetic Disorders Group Trials Register and critically reviewed and determined the quality of randomized and quasi-experimental trials that compared a polysaccharide or conjugate pneumococcal vaccine to a different regimen or no vaccine. Nine trials including 547 participants were included. Overall results suggest that the vaccine is able to induce an immune response in these patients. Clinical outcomes of effectiveness still need to be determined, but the vaccine is safe to use in children.

Data from Davies EG et al: *Cochrane Database Syst Rev* 2012(2), 2012.

BOX 30-2 DIFFERENT TYPES OF SPLENECTOMY IN CHILDREN WITH CONGENITAL HEMOLYTIC ANEMIAS

The purpose of this study was to evaluate the effectiveness of partial or total splenectomy on hematologic function and adverse events in children with sickle cell disease, hereditary spherocytosis, and thalassemias. The methodology of 93 studies was assessed on the basis of the Agency for Healthcare Research and Quality criteria. No hematologic advantage was determined between the types of splenectomy; however, adverse events were minimized with the use of laparoscopy. Results determined there is a need for additional randomized controlled trials, but both partial and total splenectomy appears to be effective.

Data from Rice HE et al: *J Pediatr* 160:684–689, 2012.

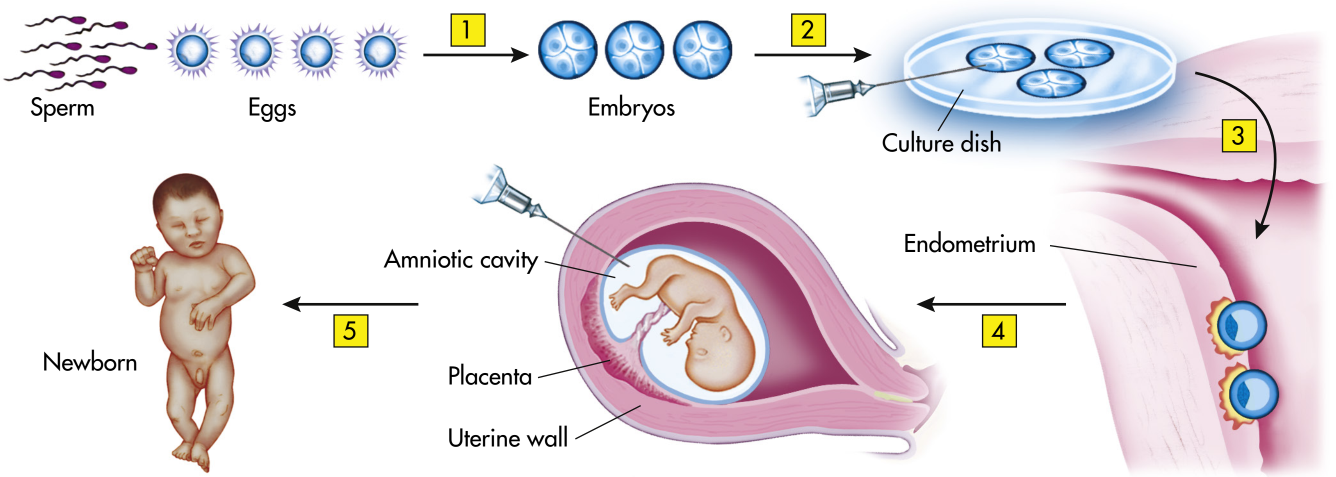

FIGURE 30-9 **Prepregnancy sickle cell test.** (This technique has potential for other inherited diseases.) **1**, Fertilization produces several embryos. **2**, The embryos are tested for the presence of the gene. **3**, The embryo(s) without the gene are implanted. **4**, Amniocentesis confirms whether the fetus (or fetuses) has the sickle cell gene. **5**, Woman has a normal child.

to diagnose whether their offspring will carry the gene for SCD. Figure 30-9 summarizes this prepregnancy sickle cell test. Genetic counseling enables people with SCD or trait to make informed decisions about transmitting this genetic disorder to their offspring because there is a 25% chance with each pregnancy that a child born to two parents with sickle cell trait will have SCD.

Thalassemias

The alpha- and beta-thalassemias are inherited autosomal recessive disorders that cause an impaired rate of synthesis of one of the two chains—α or β—of Hb A. The disorder was named **thalassemia,** which is derived from the Greek word for *sea,* because it was defined initially in people with origins near the Mediterranean Sea. Beta-thalassemia, in which synthesis of the β-globin chain is slowed or defective, is prevalent among Greeks, Italians, and some Arabs and Sephardic Jews. Alpha-thalassemia, in which the α-chain is affected, is most common among Chinese, Vietnamese, Cambodians, and Laotians. Both alpha- and beta-thalassemia are common among blacks.

Alpha- and beta-thalassemia is characterized as major or minor, depending on how many of the genes that control α- or β-chain synthesis are defective and whether the defects are inherited homozygously (thalassemia major) or heterozygously (thalassemia minor). Pathophysiologic effects range from mild microcytosis to death in utero, depending on the number of defective genes and mode of inheritance. Anemia associated with thalassemia is microcytic-hypochromic hemolytic anemia.

PATHOPHYSIOLOGY. Normally two genes control β-chain synthesis and four genes control α-chain synthesis. The number of genetic defects in the controlling genes determines the severity of the disorder. As in SCD the hemoglobin abnormality usually consists of the substitution of a single amino acid for another amino acid. Other molecular abnormalities that cause thalassemia are two amino acid substitutions, amino acid deletions or fusions, and synthesis of elongated chains.

The fundamental defect in beta-thalassemia is the uncoupling of α- and β-chain synthesis. β-Chain production is depressed—moderately in the heterozygous form, **beta-thalassemia minor,** and severely in the homozygous form, **beta-thalassemia major** (also called **Cooley anemia**). Depression of β-chain synthesis results in erythrocytes having a reduced amount of hemoglobin and accumulations of free α-chains. The free α-chains are unstable and easily precipitate in the cell. Most erythroblasts that contain precipitates are destroyed by mononuclear phagocytes in the marrow, resulting in ineffective erythropoiesis and anemia. Some of the precipitate-carrying cells do mature and enter the bloodstream, but they are destroyed prematurely in the spleen, resulting in mild hemolytic anemia.

There are four forms of alpha-thalassemia:

1. **Alpha trait** (the carrier state), in which a single α-chain–forming gene is defective
2. **Alpha-thalassemia minor,** in which two genes are defective
3. **Hemoglobin H disease,** in which three genes are defective
4. **Alpha-thalassemia major,** a fatal condition in which all four alpha-forming genes are defective; death is inevitable because α-chains are absent and oxygen cannot be released to the tissues

Beta-thalassemia occurs more commonly than does alpha-thalassemia. Occasionally synthesis of γ- or δ-polypeptide chains is defective, resulting in gamma- or delta-thalassemia. (Hemoglobin chains are described in Chapter 27.)

CLINICAL MANIFESTATIONS. Beta-thalassemia minor causes mild to moderate microcytic-hypochromic hemolytic anemia, mild splenomegaly, bronze coloring of the skin, and hyperplasia of the bone marrow. The degree of reticulocytosis depends on the severity of the anemia, resulting in skeletal changes. Hemolysis of immature (and therefore fragile) erythrocytes may cause a slight elevation in serum iron and indirect bilirubin levels. Persons with beta-thalassemia minor usually are asymptomatic.

TABLE 30-4 THE COAGULATION FACTORS

CLOTTING FACTORS	SYNONYM	DISORDER
I	Fibrinogen	Congenital deficiency (afibrinogenemia) and dysfunction (dysfibrinogenemia)
II	Prothrombin	Congenital deficiency or dysfunction
V	Labile factor, proaccelerin	Congenital deficiency (parahemophilia)
VII	Stable factor or proconvertin	Congenital deficiency
VIII	Antihemophilic factor (AHF)	Congenital deficiency is hemophilia A (classic hemophilia)
IX	Christmas factor	Congenital deficiency is hemophilia B
X	Stuart-Power factor	Congenital deficiency
XI	Plasma thromboplastin antecedent	Congenital deficiency, sometimes referred to as hemophilia C
XII	Hageman factor	Congenital deficiency is *not* associated with clinical symptoms
XIII	Fibrin-stabilizing factor	Congenital deficiency

Persons with beta-thalassemia major may become quite ill. Anemia is severe and results in a significant cardiovascular burden, with high-output congestive heart failure. In the past, death resulted from cardiac failure. Today, blood transfusions can increase life span by one to two decades, and death usually is caused by hemochromatosis (from transfusions). (Hemosiderosis and hematochromatosis are described in Chapters 27 and 28.) Liver enlargement occurs as a result of progressive hemosiderosis, whereas enlargement of the spleen is caused by extramedullary hematopoiesis and increased destruction of red blood cells. Spinal impairment that starts in infancy retards linear growth and subsequent upper and lower limb-length discrepancy. Bone marrow hyperplasia causes a characteristic deformity of the facial bones, as the nasal bridge, mandible, and maxilla widen. Osteopenia or osteochondrosis, or both, may develop.

People who inherit the mildest form of alpha-thalassemia, the alpha trait, usually are symptom free, having, at most, mild microcytosis. Alpha-thalassemia minor has clinical manifestations that are virtually identical to those of beta-thalassemia minor: mild microcytic-hypochromic reticulocytosis, bone marrow hyperplasia, increased serum iron concentrations, and moderate splenomegaly.

Signs and symptoms of alpha-thalassemia are similar to those of beta-thalassemia major but milder. Moderate microcytic-hypochromic anemia, enlargement of the liver and spleen, and bone marrow hyperplasia are evident.

Alpha-thalassemia major causes hydrops fetalis and fulminant intrauterine congestive heart failure. In addition to edema and massive ascites, the fetus has a grossly enlarged heart and liver. Diagnosis usually is made postmortem. Prenatal screening for this disorder can be performed by use of chorionic villus sampling. These cells can be analyzed, and a deoxyribonucleic acid (DNA) genetic map can be constructed and evaluated for the characteristic abnormalities associated with hydrops fetalis.

Alpha-thalassemia major and beta-thalassemia major are life threatening. Children with thalassemia major generally are weak, fail to thrive, show poor development, and experience cardiovascular compromise with high-output failure caused by anemia. Untreated, they will die by 5 to 6 years of age.

EVALUATION AND TREATMENT. Diagnosis of thalassemia is based on familial disease history, clinical manifestations, and blood tests. Peripheral blood smears show microcytosis and hemoglobin electrophoresis demonstrates diminished amounts of α- or β-chains. Analysis of fetal DNA from withdrawn amniotic fluid is used as a screening test to detect hydrops fetalis (alpha-thalassemia major). Newborn screening for thalassemia should be done according to state law.

"Silent" carriers or those who have thalassemia minor generally have few if any symptoms and require no specific treatment. Therapies to support and prolong life are necessary, however, for thalassemia major. Prenatal diagnosis and genetic counseling may be the most important therapeutic measures offered.

At present, thalassemia major is treated with the following therapies:

1. Blood transfusions, which can return hemoglobin and hematocrit levels to normal thus alleviating the anemia-induced cardiac failure; iron overload and hemochromatosis are complications of transfusion therapy
2. Iron chelation therapy in combination with hypertransfusion (transfusion to a hematocrit of 35 ml/dl)
3. Splenectomy, which can reduce the need for transfusions by eliminating the site of hemolysis, thus prolonging erythrocyte survival
4. Bone marrow, cord blood, and stem cell transplantation is currently the only cure for thalassemia

DISORDERS OF COAGULATION AND PLATELETS

Inherited Hemorrhagic Disease

Hemophilias

Awareness of a serious bleeding disorder in males was documented nearly 2000 years ago in the Babylonian Talmud, which exempted from the rite of circumcision those boys having male relatives prone to excessive bleeding. In 1803 the first description of this disorder appeared in the medical literature, where it was noted to be X linked and associated with joint bleeding and crippling.

Table 30-4 lists the coagulation factors. Until 1952 the term *hemophilia* was reserved for deficiency of factor VIII (antihemophilic factor). Since then two additional coagulation proteins, factor IX (plasma thromboplastin component [PTC]) and factor XI (plasma thromboplastin antecedent [PTA]), have been identified and their deficiency associated with similar clinical manifestations. Congenital deficiencies of these three plasma clotting factors—VIII, IX, XI—account for 90% to 95% of the hemorrhagic bleeding disorders collectively called *hemophilia.*

Types of Hemophilia. **Hemophilia A (classic hemophilia)** is caused by factor VIII deficiency and occurs in 1 in 5000 male births.[23] It is the most common of the hemophilias—80% to 85% of those with hemophilia have hemophilia A. It is inherited as an X-linked recessive disorder that affects men and is transmitted by women.

Hemophilia B (Christmas disease), caused by factor IX deficiency, also is transmitted as an X-linked recessive trait and is clinically indistinguishable from factor VIII deficiency. It occurs in 1:25,000 male births.[23] Hemophilia A and hemophilia B occur with varying degrees of clinical severity, depending on concentrations of clotting factor VIII or IX in the blood. Severe hemophilia (concentration of clotting factors less than 1% of normal) is associated with spontaneous bleeding. In moderate hemophilia (1% to 5% of normal), bleeding usually occurs only after trauma; in the mild form (5% to 35% of normal), bleeding occurs only after severe trauma or surgery. The severity of hemophilia is similar in all affected members of a family.

Hemophilia C (factor XI deficiency) occurs as an autosomal recessive disease and occurs equally in men and women. Bleeding usually is less severe than in hemophilia A or B.

von Willebrand disease results from an inherited autosomal dominant trait with variable clinical manifestations and hematologic findings. The factor VIII deficiency differs from that of hemophilia A in mode of inheritance and response to treatment. In hemophilia A the deficiency is inherited as an X-linked recessive trait, whereas in von Willebrand disease, it is inherited as an autosomal dominant trait. The most important difference, however, is in responses to the infusion of plasma. In von Willebrand disease, infusion of plasma causes factor VIII activity to increase for several days because infusion of factor VIII temporarily induces endogenous synthesis of factor VIII.

PATHOPHYSIOLOGY. Two types of defects dominate the hereditary defects of hemophilia to date: gene deletions and point mutations. Both types of genetic defects are associated with severe hemophilia A, in which no factor VIII circulates in the blood. Many different gene deletion mutations are associated with factor VIII and factor IX disease. The molecular defect that leads to the deletional mutation is identical among members of a given family.[24]

Point mutations, in which a single base in the DNA is mutated to another base, represent a second type of mutation that causes hemophilia. When a point mutation gives rise to a de novo stop codon (nonsense mutation), translation of the protein ceases and a shortened version of the protein is synthesized. Usually the protein is destroyed intracellularly and never reaches the plasma. This type of defect is associated with severe hemophilia, that is, with coagulant activity levels below 1%. Point mutations in which one amino acid is substituted for another can cause phenotypes of varying severity. The mutation of an important amino acid can destroy protein function, activation, or folding; inhibit intracellular processing; or cause protein clearance.[25] Unlike deletional mutations, point mutations at the same site have been recorded in different families with hemophilia.

Table 30-4 summarizes the types of coagulation disorders. Not all the disorders are discussed in this chapter because some are extremely rare (congenital dysfibrinogenemias) and others have no clinical significance (e.g., Hageman factor deficiency, a condition in which profound laboratory deficiency of factor XII is associated with absolutely no clinical defects).

CLINICAL MANIFESTATIONS. Children with severe hemophilia start to bleed at different ages. Although there is no transfer of maternal clotting factor to the fetus, many boys with hemophilia are circumcised without excessive bleeding. Normal hemostasis is achieved in these infants because clotting is activated through the extrinsic coagulation cascade, which does not involve factors VII, IX, or XI.

During the first year of life spontaneous bleeding often is minimal, but hematoma formation may result from immunizations and from firm holding (e.g., under the arms). Many children are diagnosed around the time they become mobile (i.e., crawling, pulling to stand) and become easily injured (i.e., increased bruising, swelling, redness at joints, mouth bleeding). By 3 to 4 years of age, 90% of children with hemophilia have had episodes of persistent bleeding from relatively minor traumatic lacerations (e.g., to the lip or tongue). This usually is the first clinical manifestation of hemophilia. Hemorrhage into the elbows, knees, and ankles causes pain, limited joint mobility, and predisposes the child to degenerative joint changes. Spontaneous hematuria and epistaxis are troublesome but minor complications.

Recurrent bleeding—spontaneous and after minor trauma—is a lifelong problem. Many affected individuals experience cycles of spontaneous bleeding episodes. Mechanisms that cause this phenomenon are unknown. Intracranial hemorrhage and bleeding into the neck or abdomen are rare but constitute life-threatening emergencies.

EVALUATION AND TREATMENT. Although laboratory tests are of primary value in the diagnosis of hemorrhagic disorders, the history and physical assessment also should be given careful consideration. The three phases of coagulation are assessed individually by simple, reliable tests. In any hemorrhagic condition, the adequacy of phase III should be determined first. Unless adequate fibrinogen is present, the blood is incapable of coagulation; thus other laboratory tests that require formation of a visible clot will be invalid. Phase III can be evaluated by the **thrombin time,** the time required for plasma to clot after the addition of bovine thrombin. Fibrinogen can be measured by chemical or immunologic methods.

Phase II is assessed by the **prothrombin time (PT),** the time required for plasma to clot after the addition of thromboplastin and calcium. If phase III is intact, a prolonged prothrombin time indicates a deficiency involving factors II, V, VII, or X, alone or in combination. Specific assays for each of the factors are available.

Phase I, the most complex part of coagulation, is evaluated by several tests. The **activated partial thromboplastin time (aPTT)** is the time required for clotting of plasma that has been activated by incubation with kaolin when calcium and platelets (or partial thromboplastin) are added. aPTT assesses the adequacy of factors XII, XI, IX, and VII. The **prothrombin consumption time** is a standard prothrombin test of serum instead of plasma. Because prothrombin is used up during coagulation,

the serum normally contains little prothrombin and the serum prothrombin time is prolonged. Deficiencies of the phase I factors are associated with poor use of prothrombin. If the serum and plasma prothrombin times are similar, deficiency of a phase I factor is likely. The **thromboplastin generation test** is the most sensitive of all phase I tests. The test can precisely identify deficiencies of factors VIII and IX. If the aPTT, prothrombin consumption, or thromboplastin generation test results are abnormal, the way in which they can be corrected identifies the specific deficiency.

The treatment of hemophilia has changed markedly since the early 1920s. Plasma first was used in the 1920s, and by the 1940s it was used routinely to treat persons with hemophilia. The disadvantages of fresh frozen plasma (FFP), which is low in factor VIII per volume of plasma, led to the development of cryoprecipitate. In 1964 cryoprecipitate (quick-frozen precipitate), which is rich in factor VIII per volume, was used to treat individuals with hemophilia. Although cryoprecipitate advanced the treatment of hemophilia A, it had several disadvantages. The most notable complication was the possibility of transmission of viral diseases, including hepatitis B and C and human immunodeficiency virus (HIV). Factor VIII concentrates were first introduced in 1965. In addition to the predictable factor VIII content, other advantages of the early factor VIII concentrates included greater purity than cryoprecipitate and less contamination with other plasma proteins. The development of recombinant factor VIII resulted in new factor VIII products that minimize the risk of transmission of viral infection (e.g., HIV and hepatitis) and are potentially less expensive than plasma-derived factor VIII.

Recombinant antihemolytic factor plasma/albumin-free method (rAHF-PFM, Advate) is a product used for the prevention and control of bleeding episodes in individuals with hemophilia A, and in the perioperative management of those with hemophilia A. By excluding proteins or raw materials derived from human or animal sources in the final product, the risk of transmission of potentially infectious agents is removed.[26]

Primary prophylaxis consists of regular infusions of factor VIII or IX with the goal of preventing joint bleeding. It is usually given to children with severe hemophilia. A 5-year, multicenter trial found prophylaxis initiated in children between 6 and 30 months of age to be effective in the prevention of joint bleeding, structural joint damage, and frequency of bleeding in boys with factor VIII deficiency.[27]

Congenital Hypercoagulability and Thrombosis

Hereditary bleeding disorders, such as hemophilia, have been recognized and treated for centuries; however, the counterpart of these disorders, **thrombophilia,** has not been recognized until very recently. The inherited thrombophilic conditions generally are caused by defects in the clotting factors that inhibit clot formation; thus the balance between bleeding and clotting is directed toward the clotting aspects of hemostasis. Defects in specific proteins (C and S) and antithrombin (AT), as well as resistance to activated protein C (APC) and hyperhomocystinemia, are the major recognized causes of inherited thrombophilia.

Both proteins C and S are inhibitors of coagulation and depend on vitamin K for synthesis in the hepatocytes of the liver. Decreased levels of either of these proteins interfere with the normal homeostatic balance of procoagulant and anticoagulant activity at the endothelial level. Protein C and S deficiency states predispose affected individuals to thrombosis, especially venous thrombosis of the lower extremities.

Inheritance of **protein C deficiency** is autosomal dominant. Heterozygotes have protein C levels 50% to 60% of normal and may develop superficial thrombophlebitis, deep venous thrombosis, or pulmonary embolism in their late teens and early 20s. The majority of these thrombotic events (75%) occur spontaneously, whereas only 25% are the result of predisposing conditions.[28] Homozygotes have less than 1% of normal levels of protein C and tend to develop thrombosis of the cutaneous vessels with large areas of skin necrosis. It is rare for individuals with protein C deficiency to develop arterial thrombosis.

Protein C deficiency exists in two forms: types I and II. Type I, the more common form, involves a reduction in both biologic and immunologic activity of protein C. Type I is caused by deletion of the entire gene. In type II, the less common form, there is a normal level of protein C antigen but decreased functional levels of activity.

Neonatal purpura fulminans is a fatal syndrome found in neonates who are homozygous or double heterozygous for types I and II protein deficiency. Ecchymosis becomes apparent on the first day of life and develops around the head, trunk, and extremities and often is accompanied by cerebral thrombosis and infarction. The ecchymotic areas often coalesce, and ulceration and necrosis develop. Treatment includes administration of FFP and heparinization, although the infant rarely survives.

Heparin is the treatment for acute episodes of thrombosis caused by protein C deficiency. Long-term therapy is required and consists of either oral warfarin sodium (Coumadin) or subcutaneous heparin. Supplemental protein C concentrates (human) are also available and have been approved for use in children.[29]

Protein S deficiency is similar to protein C deficiency, and the inheritance pattern (autosomal dominant) is also similar. Heterozygotes demonstrate a strong tendency for deep venous thrombosis, with the first incidence often occurring before age 25 years. Other manifestations include superficial thrombophlebitis and pulmonary emboli. There are predisposing conditions for thrombi development in some cases, with evidence of spontaneous thrombi development in most cases.

Protein S deficiency exists in two forms: type I and type II. Type I is identified as a quantitative deficiency and manifests as low levels of protein S antigen and activity, and type II is identified as a qualitative deficiency with low levels of free protein S and normal levels of free and total protein S antigen.[25]

Homozygotes demonstrate severe manifestations of the condition and may develop a form of purpura fulminans in the neonatal period. It also is possible that the homozygous state may lead to uterine death. Treatment with heparin, warfarin (Coumadin), and protein C concentrate is similar to that of protein C deficiency.

Antithrombin III (AT III) deficiency is inherited as an autosomal dominant condition—the heterozygous state is the most common. AT III also exists in two forms, type I and type II, with type I being a quantitative deficiency of the AT III antigen. Type II is characterized as a dysfunctional form: normal levels of AT III are present but with reduced activity.

Individuals with AT III deficiency are at risk for early development of venous thrombosis and pulmonary embolism. These events often occur in the middle to late teens, and can occur as early as 10 years of age. The deep veins of the lower extremities are usually involved, most commonly the iliofemoral vein. Other sites include the mesenteric veins, vena cava, renal veins, and retinal veins. Cerebral thromboses also have been described, and arterial thrombotic events are rare. In some cases thrombosis is precipitated by surgery, trauma, pregnancy, oral contraceptives, and infection.

The treatment of choice for AT III deficiency is heparin. Antiplatelet agents (e.g., aspirin, dipyridamole) may be used, as well as AT III concentrates.

Antibody-Mediated Hemorrhagic Disease

The antibody-mediated hemorrhagic diseases are a group of disorders caused by the immune response. Antibody-mediated destruction of platelets or antibody-mediated inflammatory reactions to allergens damage blood vessels and cause seepage into tissues. The thrombocytopenic purpuras may be intrinsic or idiopathic, or they may be transient phenomena transmitted from mother to fetus. The inflammatory, or "allergic," purpuras occur in response to allergens in the blood. All these disorders first appear during infancy or childhood.

Idiopathic Thrombocytopenic Purpura

Acute **idiopathic thrombocytopenic purpura (ITP)** (**autoimmune** or **primary thrombocytopenic purpura**) is the most common of the thrombocytopenic purpuras of childhood. It is a disorder of platelet consumption in which antiplatelet antibodies bind to the plasma membranes of platelets, causing platelet sequestration and destruction by mononuclear phagocytes in the spleen and other lymphoid tissues at a rate that exceeds the ability of the bone marrow to produce them.

PATHOPHYSIOLOGY. Platelets have several tissue-specific antigens on their plasma markers that may be targets for antiplatelet antibody. In approximately 70% of cases of ITP, there is an antecedent viral disease (e.g., cytomegalovirus [CMV], Epstein-Barr virus [EBV], HIV, parvovirus, or viral respiratory infection), suggesting that viral sensitization has occurred. The interval between infection and onset of purpura is 1 to 4 weeks. A comparison with purpura seen in adults has identified an immune mechanism as the basis for ITP. High levels of IgG have been found bound to platelets and may represent immune complexes on the platelet surface.[30]

CLINICAL MANIFESTATIONS. One to 4 weeks after a viral infection, bruising and a generalized petechial rash often occur with acute onset. Asymmetric bleeding is typical and is found most often on the legs and trunk. Hemorrhagic bullae of the gums, lips, and other mucous membranes may be prominent. Epistaxis (nosebleed) may be severe and difficult to control. Except for the signs of bleeding, the child appears well. The acute phase of the disease associated with spontaneous hemorrhages lasts 1 to 2 weeks, but thrombocytopenia often persists. Intracranial hemorrhage is the most serious complication of ITP, although the incidence is less than 1%. In some cases the onset is more gradual and clinical manifestations consist of moderate bruising and scattered petechiae.

EVALUATION AND TREATMENT. Laboratory examination reveals a reduced platelet count, and the few platelets observed on a peripheral blood smear are large in size, reflecting increased bone marrow production. Bone marrow aspiration reveals megakaryocytes in normal or increased numbers and normal erythrocytes and granulocytes. The use of bleeding time for diagnosis is not recommended because the results are often confounded by a child who is crying or moving, the depth and direction of the cut, and the device used.

Even without treatment the prognosis for children with ITP is excellent—75% recover completely within 3 months. After the initial acute phase spontaneous clinical manifestations subside. By 6 months after onset, 80% to 90% of affected children have regained normal platelet counts.[27]

Because of the short life span of platelets (10 days), fresh blood or platelet transfusions are only a transient benefit; however, their use is indicated when life-threatening hemorrhage occurs. Corticosteroid therapy reduces the severity and shortens the duration of the initial phase by suppressing the immune attack on platelets. Recent evidence indicates that the use of high-dose methylprednisolone increases bone resorption and may cause osteonecrosis in children with ITP.[28] Intravenous IgG has been demonstrated to increase the platelet count in some children with ITP, but it is quite costly. Anti-D, is a gamma globulin fraction containing a high proportion of antibodies to the Rh_o(D) antigen of the RBCs. Intravenous anti-D is a safe and effective treatment for Rh-positive, nonsplenectomized individuals with ITP. It is an effective treatment for Rh-positive nonsplenectomized children with ITP, although it is associated with side effects including chills, fever, headache, and a decrease in hemoglobin levels. Administration of steroids and antipyretics prior to the anti-D treatment may prevent side effects. Rituximab, a chimeric monoclonal antibody against the protein CD20, has been tested in children with ITP and demonstrated an overall response rate of 69% (see What's New? Clinical Trials of TPO Receptor Agonists for Treatment of Idiopathic Thrombocytopenic Purpura [ITP]). Only mild and self-limited side effects were observed in 18%, and no major infections or long-term toxicities were reported.[31]

WHAT'S NEW?

Clinical Trials of Thrombopoietin (TPO) Receptor Agonists for Treatment of Idiopathic Thrombocytopenic Purpura (ITP)

Rituximab, a chimeric monoclonal antibody against the protein CD20, has been tested in children with ITP. Long-term follow-up at 39.5 months of 49 children with ITP who were treated with rituximab demonstrated an overall response rate of 69%: 21 children had platelet counts of greater than 50,000/mm^3 at 20 months' post-treatment. Only mild and self-limited side effects were observed in 18%, and no major infections or long-term toxicities were reported.

Data from Parodi E et al: *Br J Haematol* 144(14):552–558, 2009.

Parents should be instructed to discourage activities that might cause trauma that could result in bleeding (e.g., contact sports, skateboarding, skiing, bicycle riding). Splenectomy should be reserved for chronic cases that fail to respond to nonsurgical intervention.

Autoimmune Neonatal Thrombocytopenias

Antibody-mediated thrombocytopenic purpura occurs in neonates in either autoimmune or alloimmune form. Both forms are characterized by the immunologic destruction of platelets by antibodies (IgG) against tissue-specific antigens expressed by the platelets (i.e., platelet-specific antigens).

Autoimmune neonatal thrombocytopenia was first noted in the early 1950s, when it was observed that mothers with ITP often delivered infants who were transiently thrombocytopenic. Neonatal thrombocytopenia was observed in approximately 50% of infants at risk and lasted an average of 1 month. As platelet counts returned to normal, a concomitant drop in the level of maternal antiplatelet antibody on the child's platelets occurred. The antibody is directed against antigens common to maternal and neonatal platelets. The prognosis generally is favorable and the frequency of intracranial hemorrhage is rare (1% to 3% of cases). Medical management of affected infants is to prevent the severe thrombocytopenia that can cause significant morbidity by administering intravenous immunoglobulins.

Neonatal alloimmune thrombocytopenic purpura (NATP) is less common, estimated to occur in 1 to 2 per 1000 live births. NATP is caused by maternal immunization against fetal paternally derived platelet-specific antigens (similar to rhesus [Rh] disease). The mother has a normal platelet count, while the fetus can be severely thrombocytopenic.

The diagnosis of NATP is confirmed by detection in the maternal serum of antibody that reacts with platelets from the infant and father but not with platelets from the mother. In approximately 75% to 85% of cases, NATP recurs in subsequent pregnancies. Purpura usually develops in the affected infant shortly after delivery, and intracranial, renal, and gastrointestinal hemorrhages are possible. The mortality rate from intracranial hemorrhage has been estimated at 10% to 15%. Management of the newborn with NATP includes an immediate cranial ultrasound because of the significant risk of intracranial hemorrhage. Severely thrombocytopenic newborns (<10,000/μL) or newborns with intracranial or visceral hemorrhages should receive a matched platelet transfusion (maternal or homozygous human platelet antigen 1b [HPA-1b] donor) as soon as possible. If maternal platelets are used, they must be processed to remove platelet alloantibodies. Newborn thrombocytopenia is difficult to predict because newborn platelet counts do not correlate with maternal platelet counts or antiplatelet antibody titers.[32]

Most of the life-threatening clinical manifestations of transient neonatal thrombocytopenia and NATP can be avoided through cesarean delivery. If the mother has antiplatelet disease, however, surgery can result in hemorrhage and serious maternal morbidity. Maternal morbidity resulting from NATP during pregnancy is low (less than 5%): the principal maternal risk is bleeding from surgical incisions during cesarean delivery. The incidence of transient thrombocytopenia in infants born to mothers with NATP is about 50%. If all deliveries were cesarean, half the mothers would undergo cesarean delivery unnecessarily. Conversely, if all deliveries were vaginal, half the infants—those with thrombocytopenia—would be at risk for intracranial bleeding. Therefore, in the absence of any clear benefit to the neonate (given the low rate of intracranial hemorrhage in infants born to mothers with ITP), cesarean delivery should be reserved for the usual obstetric indications.

Autoimmune Vascular Purpura

Autoimmune vascular purpura (allergic purpura) is caused by antibody-mediated injury of blood vessel walls, typically arterioles and capillaries. The inflammatory reaction is to foreign proteins or chemicals in the blood (microorganisms, drugs, or other chemicals).

Autoimmune vascular purpura usually is seen in young children, with the incidence decreasing in adolescents and adults and occurring only rarely in older adults. The average age at onset is 5 years, with a slightly higher proportion of males affected. Purpura occurs as vessel integrity is disrupted by inflammatory processes, causing effusion of serosanguineous exudate to perivascular tissues.

Clinical manifestations include headache, anorexia, fever, abdominal pain, constipation, arthralgias and urticaria, and erythema that are located symmetrically on the proximal portions of the extremities, particularly on the legs and buttocks, and may be accompanied by itching or paresthesias. Abdominal pain results from hemorrhage into the bowel, which may lead to colic, nausea, and vomiting. These symptoms may precede the appearance of skin lesions. The pain usually is midabdominal but may radiate to other parts of the abdomen. Joint pain and tenderness may be present, but hemarthrosis does not occur. Periarticular swelling and edema of the hands and feet are common and may precede the onset of abdominal pain and purpura. Subacute glomerulonephritis occurs in some cases but usually is reversible.

The characteristic skin lesions (purpura and cutaneous manifestations of allergy), accompanied by a history of joint and abdominal pain, are suspicious for diagnosis. Laboratory test results often reveal no major abnormalities. Attacks may last several weeks and may recur at odd intervals and with changing manifestations with each episode. Treatment, if necessary, consists of symptom management.

LEUKEMIA AND LYMPHOMA

Leukemia, the most common malignancy of childhood, represents approximately 40% of all childhood cancers. Childhood lymphoma is the third most common malignant neoplasm of children in the United States, representing approximately 11% of all childhood cancers. (See Chapter 29 for a discussion of leukemia in adults.)

Leukemia

Of the varieties of childhood leukemia, 75% to 80% of leukemias in children are acute lymphocytic leukemia (ALL) or acute undifferentiated leukemia (AUL). The remaining 20% to 25% are acute nonlymphocytic leukemias (ANLLs) (which include

myeloblastic, promyelocytic, monocytic, and myelomonoblastic leukemias) and the very rare red blood cell leukemia, erythroleukemia. Because the vast majority of ANLLs involve the myeloblastic cell, many experts refer to the disease as *acute myelogenous leukemia (AML)*. Leukemia accounts for 25% of cases of cancer in black children and 34% of cases of cancer in white children. Approximately 4100 new cases are diagnosed each year in the United States.[33]

The peak incidence for childhood ALL is between 2 and 6 years of age. ALL affects more white and Hispanic than black children and more males than females. Male predominance is greater in T-cell disease. Incidence of ALL is higher in Western and industrialized nations.[33]

Types of Leukemia

A number of different classifications are used for the leukemias. First, acute leukemia is differentiated from chronic leukemia. Second, the cell line determines whether lymphoid cells or myeloid cells are involved. In acute leukemia this difference separates ALL from AML and vice versa. Within each of these categories, further subdivisions have been developed. (See Chapter 29 for a discussion of leukemias in adults.)

Cytogenic studies of leukemic cells are performed routinely at most major treatment centers during the diagnostic process. Abnormal morphologic characteristics, as well as abnormalities in the number of copies of chromosomes, are found in leukemic cells. Hyperdiploidy (increased number of chromosome copies) is associated with a good prognosis. Common translocations associated with ALL are TEL-AML1, BCR-ABL, and MLL. TEL-AML1 is the most common abnormality (in 20% to 30% of cases) and occurs when the *TEL* gene on chromosome 12p13 fuses with the *AML1* gene on chromosome 21q22. TEL-AML1 is associated with a favorable outcome. MLL arrangement, t(4;11), is located on chromosome 11q23. This translocation, the most common within this subtype, is found in infant ALL and is associated with a poor prognosis despite intensive therapy. Philadelphia chromosome–positive (Ph+) leukemia expresses the BCR-ABL protein and is characterized by the presence of t(9;22)(q34;q11) translocation. Ph+ leukemia can be ALL or chronic myelocytic leukemia (CML), depending where the breakpoint on chromosome 22 occurs. In CML, the translocation can be detected in multiple cell lines. Ph+ ALL occurs in 2% to 3% of cases and responds poorly to conventional chemotherapy. In CML, 99% of cases are characterized by the presence of t(9;22).[34]

Classification of childhood leukemia has become a complex but essential process to determine treatment. Previous classification by the French-American-British Cooperative Group (FAB) was based primarily on the morphologic and biochemical system. A classification scheme developed by the World Health Organization (WHO) is based on a more comprehensive system that uses morphology, immunophenotyping, and cytogenic and clinical features. The three major classifications of childhood leukemia are ALL (75% to 80%), AML (15% to 20%), and CML (less than 5%).

Flow cytometric immunophenotyping has made distinguishing between lymphoblastic and nonlymphoblastic leukemia much easier than in the past, when the degree of immaturity of the cell sometimes made such distinction difficult.

Immunologic classification has been used on identification of various surface markers. Five categories of ALL have been identified on the basis of their presumed origin from thymic cells (T cells) and bursa-equivalent cells (B cells) of normal lymphocytes:

1. T-cell ALL—characterized by the presence of abnormal T lymphocytes and found more commonly in older boys whose diagnosis includes mediastinal masses, high white blood cell counts, and hepatosplenomegaly (20% of ALL)
2. B-cell ALL—characterized by the presence of abnormal B lymphoblasts and associated with a poor prognosis (5% of ALL)
3. Pre—B-cell ALL—characterized by the presence of pre-B lymphoblasts (20% of ALL)
4. Unclassified ALL—also known as null cell (meaning neither T nor B lymphoblasts), and now classified as early B-cell lineage (15% of ALL)
5. Common ALL—characterized by the presence of a specific antigen known as common ALL antigen, or common acute lymphocytic leukemia antigen (CALLA), recently designated cellular differentiation 10 or CD10, in which the actual cell usually is considered to be of the B lineage (39% of ALL)

PATHOGENESIS. The exact cause of childhood leukemia is unclear. Investigations have focused on genetic susceptibility, environmental factors, and viral infections (see Chapter 14). Extraordinary doses of radiation and certain cancer therapies are possible causes (Facts, Spring 2013; Leukemia & Lymphoma Society, White Plains, NY. Accessed June 2013). Repeated exposure to benzene may cause AML. The relationship between childhood cancer and radon[35] and electromagnetic fields has been the focus of many epidemiologic studies, yet no conclusive evidence has been observed. In 2007 a task group of scientific experts convened by WHO reported that it could not confirm the existence of any health consequences from exposure to low-level magnetic fields.[36]

Although not determined to be genetically transmitted, a child who has a sibling with leukemia has a risk for the development of leukemia that is two to four times greater than for children with healthy siblings. The occurrence of leukemia in monozygous twins is estimated as being as high as 25%. In 2006, the Office of the U.S. Surgeon General suggested evidence of a causal relationship between childhood leukemia, lymphoma, and brain tumors and prenatal or postnatal environmental tobacco smoke exposure; the results have suggested an association between parental exposure to pesticides before or during pregnancy.[37] A later study suggested that the risk of leukemia and lymphoma increased when the mother was exposed to pesticides in the prenatal period, and the risk of brain tumors was correlated with paternal exposure (occupational or household use) either before or after birth.[38]

Inherited diseases that predispose a child to leukemia (ALL and AML) include Down syndrome, Fanconi anemia, Bloom syndrome, Diamond-Blackfan anemia, Klinefelter syndrome, Shwachman-Diamond syndrome, and ataxia-telangiectasia. Leukemia also has been associated with known genetic diseases, such as congenital agammaglobulinemia. AML in children sometimes is associated with loss or deletion of chromosome 7.

(see Figure 29-5). AML can develop from preexisting myeloproliferative disorders that also are preleukemia syndromes (i.e., myelodysplastic syndrome).

Childhood exposure to ionizing radiation, drugs, or viruses has been associated with the risk of developing cancer. Retrospective research has shown a significant correlation between radiation-induced malignancies from radiotherapy (as cancer treatment) or from radiation exposure from diagnostic imaging. The relationship between childhood cancer and electromagnetic fields, small appliances, radon, and other sources has been the focus of many epidemiologic studies; however, no conclusive evidence has been observed.[39]

Although chemicals such as benzene have been associated with the development of AML in adults, no evidence suggests a similar chemical or drug association in childhood leukemia. Leukemia (primarily AML) has been reported as a secondary malignancy (development of a second cancer after the first) in children treated for Hodgkin disease and Wilms tumor, although such cases are rare. In most cases the children received chemotherapy (alkylating agents or dactinomycin) and radiation therapy for the primary cancer, perhaps accounting for the subsequent development of another cancer.

Leukemic "clusters" that represent a greater number of leukemia cases occurring in a particular geographic location have raised speculation about environmental factors or infectious patterns of transmission. Careful follow-up, however, has failed to document the abnormal clustering.[40]

The strongest association between viruses and the development of cancer in children has been EBV and Burkitt lymphoma, and nasopharyngeal carcinoma and Hodgkin disease. Children with acquired immunodeficiency syndrome (AIDS) have an increased risk of developing non-Hodgkin lymphoma and Kaposi sarcoma. However, with the use of highly active antiretroviral therapy in the developed world, the incidence of AIDS-related malignancies has declined dramatically. Retroviruses have not been linked with childhood leukemia.

CLINICAL MANIFESTATIONS. Few variations appear in the presenting symptoms of the various cell types of acute leukemias. The onset may be abrupt or insidious, but the most common symptoms reflect the consequence of bone marrow failure, which results in decreased red blood cells and platelets and changes in white blood cells. Pallor, fatigue, petechiae, purpura, bleeding, and fever generally are present. Approximately 45% of children have a hemoglobin level less than 7 g/dl; in contrast to adults, children seem to demonstrate fewer symptoms. If acute blood loss occurs, however, characteristic symptoms of tachycardia, air hunger, restlessness, and thirst may be present. Epistaxis, excessive bruising, and hematuria often occur in children with severe thrombocytopenia. Three quarters of children with ALL have platelet counts less than 100,000/mm^3 at diagnosis, and 28% have platelet counts less than 20,000/mm^3. Half of all children newly diagnosed with AML have platelet counts less than 50,000/mm^3. Disseminated intravascular coagulation occurs more commonly with AML, particularly with promyelocytic leukemia. The granules in the leukemic promyelocytes may then indicate thromboplastin activity.

Fever usually is present as a result of two causes: (1) infection associated with the decrease in functional neutrophils and (2) hypermetabolism associated with the ongoing rapid growth and destruction of leukemic cells. In most children with ALL, the total white blood count is less than 10,000/mm^3, and with AML most have white cell counts less than 50,000/mm^3. In a few children, however, the peripheral white blood count can go well above 100,000/mm^3. White blood cell counts greater than 200,000/mm^3 can cause leukostasis, an intravascular clumping of cells that result in infarction and hemorrhage, usually in the brain and lung. The three most important favorable prognostic factors are age at diagnosis (2 to 10 years), initial leukocyte count (<50,000/mm^3), and initial response to treatment.

Renal failure as a result of hyperuremia (high uric acid levels) can be associated with ALL, particularly at diagnosis. Cell breakdown results as a natural process in the presence of a high white blood cell count or as a result of cellular breakdown caused by chemotherapy. Uric acid levels rise as an end product of purine metabolism from cellular destruction. Because the major excretory pathway is through the kidney, urates can precipitate in renal tubules or ureters and can lead to oliguria and acute renal failure. Renal failure is preventable if uric acid levels are monitored and treatment is aimed at optimal hydration, alkalinization of urine to assist with the excretion of soluble urates, and blockage of further uric acid formation by administration of the drug allopurinol.

Extramedullary invasion with leukemic cells can occur in nearly all body tissue. Most children with ALL have some extramedullary involvement at diagnosis. Leukemic invasion of tissue other than bone marrow is believed to represent metastatic infiltration. Hepatosplenomegaly and lymphadenopathy, resulting from extramedullary hematopoiesis, occur in nearly half of children with ALL, but they are less common in children with AML.

The CNS is a common site of infiltration of extramedullary leukemias, although less than 10% of children with ALL have CNS involvement at diagnosis. CNS infiltration manifests later in the course of the disease. Because successful chemotherapy prolongs the time of remission, the incidence of CNS involvement has increased. The most common symptoms of CNS involvement relate to increased intracranial pressure, causing early morning headaches, nausea, vomiting, irritability, and lethargy. Prophylactic CNS treatment therefore is necessary because systemic treatment with chemotherapy does not cross the blood-brain barrier.

Gonadal involvement, with testicular and ovarian infiltration, has been demonstrated in postmortem examination in 57% and 35% of children, respectively. Clinical detection of gonadal involvement is much less frequent. The incidence of testicular involvement, like CNS involvement, has increased with lengthened duration of remission. Prophylactic treatment has not been successful and currently is not recommended.

Leukemic infiltration into bones and joints is common in children. Reports of bone or joint pain actually lead to the diagnosis of leukemia in some children. In most children bone pain is characterized as migratory, vague, and without areas of

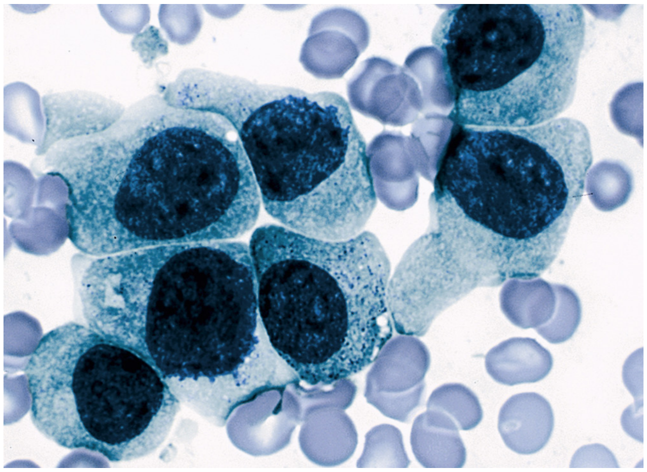

FIGURE 30-10 Monoblasts from Acute Monoblastic Leukemia. Monoblasts in a marrow smear from an individual with acute monoblastic leukemia (M5A). The monoblasts are larger than myeloblasts and usually have abundant cytoplasm, often with delicate scattered azurophilic granules (an element that stains well with blue aniline dyes). (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

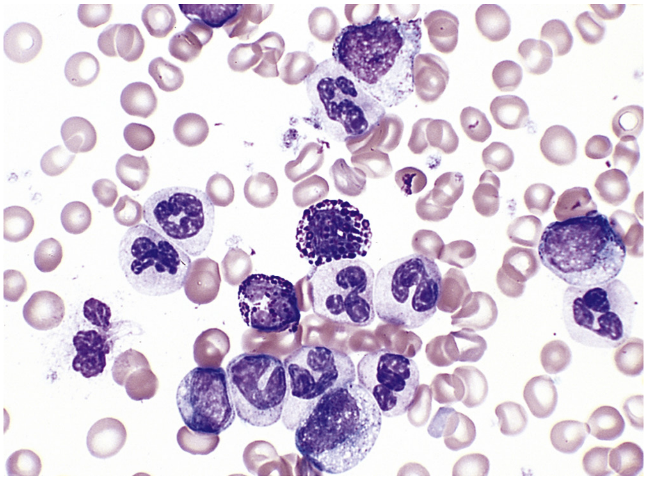

FIGURE 30-11 Leukocytosis and Basophilia in Chronic Myeloid Leukemia. Blood smear from a child with chronic myeloid leukemia (blasts) showing marked leukocytosis and basophilia. Karyotype analysis identified a Philadelphia chromosome (Wright-Giemsa stain). (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

swelling or inflammation. If joint pain is the primary symptom and some swelling is associated with the pain, however, misdiagnoses of rheumatoid arthritis may occur.

Other organs reported to be sites of leukemic invasion include the kidneys, heart, lungs, thymus, eyes, skin, and gastrointestinal tract. Of these, the kidneys, lungs, and gastrointestinal tract are the most frequently reported sites. Skin involvement is more common in AML than in ALL.

EVALUATION AND TREATMENT. A bone marrow aspiration and biopsy are required to establish the diagnosis. The **blast cell** is the hallmark of acute leukemia (Figure 30-10). The blast cell is a relatively undifferentiated cell characterized by diffusely distributed nuclear chromatin, with one or more nucleoli and basophilic cytoplasm (Figure 30-11).

TABLE 30-5 PROGNOSTIC FACTORS IN ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)

PROGNOSTIC FACTOR	BETTER PROGNOSIS	WORSE PROGNOSIS
Age*

Early pre–B-cell or common acute lymphocytic leukemia antigen (CALLA)	X	
Leukemic involvement		
Mediastinal mass		X
Central nervous system involvement at diagnosis		X
Splenic enlargement		X

*The four most reliable prognostic factors. Initial prognostic factors become less effective predictors with increasing length of remission. Age and gender are not significant after 15 months of continuous remission, and white blood cell count is not significant after 24 months of continuous remission.

Healthy children have less than 5% blast cells in the bone marrow and none in the peripheral blood. The bone marrow is categorized on the basis of blast percentage. Normal bone marrow is called M1 marrow; M2 and M3 represent an increased percentage of blasts in the sample. This categorization system should not be confused with the similar terminology used to denote subtypes of AML. In ALL the bone marrow often is replaced by 80% to 100% blast cells, with a reduction in normally developing red blood cells and granulocytes. The marrow, which is considered hypercellular, is composed of a homogeneous population of cells. Occasionally, however, the marrow appears hypocellular, making the diagnosis difficult to differentiate from aplastic anemia. When this occurs, the result of the bone marrow biopsy is necessary to confirm the diagnosis.

Combination chemotherapy, with or without radiation therapy to localized sites, such as the CNS, is the treatment of choice for acute leukemia. In ALL, identification of various risk groups has led to the development of different intensities of drug protocols. Thus treatment is tailored specifically for a particular risk group. (Table 30-5 outlines the various prognostic factors for ALL that are considered in determining the degree of risk.).

Most ALL treatment programs have four distinct phases: (1) induction of remission, (2) preventive therapy for the CNS, (3) intensification (also called *consolidation*), and (4) maintenance. In remission induction, the goal is no clinical evidence of disease

and a normal bone marrow biopsy result, which is achieved in 95% of children with ALL. Children with persistent leukemia at the end of 1 month of induction therapy have a dismal prognosis. Prophylactic CNS treatment historically included both chemotherapy and radiation, but therapy, although effective in preventing CNS leukemia, adversely affects neurologic and intellectual function. A marked incidence of learning disabilities has been identified in children previously treated to prevent CNS disease.[41] CNS radiation is no longer given and intrathecal regimens are less toxic. Once remission is achieved, an intensification phase of treatment begins. This treatment is necessary because leukemic cells will continue to be present despite successful remission. Thus the goal of the intensification phase is to further decrease and eliminate the remaining leukemic cells. Intensification therapy often overlaps prophylactic CNS treatment. The final phase of initial treatment is called *maintenance therapy*. The goal of this phase is to maintain disease control. The optimal duration of maintenance therapy is not well defined, but it usually continues for 2.5 to 3 years. During maintenance therapy intermittent "pulses" of new drugs are usually given. Periods of intensified therapy are believed to minimize development of drug-resistant leukemic cells.

An estimated 1310 cancer deaths are expected to occur among children ages 0 to 14 in 2013, about one third from leukemia. However, death rates from childhood cancer have decreased by 66% since 1969 so impressive strides have been made in the treatment of these children.[33] Today, with prompt and appropriate treatment, 80% of children with ALL are cured. Those children with the more favorable early pre–B-cell or CALLA-positive ALL have a survival rate of 90%.[42]

Prognostic factors in AML are not as well defined as they are for ALL because of the small number of affected children and their overall poor prognosis. The goal of treatment for AML is similar to that of ALL except that much more aggressive chemotherapy is administered. With intensive chemotherapy, significant bone marrow suppression is necessary but predisposes children to infection, bleeding, and anemia. The use of colony-stimulating factor (CSF), which stimulates the rapid proliferation of specific blood cell lines, is an advance that shortens this period of bone marrow aplasia (CSFs are discussed in Chapter 27). Although initial remission is achieved relatively easily in all cases of ALL, successful and lasting remission can be achieved in only 70% to 80% of children with AML.[31] If remission is achieved, further treatment, called *continuation therapy*, is required. The specific intensity, timing, and length of continuation therapy are controversial. The use of either a stem cell or bone marrow transplantation (BMT) is an important treatment consideration in AML. Because long-term remission and cure of AML are difficult to achieve with chemotherapy alone, transplant often is recommended after the first remission is achieved. Transplant is the treatment of choice after relapse of AML. The long-term survival rate for children with AML, whether treated with chemotherapy or chemotherapy and BMT, is approximately 50%.[33]

Lymphomas

Non-Hodgkin lymphoma (NHL) and Hodgkin disease make up approximately 15% of all childhood cancer. Approximately 800 cases of childhood lymphoma are diagnosed in the United States annually.[33] Either group of diseases is rare before age 5 years, and the relative incidence increases throughout childhood. NHL is 1.5 times more common than Hodgkin disease in children. Boys are more likely to be diagnosed with a malignant lymphoma than are girls. There is an increased incidence of lymphoma in children with congenital immunodeficiency syndromes such as Wiskott-Aldrich syndrome, severe combined immunodeficiency (SCID), X-linked lymphoproliferative disease, and ataxia-telangiectasia. Increased incidence of NHL also is associated with immunosuppression after solid organ and stem cell transplants, particularly T-cell–depleted stem cell transplantation. The strongest association between viruses and the development of cancer in children has been the EBV, Burkitt lymphoma, and Hodgkin disease. Children with AIDS have an increased risk of developing NHL. However, with the use of highly active antiretroviral therapy in the developed world, the incidence of AIDS-related malignancies has declined dramatically.[43]

Non-Hodgkin Lymphoma

The classification of **non-Hodgkin lymphoma (NHL)** has been confusing because of the heterogeneity of this group of diseases. Generally most classification systems divide NHL into two categories—nodular or diffuse—on the basis of cellular pattern. Whereas half of all adults with NHL have a nodular form of the disease, children rarely demonstrate this pattern. Nodular disease represents a less aggressive form of lymphoma. Almost without exception, childhood NHL becomes evident as a diffuse disease and can be further subdivided into three groups: (1) large cell (histiocytic), (2) lymphoblastic, and (3) small noncleaved cell (Burkitt or non-Burkitt lymphoma). Large-cell NHL often involves chromosomal translocations. Disease sites commonly involve extranodal sites, such as brain, lung, bone, and skin. Lymphoblastic NHL also shows chromosomal translocations, particularly chromosomes 7 and 14. Disease sites commonly include the mediastinum and peripheral lymph nodes. Small noncleaved cell NHL involves chromosome translocations of 8 and 14. It is believed that this translocation triggers the *c-myc* oncogene. Children with small noncleaved cell NHL commonly have intra-abdominal disease at diagnosis.

An area of intensive study concerns the apparent biologic similarities of NHL and ALL in children. These two diseases are cytologically identical, and the histologic distinction between them is indicated by the degree of infiltration in the blood and bone marrow. The more bone marrow involvement and the less nodal and organ infiltration present, the more likely the disease is to be classified as ALL. Childhood NHL also is much more like ALL in its clinical manifestations and much less like Hodgkin disease or adult NHL.

As in ALL, immunophenotyping is an important part of the classification of childhood NHL. Almost 45% of the disease in children originates from T cells; an equal number originates from B cells. The remaining group, which represents 10% of childhood NHLs, is classified as non-T, non-B.

PATHOGENESIS. The origin of NHL in childhood is still elusive. Although defective host immunity is implicated in most children in whom NHL develops, an immune deficit cannot be

identified. Viral etiology is suggested, but the role in development of human lymphoma is still unclear. The strongest correlation exists between EBV and African Burkitt lymphoma. This form of NHL is associated with a breakpoint on chromosome 8 that is located near the *c-myc* oncogene.[44] The relationship between EBV infection and Burkitt lymphoma outside Africa is weak, however, even though the tumor is histopathologically and clinically indistinguishable. Chronic immunostimulation also has been suggested as a factor in the development of lymphomas because these diseases are seen more often when chronic persistent antigenic stimulation occurs from infection, such as malaria or intestinal parasites. Genetic susceptibility also may play a role in the process of malignant transformation.

CLINICAL MANIFESTATIONS. In children, NHL has been found to arise from any lymphoid tissue. Signs and symptoms therefore are specific for the site involved. Some children have such widespread involvement that no original site can be determined. Because childhood NHL is a rapidly progressive disease, symptoms generally are present only a few weeks before diagnosis is made. Rapidly enlarging lymphoid tissue and painless lymphadenopathy are common in about one third of children with abdominal sites of involvement, usually representing a gastrointestinal origin for the disease. Symptoms often include abdominal pain and vomiting, but a palpable mass is not always present. Most children with abdominal symptoms have diffuse, small noncleaved cell NHL (Burkitt or non-Burkitt) of B-cell origin. If the tumor recurs, it appears again in the abdomen before distant spread.

The other common site of childhood NHL is the chest region. An anterior mediastinal mass, with or without pleural effusion, often is present. If the mass is large enough, respiratory compromise, tracheal compression, and superior vena cava syndrome may arise, which constitute a medical emergency. Children with anterior mediastinal involvement often are male adolescents and usually have diffuse lymphoblastic lymphoma of T-cell origin. This form of diffuse lymphoblastic lymphoma often evolves into extensive bone marrow involvement and is considered to be an overt leukemic phase (Figure 30-12); therefore, it is referred to as *leukemic transformation.* CNS involvement and testicular infiltration often then occur. CNS involvement occurs in about 30% of individuals with NHL, usually causing multiple deep-seated lesions within the brain parenchyma. In children with AIDS, NHL is the most common mass lesion found in the brain.

Bone marrow involvement is less common than other primary sites, whereas CNS involvement is common. Relatively few children (10% to 20%) with NHL have lymphoid tissue involvement of the head and neck (Waldeyer ring, nasopharynx, sinuses). Signs and symptoms include tonsillitis, sinusitis, and a painless nasopharyngeal mass. In African Burkitt lymphoma, involvement of facial bones, particularly the jaw, is common, although this occurs infrequently in non-African cases.

EVALUATION AND TREATMENT. Diagnosis is made by biopsy of disease sites, usually the involved lymph nodes. Other sites of biopsy include the tonsils, bone marrow, spleen, liver, bowel, or skin. Advances in understanding the disease and progress in treatment strategies have meant that most children with NHL are cured of the disease. The primary therapeutic modality for childhood NHL is chemotherapy, regardless of stage or site(s) of the disease. The tumor responds to many different agents. Many children with NHL receive intrathecal agents (methotrexate [Mexate] or cytarabine [cytosine arabinoside], or both) for CNS prophylaxis. Radiation is not routinely used to treat childhood NHL, with the exception of emergent situations when airway, intestinal, or spinal obstruction requires immediate reduction in tumor size. Cranial radiation therapy (RT) may be used for children with T-cell lymphoblastic lymphoma.

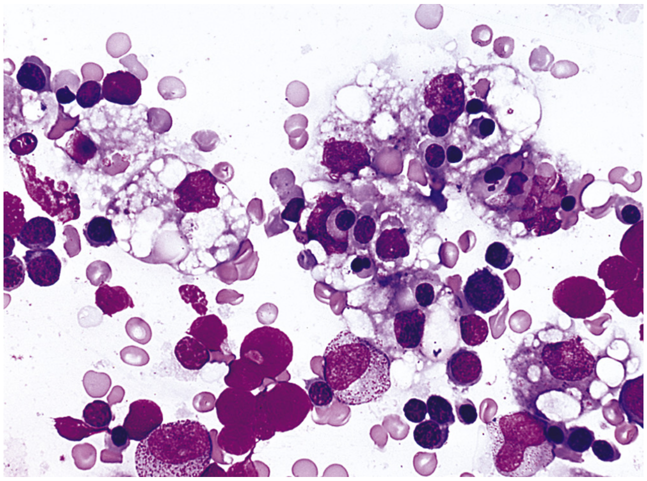

FIGURE 30-12 **Bone Marrow Aspirate from a Child with T-Cell Lymphoma in a Lymph Node Biopsy.** There is marked histiocytic hyperplasia. Two of the histiocytes contain phagocytosed red cells. The histiocytic hyperplasia regressed with disease remission and recurred with relapse of the lymphoma (Wright-Giemsa stain). (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

Children with advanced small noncleaved cell lymphoma of the abdomen have the poorest prognosis. Although remission occurs in more than 90% of these children, most experience subsequent relapses. Even in the presence of advanced lymphoblastic lymphoma, however, 70% to 80% of children can be cured. Children with localized disease in more easily treated sites are likely to be cured with prompt and appropriate treatment. Overall, children with localized diseases have a 90% survival rate and those with advanced disease have a 70% to 80% survival rate.[33]

Hodgkin Lymphoma

Hodgkin lymphoma accounts for 6% of all childhood cancers with a significant male-to-female dominance of 4:1 in young children. There is an increased incidence in children with immunologic disorders, whether caused by genetics, infection, or iatrogenic agents. EBV has been associated with Hodgkin lymphoma. Approximately 15% to 25% of adolescents and young adults have EBV-positive Hodgkin lymphoma.[45] Clustering of cases within families may suggest a genetic predisposition to the disease or common exposure to a causative agent.[46]

Hodgkin lymphoma accounts for 6% of all childhood cancers. It occurs infrequently in children younger than 2 years, and few cases are observed before age 5 years. A gradual rise in incidence occurs through age 11 years, with a marked increase through adolescence that continues into the 30s.

Individuals typically have painless supraclavicular or cervical adenopathy. These nodes are firm and rubbery and may be sensitive to palpation if they have grown rapidly. At least two thirds of individuals have mediastinal involvement that may cause symptoms ranging from a nonproductive cough to tracheal or bronchial compression leading to airway obstruction. Systemic symptoms may include fatigue, anorexia, weight loss, fever, drenching night sweats, and pruritus.

The Ann Arbor staging system considers extent and location of disease, as well as substage classifications that consider systemic symptoms (presence of fever of 38° C [100.4° F] for 3 consecutive days, drenching night sweats, or unexplained loss of 10% or more of body weight in the 6 months preceding diagnosis), extranodal, or bulky disease. Combination chemotherapy used in conjunction with involved field low-dose radiation has been shown to be an effective treatment, with long-term cure rates reported from 90% to 95%.[45]

SUMMARY REVIEW

Fetal and Neonatal Hematopoiesis

1. After 2 weeks of gestation, circulating erythrocytes play a major role in delivering oxygen to the tissues.
2. Erythropoiesis in the liver and, to a lesser extent, in the spleen and lymph nodes reaches a peak at about 4 months.
3. By the fifth month of gestation, hematopoiesis begins to occur in the bone marrow, and by the time of delivery it is the only significant site of hematopoiesis.
4. A biochemically distinct type of hemoglobin is synthesized during fetal life, including Gower 1, Gower 2, and Portland.

Postnatal Changes in the Blood

1. Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood.
2. The immediate rise in blood cell counts is the result of increased hematopoiesis during fetal life, trauma of birth, and cutting of the umbilical cord.
3. The active rate of fetal erythropoiesis is observed in the large numbers of reticulocytes in the peripheral blood of the full-term neonate.
4. Erythrocyte values are age dependent, and values in males and females are apparent in adolescence.
5. The lymphocyte count is high at birth, and continues to rise in some healthy infants during the first year of life.
6. Platelet counts in full-term neonates are comparable to platelet counts in children and adults.

Disorders of Erythrocytes

1. Iron deficiency anemia is the most common blood disorder of infancy and childhood; the highest incidence occurs between 6 months and 2 years of age.
2. Hemolytic disease of the newborn (HDN) results from incompatibility between the maternal and the fetal blood, which may involve differences in Rh factors or blood type (ABO). Maternal antibodies enter the fetal circulation and cause hemolysis of fetal erythrocytes. Because the immature liver is unable to conjugate and excrete the excess bilirubin that results from the hemolysis, icterus neonatorum, or kernicterus or both can develop.
3. Kernicterus, which may result from other causes as well, results in increased breakdown of red blood cells or decreased liver output of enzymes.
4. Infections of the newborn, often acquired by the mother and transmitted to the infant, may result in hemolytic anemia.
5. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an inherited enzyme deficiency in erythrocytes that results in a disruption of a common pathway of glycolysis, shortening erythrocyte life span.
6. Hereditary spherocytosis is the most common of the hereditary hemolytic states in which there is no abnormality of hemoglobin. The basic defect is an undefined abnormality of the proteins or spectrins of the erythrocyte membrane in which affected cells are unduly permeable to sodium and acquire a characteristic structure.
7. Sickle cell disease (SCD) is a genetically determined defect of hemoglobin synthesis, inherited by an autosomal recessive transmission; it causes a change in the shape of a red blood cell that results in decreased oxygen or hydration. This disease is most common among Africans, blacks, and those of Mediterranean descent.
8. The thalassemias are a heterogeneous group of hereditary hypochromic anemias of varying severity. Basic genetic defects include abnormalities of messenger ribonucleic acid (mRNA) processing or deletion of genetic materials, resulting in a decrease in the chains for hemoglobin.

Disorders of Coagulation and Platelets

1. Hemophilia is a condition characterized by impairment of the coagulation of blood and subsequent tendency to bleed. The classic disease is hereditary and limited to males, being transmitted through the female to the second generation. Many similar conditions attributable to the absence of various clotting factors are recognized.
2. von Willebrand disease is a dominantly inherited disease characterized by a vascular abnormality that produces a prolongation of bleeding time and by decreased levels of clotting factor VIII. The platelets in von Willebrand disease have decreased adhesiveness because the plasma factor is absent.
3. Disorders of congenital hypercoagulability and thrombosis include protein C deficiency, protein S deficiency, neonatal purpura fulminans, and antithrombin III deficiency.
4. The acquired antibody-mediated hemorrhagic diseases include idiopathic thrombocytopenic purpura (ITP), autoimmune neonatal thrombocytopenia, and autoimmune vascular purpura.
5. ITP, the most common of the childhood thrombocytopenic purpuras, is a disorder of platelet consumption in which

SUMMARY REVIEW—cont'd

antiplatelet antibodies bind to the plasma membranes of platelets. This results in platelet sequestration and destruction by mononuclear phagocytes at a rate that exceeds the ability of the bone marrow to produce them.

6. Autoimmune neonatal thrombocytopenia is an antibody-mediated disorder that occurs in either autoimmune or alloimmune form.
7. The autoimmune vascular purpuras (allergic purpuras) are caused by the body's responses to allergens in the blood.

Leukemia and Lymphoma

1. The types of childhood leukemia include, in order of their rate of incidence, ALL, AML, and CML.
2. Although the cause of childhood leukemia is not known, it is probably the result of multiple interactions between hereditary or genetic predisposition and environmental influences.
3. Acute lymphoblastic leukemia is a potentially curable disease, with more than 80% of cases cured.
4. The lymphomas of childhood are non-Hodgkin lymphoma and Hodgkin lymphoma.
5. The origin of non-Hodgkin lymphoma is unknown. Factors that have been implicated include defective host immunity, a viral agent, chronic immunostimulation, and genetic predisposition.
6. Non-Hodgkin lymphoma has a favorable prognosis, with a 70% to 80% cure rate.
7. The risk of Hodgkin lymphoma is associated in part with infectious diseases, immune deficits, and genetic susceptibility.
8. Hodgkin lymphoma is a readily curable disease with long-term cure rates of 90% to 95%.

CHAPTER OUTLINE

The functions of the circulatory system include delivery of oxygen, nutrients, hormones, cells of the immune system, and other substances to body tissues and removal of the waste products of cellular metabolism. Delivery and removal are achieved by a complex array of tubing—the blood and lymphatic vessels—connected to a pump—the heart. The heart continuously pumps blood through the blood vessels in collaboration with other systems, particularly the nervous and endocrine systems, which are intrinsic regulators of the heart and blood vessels. Immune system cells, nutrients, and oxygen are supplied by the immune, digestive, and respiratory systems; gaseous wastes of cellular metabolism are blown off by the lungs; and other wastes are removed by the kidneys and digestive tract.

A critical component of the circulatory system is the vascular endothelium, which is considered by some to be a separate organ. It is a multifunctional tissue whose health is essential to normal vascular and hemostatic physiology and whose dysfunction is an important factor in the pathogenesis of vascular and other diseases.[1]

CIRCULATORY SYSTEM

The heart is comprised of two conjoined pumps that power the movement of blood through two separate circulatory systems, one to the lungs and one to all other parts of the body. Structures on the right side of the heart, or **right heart,** pump blood through the lungs. (This system, termed the **pulmonary circulation,** is described in Chapter 34.) The left side of the heart, or **left heart,** sends blood throughout the **systemic circulation,** which supplies all of the body except the lungs (Figure 31-1).

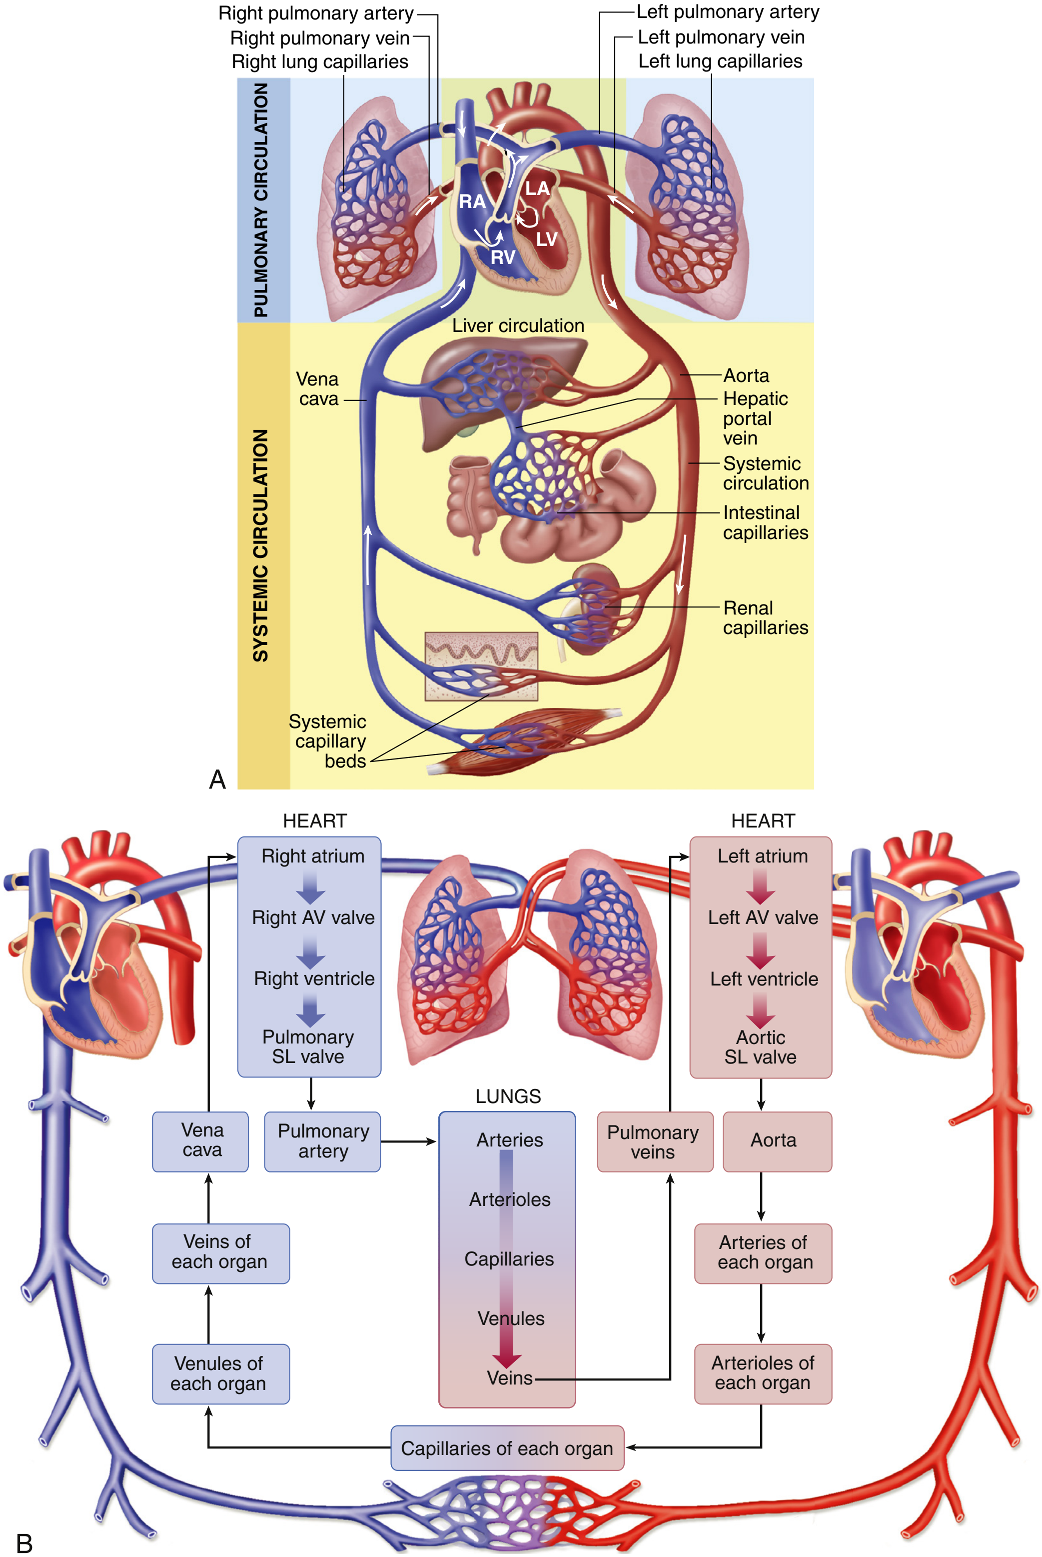

FIGURE 31-1 Diagram Showing Serially Connected Pulmonary and Systemic Circulatory Systems and How to Trace the Flow of Blood. **A,** Right heart chambers propel unoxygenated blood through the pulmonary circulation, and the left heart propels oxygenated blood through the systemic circulation. **B,** The direction of blood flow begins at the left ventricle of the heart; flows to the arteries, arterioles, capillaries of each body organ, venules, veins, right atrium, right ventricle, pulmonary artery, lung capillaries, pulmonary veins, and left atrium; and then returns to the left ventricle. *LA,* Left atrium, *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *SL,* semilunar. (**A** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby. **B** from Thibodeau GA, Patton KT: *The human body in health & disease,* ed 6, St Louis, 2014, Mosby.)

These two systems are serially connected so that the output of one pump becomes the input of the other.

Arteries carry blood from the heart to all parts of the body, where they branch into arterioles and even smaller vessels until they become a fine meshwork of capillaries. Capillaries allow the closest contact and exchange between the blood and the interstitial space, or interstitium—the environment in which the cells live. Veins then carry blood from capillaries back to the heart. Some of the plasma or liquid component of the blood passes through the walls of the capillaries into the interstitial space. This fluid, called lymph, is returned to the cardiovascular system by vessels of the lymphatic system. The lymphatic system is also a critical component of the immune system as described in Chapter 8.

THE HEART

The adult heart weighs between 200 and 350 g and is about the size of a fist. It lies obliquely (diagonally) in the **mediastinum,** the area above the diaphragm and between the lungs. Women's hearts are typically about 0.40% of their total body weight whereas men's hearts are about 0.45% of total body weight.[2]

Heart structures can be categorized by function:

1. *Structural support of heart tissues and circulation of pulmonary and systemic blood through the heart.* This category includes the heart wall and fibrous skeleton, which enclose and support the heart and divide it into four chambers; the valves that direct flow through the chambers; and the great vessels that conduct blood to and from the heart.
2. *Maintenance of heart cells.* This category comprises vessels of the coronary circulation—the arteries and veins that serve the metabolic needs of all the heart cells—and the lymphatic vessels of the heart.
3. *Stimulation and control of heart action.* Among these structures are the nerves and specialized muscle cells that direct the rhythmic contraction and relaxation of the heart muscles, propelling blood throughout the pulmonary and systemic circulatory systems.

Structures That Direct Circulation Through the Heart

Heart Wall

The heart wall has three layers—the epicardium, myocardium, and endocardium—and is enclosed in a double-walled membranous sac, the **pericardium** (Figure 31-2). The **pericardial sac** has several functions. It (1) prevents displacement of the heart during gravitational acceleration or deceleration, (2) acts as a physical barrier that protects the heart against infection and inflammation from the lungs and pleural space, and (3) contains pain receptors and mechanoreceptors that can elicit reflex changes in blood pressure and heart rate. The outer layer of the pericardium, the **parietal pericardium,** is composed of a surface layer of mesothelium over a thin layer of connective tissue. The **visceral pericardium,** or **epicardium,** is the inner layer of the pericardium. At one point the visceral pericardium folds back and becomes continuous with the parietal pericardium, allowing the large vessels to enter and leave the heart without breaching the pericardial layers.

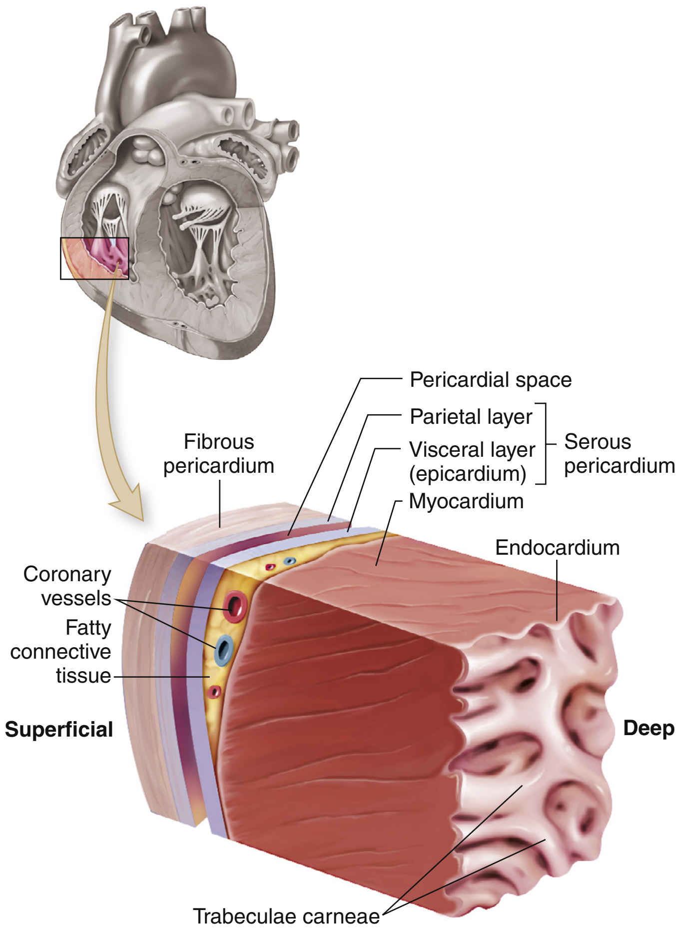

FIGURE 31-2 Wall of the Heart. The cutout section of the heart wall shows the outer fibrous pericardium and the parietal and visceral layers of the serous pericardium (with the pericardial space between them). Note that a layer of fatty connective tissue is located between the visceral layer of the serous pericardium (epicardium) and the myocardium. Note also that the endocardium covers beamlike projections of myocardial muscle tissue, called *trabeculae carneae.* (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

The visceral and parietal pericardia are separated by a fluid-containing space called the **pericardial cavity.** The **pericardial fluid** (about 20 ml), which is secreted by cells of the mesothelium, lubricates the membranes that line the pericardial cavity, enabling them to slide over one another with a minimum of friction as the heart beats.[2] The amount and character of the pericardial fluid are altered by inflammation of the pericardium (see Chapter 32).

The outer layer of the heart, the epicardium, provides a smooth surface that allows the heart to contract and relax within the pericardium with a minimal amount of friction. The thickest layer of the heart wall, the **myocardium,** is composed of cardiac muscle and is anchored to the heart's fibrous skeleton. The thickness of the myocardium varies tremendously from one heart chamber to another. Thickness is related to the amount of resistance the muscle must overcome to pump blood from the different chambers. The internal lining of the myocardium

is composed of connective tissue and a layer of squamous cells called the **endocardium** (see Figure 31-2). The endocardial lining of the heart is continuous with the endothelium that lines all the arteries, veins, and capillaries of the body, creating a continuous, closed circulatory system (see What's New? The Potential for Using Epicardial Cells in Myocardial Repair).

Chambers of the Heart

The heart has four chambers: the **right atrium, left atrium, right ventricle,** and **left ventricle**. These chambers form two pumps in series: the right heart, which is a low-pressure system pumping blood through the lungs; and the left heart, which is a high-pressure system pumping blood through the rest of the body. (Blood flow through these chambers is illustrated in Figure 31-3.) The atria are smaller than the ventricles and have

WHAT'S NEW?

The Potential for Using Epicardial Cells in Myocardial Repair

With cardiovascular disease, including myocardial infarction as one of the leading causes of death and disability, there is great interest in regenerative therapies for the heart muscle. Bone marrow transplants have been tried in an attempt to grow new myocardium but the results are unimpressive. Because studies of heart development in the embryo have shown that both the epicardium and the myocardium develop from a common progenitor, called epicardium-derived cells (EPDCs), there is now great interest in identifying these precursor cells and using them to repair ischemic or dying myocardial tissue. One advantage of using these cells that apparently can be isolated from an adult's heart is that in addition to forming new heart muscle they also will release the appropriate cytokines and growth factors for muscle regeneration and the growth of nourishing blood vessels.

Data from Gittenberger-de Groot AC et al: *Differentiation* 84(1):41–53, 2012; Limana F, Capogrossi MC, Germani A: *Pharmacol Ther* 129(1):82–96, 2011.

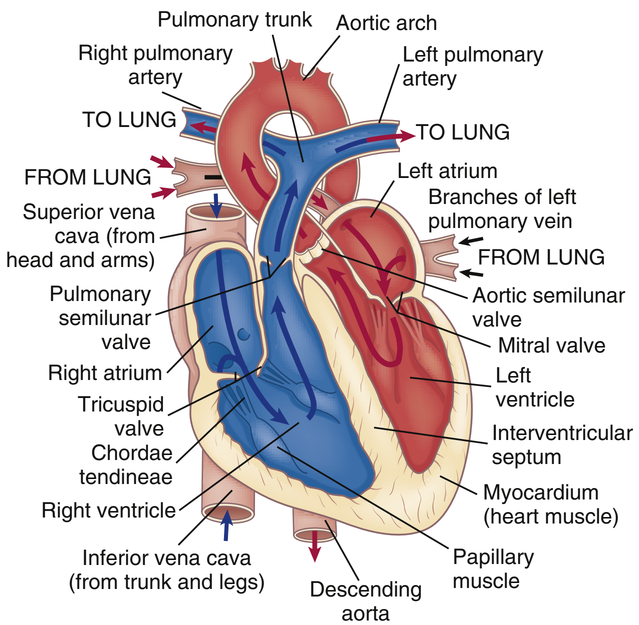

FIGURE 31-3 Structures That Direct Blood Flow Through the Heart. Arrows indicate path of blood flow through chambers, valves, and major vessels.

thinner walls. The walls of the right and left atria are about 1 to 2 mm thick. The ventricles have a thicker myocardial layer and make up much of the bulk of the heart. The wall of the right ventricle is about 4 to 5 mm thick, and that of the left ventricle, the most muscular chamber, is about 12 to 15 mm.[2] The ventricles are formed by a continuum of muscle fibers that originate from the fibrous skeleton at the base of the heart (chiefly around the aortic orifice).

The wall thickness of each cardiac chamber depends on the amount of pressure or resistance it must overcome to eject blood. The two atria have the thinnest walls because they are low-pressure chambers that serve as storage units and conduits for blood that is emptied into the ventricles. Normally, there is little resistance to flow from the atria to the ventricles. The ventricles, on the other hand, must propel blood all the way through the pulmonary or systemic circulation. The ventricular myocardium must be strong enough to pump against pressures in the pulmonary or systemic vessels. The mean pulmonary capillary pressure, the force the right ventricle must overcome, is only 15 mmHg whereas the mean arterial pressure, the force the left ventricle must overcome, is about 92 mmHg. Because the pressure is markedly higher in the systemic circulation, the left ventricle's myocardial wall is several times thicker than that of the right ventricle.

The right ventricle is shaped like a crescent, or triangle, enabling it to function like a bellows and efficiently eject large volumes of blood through the pulmonary semilunar valve into the low-pressure pulmonary system. The left ventricle is larger and bullet shaped, helping it to eject blood through the larger aortic semilunar valve into the high-pressure systemic circulation.

The ventricles are structurally more complex than the atria. Each ventricle contains muscle fibers that divide it roughly into an **inflow tract,** which receives blood from the atrium, and an **outflow tract,** which sends blood to the circulation (see Figure 31-3).

Normally blood does not flow between the chambers of the right side of the heart and the chambers of the left side of the heart except in the fetus before delivery. The adult right and left sides of the heart are separated by intact septal membranes. The atria are separated by the interatrial septum and the ventricles by the interventricular septum. There is an opening between the right and left atria before birth called the foramen ovale; however, this opening closes shortly after birth in most individuals (see Chapter 33). The interventricular septum is an extension of the fibrous skeleton of the heart. Indentations of the endocardium form valves that separate the atria from the ventricles and the ventricles from the aorta and pulmonary arteries.

Fibrous Skeleton of the Heart

Four rings of dense fibrous connective tissue provide a firm anchorage for the attachments of the atrial and ventricular musculature, as well as the valvular tissue. The fibrous rings are adjacent and form a central, fibrous supporting structure collectively termed the annuli fibrosi cordis.

Valves of the Heart

One-way blood flow through the heart is ensured by the four heart valves as well as the pressure gradients that they maintain.

During ventricular relaxation the two **atrioventricular valves** open and blood flows from the relatively higher pressure in the atria to the lower pressure in the relaxed ventricles. With increasing ventricular pressure these valves close and prevent backflow into the atria as the ventricles contract. The **semilunar valves** of the heart open when intraventricular pressure exceeds aortic and pulmonary pressures and blood flows out of the ventricles and into the systemic and pulmonary circulations, respectively. After ventricular contraction and ejection, intraventricular pressure falls and the **pulmonic** and **aortic semilunar valves** close when the pressure in the vessels is greater than the pressure in the ventricles, thus preventing backflow into the right and left ventricles, respectively (Figure 31-4; also see Figure 31-3).

The atrioventricular (AV) (tricuspid and mitral) valve openings are composed of flaps of tissue called *leaflets or cusps* that

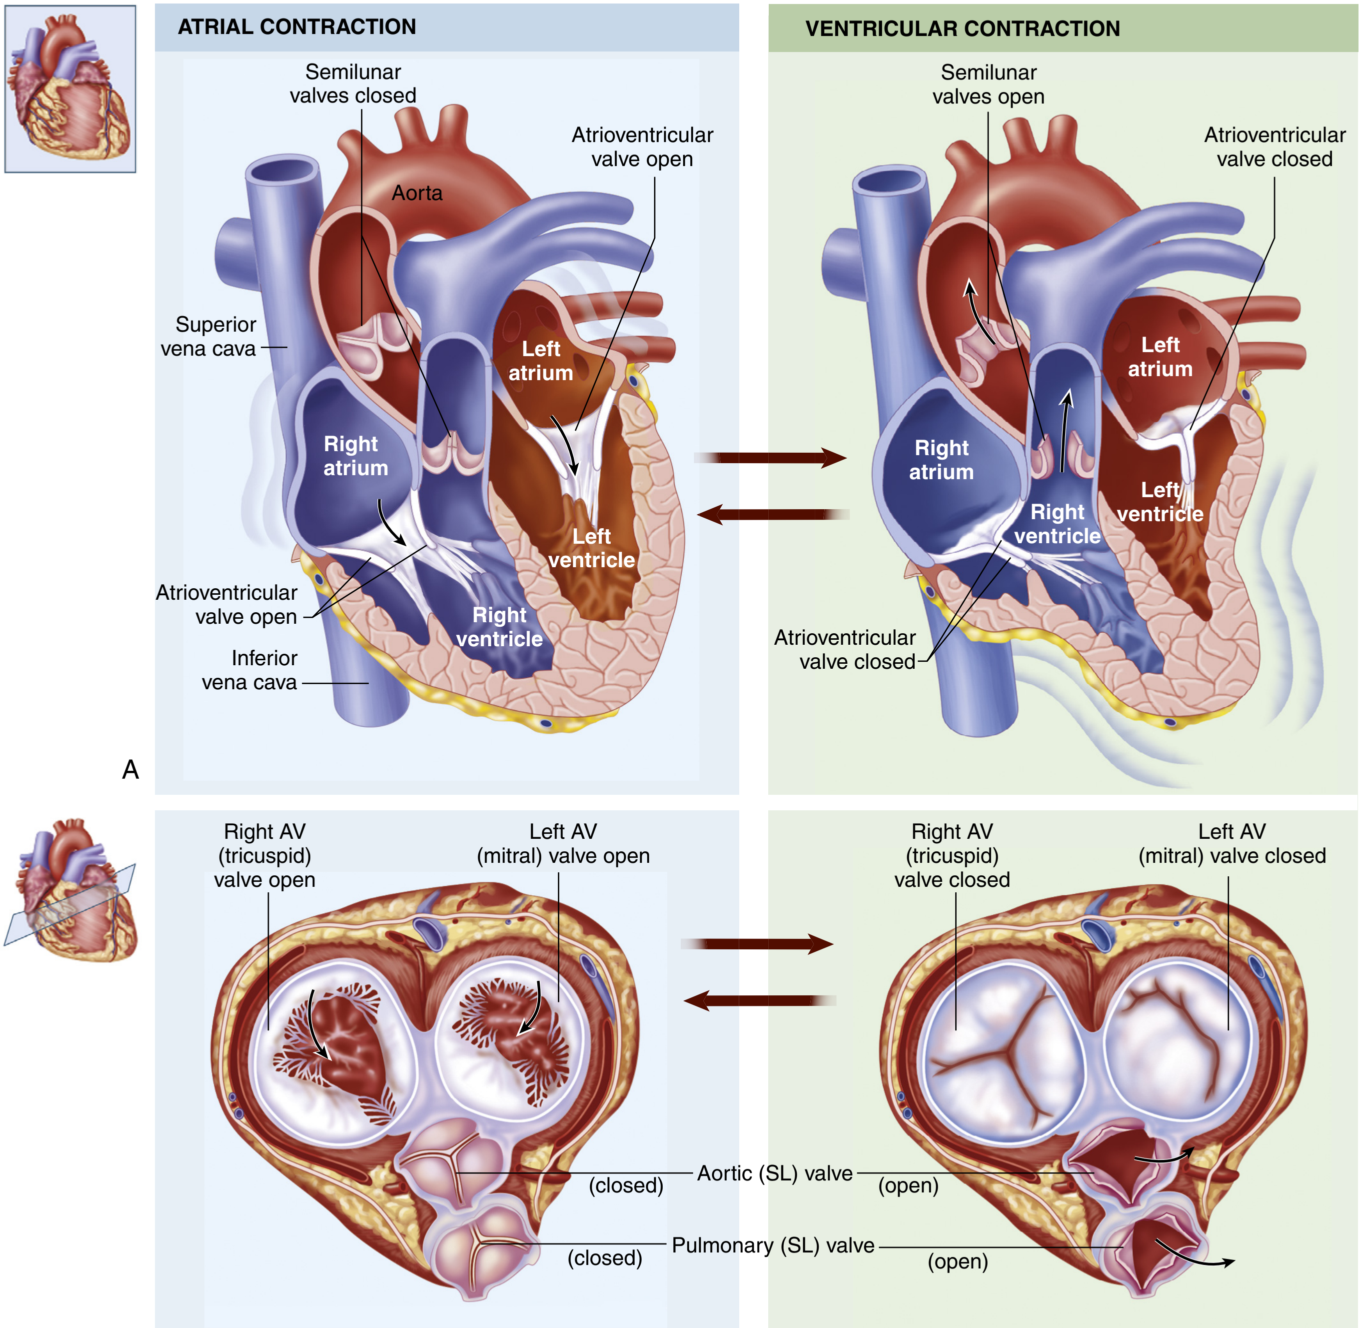

FIGURE 31-4 Chambers and Valves of the Heart. Chambers and valves of the heart. **A,** During atrial contraction cardiac muscle in the atrial wall contracts, forcing blood through the atrioventricular *(AV)* valves and into the ventricles. Bottom illustration shows superior view of all four valves, with semilunar *(SL)* valves closed and AV valves open. **B,** During ventricular contraction that follows, the AV valves close and the blood is forced out of the ventricles through the SL valves and into the arteries. Bottom illustration shows superior view of SL valves open and AV valves closed. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

are attached at the upper end to one of the rings in the fibrous skeleton of the heart and at the lower end to papillary muscles by the **chordae tendineae** (see Figure 31-3). The **papillary muscles** are extensions of the myocardium that help hold the cusps together and downward at the onset of ventricular contraction, thus preventing their backward expulsion, or **prolapse,** into the atria (see p. 1087 for a description of pressure changes and valvular function).

The right AV valve is called the **tricuspid valve** because it has three cusps. The tricuspid opening (orifice) has the largest diameter of all the heart valves. The left AV valve is a bicuspid (two cusps) valve called the **mitral valve.** The mitral valve resembles a cone-shaped funnel that extends into the cusps, which are connected by a fibrous tissue called the *commissure.* The anterior cusp of the mitral valve is continuous with supporting tissues of the aortic semilunar valve cusps and the left coronary valve cusps. (The coronary circulation is described on p. 1090.) Thus damage to this continuous tissue can alter function of the aortic as well as the mitral valves.

The tricuspid and mitral valves function as a unit because the atrium, fibrous rings, valvular tissue, chordae tendineae, papillary muscles, and ventricular walls are all connected. Collectively, these six structures are known as the **mitral and tricuspid complex.** Damage to any one of the complex's six components can alter function significantly.

Blood leaves the right ventricle through the pulmonic semilunar valve, and it leaves the left ventricle through the aortic semilunar valve (see Figures 31-3 and 31-4). The pulmonic and aortic semilunar valves have three cup-shaped cusps that arise from the fibrous skeleton. The pulmonic cusps are slightly thinner than the aortic cusps. The lower edges of each cusp are suspended from the root of the pulmonary artery or aorta, with the upper valve edges freely projecting into the vessel lumen. When the ventricles contract, the cusps behave like one-way swinging doors. The force of the blood propels the cusps outward against the vessel wall. When the ventricles relax, blood fills the cusps and causes their free edges to meet in the middle of the vessel, closing the valve and preventing any backflow.

Great Vessels

Blood moves in and out of the heart through several large vessels (see Figure 31-3). The right heart receives venous deoxygenated blood from the systemic circulation through the **superior vena cava** and the **inferior vena cava,** which enter the right atrium. Blood leaves the right ventricle and enters the pulmonary circulation through the pulmonary artery. The **pulmonary artery** divides into **right** and **left pulmonary arteries** to transport unoxygenated blood from the right heart to the right and left lungs. The pulmonary arteries branch further into the pulmonary capillary bed, where oxygen enters the blood and carbon dioxide leaves it as each gas moves from its higher to lower concentration gradient.

Four **pulmonary veins,** two from the right lung and two from the left lung, carry oxygenated blood from the lungs to the left side of the heart. The oxygenated blood moves through the left atrium and ventricle and out into the **aorta,** which delivers it to systemic vessels that supply the body.

Blood Flow During the Cardiac Cycle

The pumping action of the heart consists of contraction and relaxation of the heart muscle or myocardium. Each ventricular contraction and the relaxation that follows it constitute one **cardiac cycle.** (Blood flow through the heart during a single cardiac cycle is illustrated in Figure 31-4.) During the period of relaxation, termed **diastole,** blood fills the ventricles. The contraction that follows, termed **systole,** propels the blood out of the ventricles and into the pulmonary and systemic circulations. Contraction of the left ventricle occurs slightly earlier than contraction of the right ventricle.

During ventricular systole, blood from the veins of the systemic circulation enters the thin-walled right atrium from the superior and inferior venae cavae (see Figures 31-3 and 31-4). Venous blood from the coronary circulation enters the right atrium through the coronary sinus. The right atrium fills, which, along with the falling right ventricular pressures, allows the right AV (tricuspid) valve to open and fill the right ventricle during ventricular diastole (occasionally called atrial systole). The same sequence of events occurs a split second earlier in the left heart. The four pulmonary veins, two from the right lung and two from the left lung, carry blood from the pulmonary circulation to the left atrium. As the left atrium fills and left ventricular pressure falls, the mitral valve opens and blood flows into the left ventricle. Left atrial contraction, termed "atrial kick," provides significant increases in the volume of blood entering the left ventricle at the end of diastole. Filling of the right and left ventricles occurs during one period of diastole.

Five phases of the cardiac cycle can be identified (Figures 31-5 and 31-6):

Phase 1: Ventricular diastole or atrial systole begins with opening of the mitral and tricuspid valves and then ventricular filling from the atria occurs. The ventricles fill rapidly in early diastole and again in late diastole when the atria contract.

Phase 2: Ventricular systole begins with "isovolumetric contraction," so-called because ventricular volume is constant since both the AV and the semilunar valves are closed. The first detectable rise in ventricular pressure occurs during isovolumetric contraction. This contraction pushes the AV valves shut. Their cusps bulge slightly into the atria but are prevented from opening back into the atria by their anchors, the chordae tendineae (see Figure 31-3).

Phase 3: When ventricular pressure reaches and then slightly exceeds that of the pulmonary artery and aorta, the semilunar valves open and ventricular ejection occurs. Intraventricular pressure and ventricular volume decrease rapidly.

Phase 4: With ventricular relaxation and decreased ventricular pressure, the aortic valve closes and "isovolumetric relaxation" occurs. Again, both the AV and the semilunar valves are closed during this phase.

Phase 5: When left ventricular pressure falls below atrial pressure, the mitral and tricuspid valves open and *passive ventricular filling occurs.*

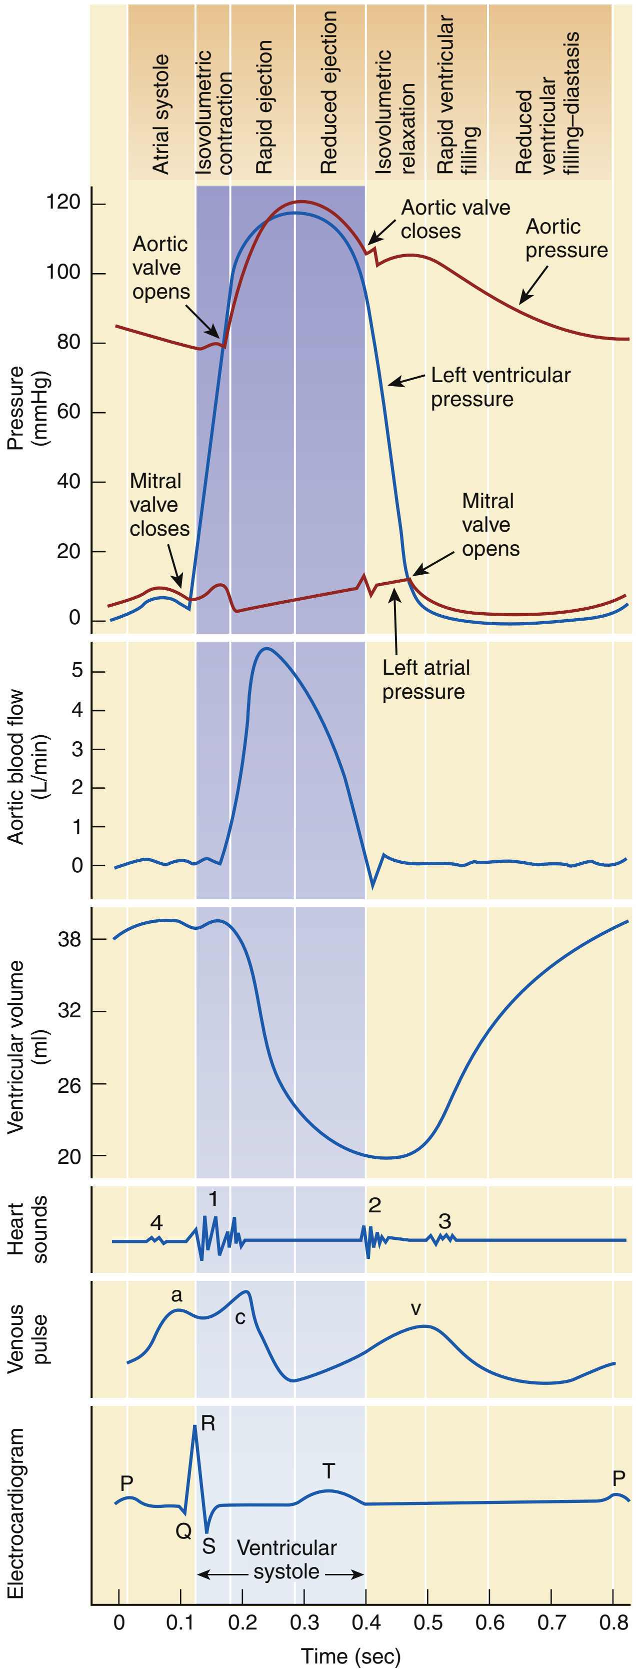

FIGURE 31-5 **Composite Chart of Heart Function.** This chart is a composite of several diagrams of heart function (blood pressure, blood flow, volume, heart sounds, venous pulse, and electrocardiogram [ECG]), all adjusted to the same time scale.

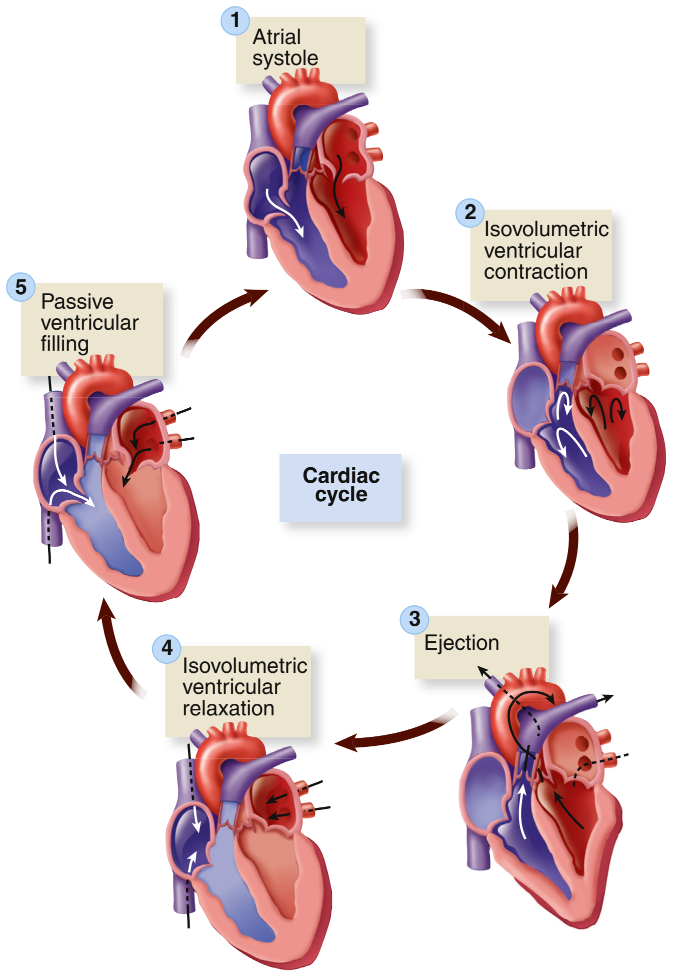

FIGURE 31-6 **Phases of the Cardiac Cycle. 1,** Atrial systole. **2,** Isovolumetric ventricular contraction. Ventricular volume remains constant as pressure increases rapidly. **3,** Ejection. **4,** Isovolumetric ventricular relaxation. Both sets of valves are closed, and the ventricles are relaxing. **5,** Passive ventricular filling. The atrioventricular *(AV)* valves are forced open, and the blood rushes into the relaxing ventricles. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

As blood is pushed through the inflow and outflow tracts of the ventricles, it flows around the **crista supraventricularis**—the muscle that separates the inflow from the outflow tracts—and is mixed by passing through the strands of the **trabeculae carneae.**

Normal Intracardiac Pressures

Normal intracardiac pressures are shown in Table 31-1 and Figure 31-7. Atrial pressure (see venous pulse in Figure 31-5) curves are composed of the **a wave,** which is generated by atrial contraction, and the **v wave,** which is an early diastolic peak caused by filling of the atrium from the peripheral veins. A smaller pressure increase, the **c wave,** occurs after the a wave in early systole and may represent bulging of the mitral valve into the left atrium during early systole. Two aspects of falling atrial pressure have also been named. The **x descent** follows the a wave and is produced by the descent of the tricuspid valve ring and by the ejection of blood from both ventricles. The **y descent** that follows the v wave reflects the rapid

flow of blood from the great veins and right atrium into the right ventricle. Left ventricular pressures are illustrated by a peak systolic pressure and an end-diastolic pressure, which is the ventricular pressure immediately before the onset of systole. The minimal left ventricular pressure occurs in early diastole.

Structures That Support Cardiac Metabolism: The Coronary Vessels

To supply oxygen and other nutrients to the myocardium, heart structures are nourished by vessels of the systemic circulation, the *coronary circulation*. The coronary arteries receive blood through openings in the aorta, called the *coronary ostia.* The cardiac veins empty into the right atrium through another ostium, the opening of a large vein called the *coronary sinus* (Figure 31-8).

TABLE 31-1 NORMAL INTRACARDIAC PRESSURES

	MEAN (mmHg)	RANGE (mmHg)
Right atrium	4	0-8
Right ventricle		
Systolic	24	15-28
End-diastolic	4	0-8
Left atrium	7	4-12
Left ventricle		
Systolic	130	90-140
End-diastolic	7	4-12

Coronary Arteries

The major coronary arteries are the **right coronary artery (RCA)** and the **left coronary artery (LCA)** (see Figure 31-8). These arteries traverse the epicardium and branch several times. The right coronary artery has greater flow than the left in 70% of individuals, the left greater than the right in 10%, and equal flow in each is found in 20% of individuals.[3] The pattern of branching through the visceral pericardium differs among individuals. The branches of the coronary arteries enter the myocardium and endocardium and branch further to become arterioles and then capillaries. The coronary arteries are smaller in women than in men, a fact that is attributed to differences in heart weight.

The left coronary artery arises from a single ostium (opening) behind the left cusp of the aortic semilunar valve. This artery ranges from a few millimeters to a few centimeters in length. It passes between the left atrial appendage and the pulmonary artery and generally divides into two branches—the left anterior descending artery and the circumflex artery. Other branches of the left main coronary artery are distributed diagonally across the free wall of the left ventricle.

The **left anterior descending (LAD) artery** delivers blood to portions of the left and right ventricles and much of the interventricular septum. The left anterior descending artery initially travels in a groove between the left and right ventricles down the anterior surface of the interventricular septum toward the apex of the heart.

The **circumflex artery** travels in a groove called the **coronary sulcus,** which separates the left atrium from the left ventricle, to the left border of the heart. It supplies blood to the left atrium and the lateral wall of the left ventricle. The circumflex

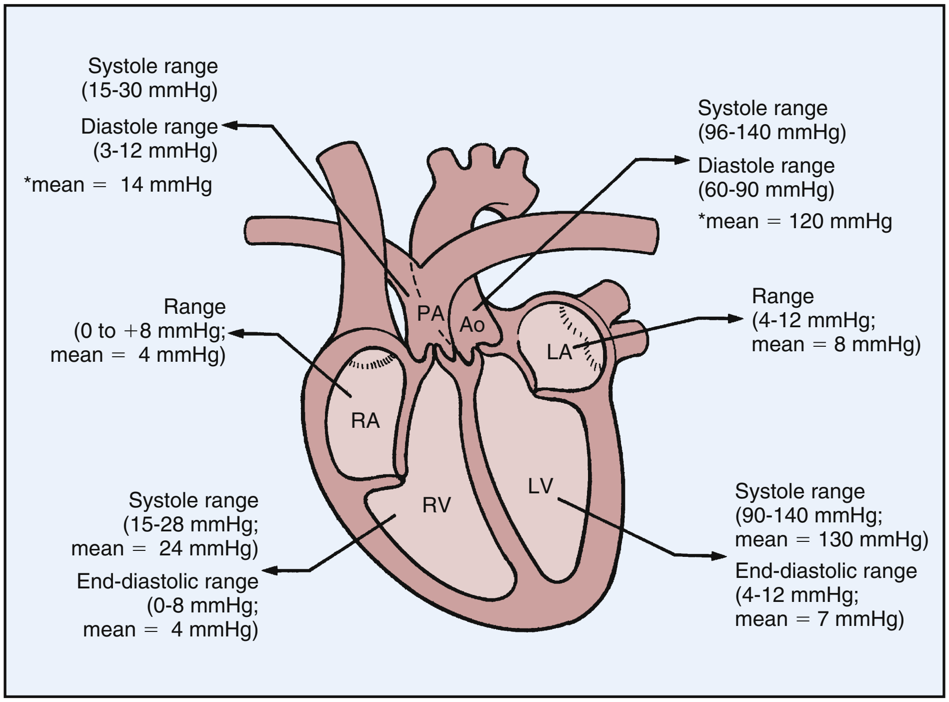

FIGURE 31-7 Normal Intracardiac Pressures. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle. *Main mean pressure.

artery often branches to the posterior surfaces of the left atrium and left ventricle (see Figure 31-8).

The right coronary artery originates from an ostium behind the right aortic cusp, travels behind the pulmonary artery, and extends around the right heart to the heart's posterior surface, where it branches to the right atrium and ventricle. The three major branches of the right coronary artery include the conus, which supplies blood to the upper right ventricle; the right marginal branch, which traverses the right ventricle to the apex; and the posterior descending branch, which lies in the posterior interventricular sulcus and supplies smaller branches to both ventricles.

Collateral Arteries

The **collateral arteries** are connections, or anastomoses, between branches of the same coronary artery or connections of branches of the right coronary artery with branches of the left. They are particularly common within the interventricular and interatrial septa, at the apex of the heart, over the anterior surface of the right ventricle, and around the sinus node. The epicardium contains more collateral vessels than the endocardium.

The functional importance of the collateral circulation is that it protects the heart from ischemia. The collateral circulation is responsible for supplying blood and oxygen to the myocardium that has been deprived of oxygen following narrowing

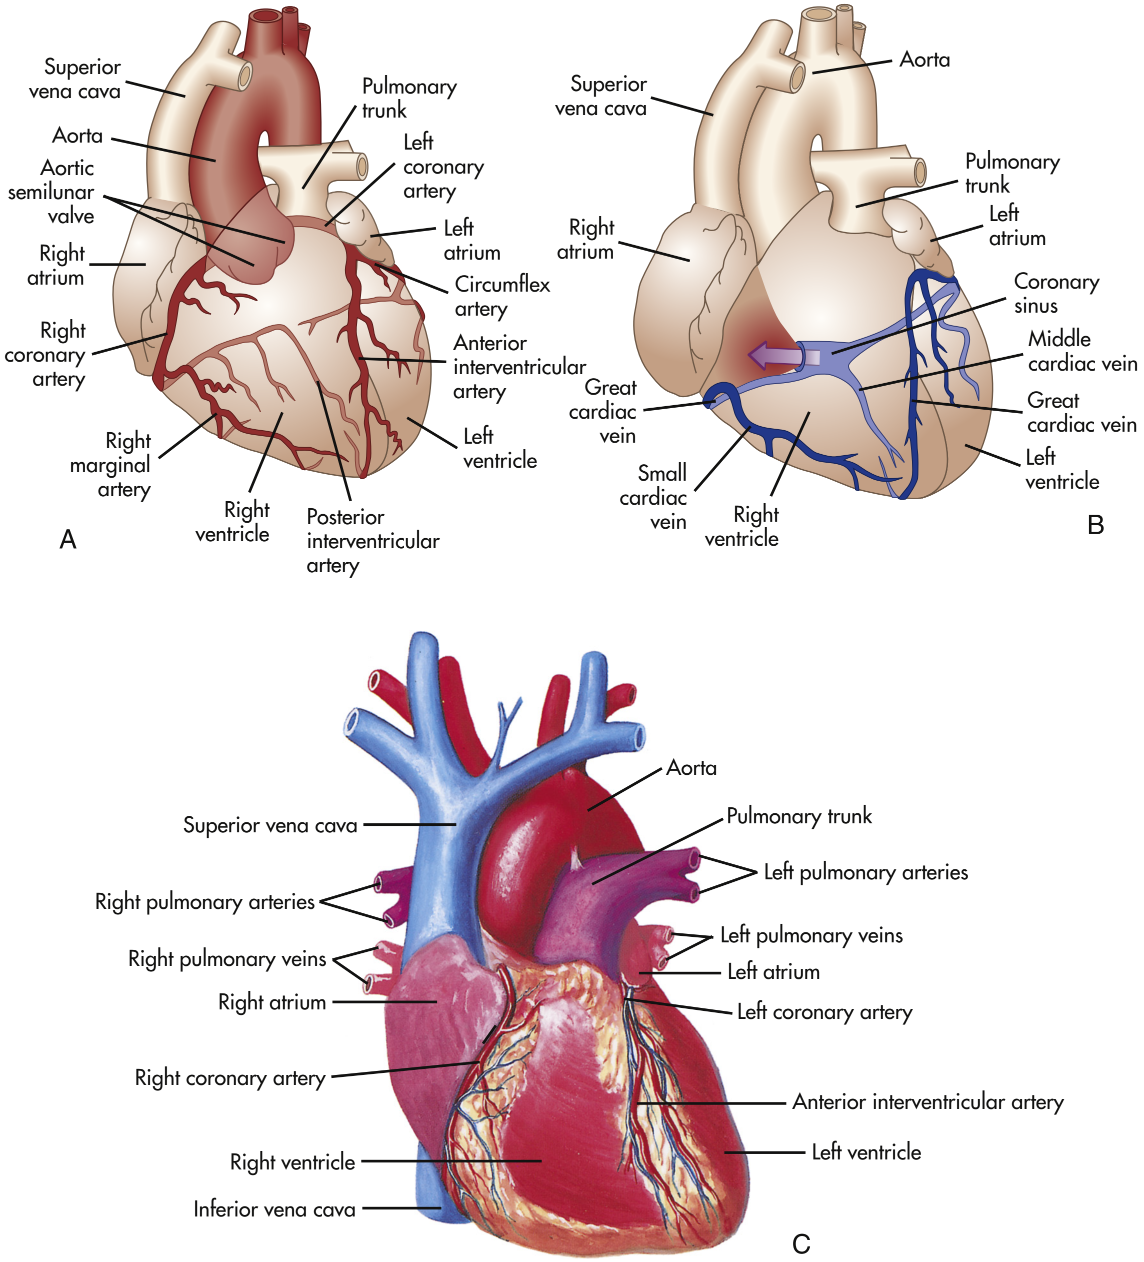

FIGURE 31-8 Coronary Circulation. **A,** Arteries. **B,** Veins. Both **A** and **B** are anterior views of the heart. Vessels near the anterior surface are more darkly colored than vessels of the posterior surface seen through the heart. **C,** View of the anterior (sternocostal) surface. (**A** and **B** modified from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby. **C** from Seeley RR, Stephens TD, Tate P: *Anatomy & physiology,* ed 3, St Louis, 1995, Mosby.)

of a major coronary artery (coronary artery disease). Gradual coronary occlusion results in the growth of coronary collaterals. New collateral vessels are formed through two processes: **arteriogenesis** (new artery growth branching from pre-existing arteries) and **angiogenesis** (growth of new capillaries within a tissue).[4] A key stimulus to collateral growth is the **shear stress** caused by increased blood flow velocity that occurs close to sites of **stenosis** (narrowing) or occlusion. Shear stress activates the endothelium of the pre-existing arterioles and stimulates the production of growth factors and cytokines, including monocyte chemoattractant protein-1 (MCP-1) and vascular endothelial growth factor (VEGF).[5] Current research is focused on identifying whether some of these factors that stimulate collateral growth might prove to be useful treatments for persons with myocardial ischemia, although to date none have been demonstrated to be effective.[5]

Coronary Capillaries

The heart has an extensive capillary network, with approximately 3300 capillaries per square millimeter (ca/mm^2) or about one capillary per muscle cell (muscle fiber). Blood travels from the arteries to the arterioles and then into the capillaries, where exchange of oxygen and other nutrients takes place.

Alterations of the cardiac muscles dramatically affect blood flow in the capillaries. For example, in ventricular hypertrophy (enlargement of the ventricular myocardium), the capillary network does not expand along with muscle fiber size. Therefore, the same number of capillaries must now perfuse a larger area. This results in decreased exchange of oxygen and nutrients. At rest, the heart extracts 70% to 80% of the oxygen delivered to it and coronary blood flow is directly correlated with myocardial oxygen consumption.[6]

Coronary Veins and Lymphatic Vessels

After passing through the extensive capillary network, blood from the coronary arteries drains into the cardiac veins, which travel alongside the arteries. Most of the venous drainage of the heart occurs through veins in the visceral pericardium. The veins then feed into the great cardiac vein (see Figure 31-8) and coronary sinus on the posterior surface of the heart, between the atria and ventricles, in the coronary sulcus. Venous coronary blood empties into the right atrium from the coronary sinus. Blood from the left ventricular walls generally is drained through the coronary sinus and its tributaries, which together form the largest system of coronary veins. The anterior interventricular vein flows beside the LAD artery and then turns to join the circumflex artery and becomes the **great cardiac vein** that primarily drains the anterior surface of the heart. The **posterior vein of the left ventricle,** the largest on the posterior surface of the heart, branches from the coronary sinus and accompanies the circumflex artery and then joins the great cardiac vein.[3]

The myocardium has an extensive system of lymphatic capillaries and collecting vessels within the layers of the myocardium and also in the valves. With cardiac contraction the lymphatic vessels drain fluid to the paratracheal lymph nodes in the anterior mediastinum and then continue to join the mediastinal lymphatic vessels. Impairment of cardiac lymphatic function has been hypothesized to impact cardiac conduction, protection from infection, and the development of myocardial fibrosis and atherosclerosis.[7]

Structures That Control Heart Action

Our lives depend on the continuous repetition of the cardiac cycle (systole and diastole) that occurs because of the transmission of electrical impulses, termed **cardiac action potentials,** through the myocardium. (Action potentials are described in Chapters 1 and 3.) As an electrical impulse passes from cell to cell (fiber to fiber) in the myocardium, it stimulates an intracellular process that results in fiber shortening—that is, muscular contraction or systole. Between action potentials, the fibers relax and return to their resting length, causing diastole. The muscle fibers of the myocardium are electrically coupled so that action potentials pass from cell to cell very rapidly and efficiently. The myocardial structures that allow the action potentials to move so rapidly through the heart are the gap junctions in the intercalated disks. In the intercalated disks, the channel-forming proteins, called **connexins,** form pores in the gap junctions.[8] As a result of these structures plus the heart's conduction system, an action potential generated in one part of the myocardium passes very quickly throughout the heart, causing rapid, organized, sequential contraction of the atria and then the ventricles.

The myocardium differs from skeletal muscle tissue in that it contains its own pacemakers and **conduction system**—specialized cells that enable it to generate and transmit action potentials without input from the nervous system (Figure 31-9). The pacemaker cells are concentrated at two sites in the myocardium called **nodes,** the sinoatrial (SA) node and the atrioventricular (AV) node. Although the heart is innervated by the autonomic nervous system (sympathetic and parasympathetic fibers), neural impulses are not needed to maintain the cardiac cycle. Thus the heart will beat in the absence of any nervous connection, one of the many factors that allow heart transplantation to be successful. The cardiac cycle is stimulated by the nodes of specialized cells and then adjusted to the physical needs of the body by the autonomic fibers. The sympathetic and parasympathetic nerves affect the speed of the cardiac cycle (**heart rate,** or beats per minute), the force of contraction, and the diameter of the coronary vessels (Figure 31-10). The sympathetic nervous system increases heart rate and conduction through the nodes, the parasympathetic nervous system slows heart rate and prolongs intranodal conduction time, and both systems cause coronary vasodilation.[9]

Heart action is also influenced by substances delivered to the myocardium in coronary blood. Nutrients and oxygen are needed for cellular survival and normal function, and hormones and biochemicals, including medications, can affect the strength and duration of myocardial contraction and the degree and duration of myocardial relaxation. Normal or appropriate function depends on the availability of these substances, which is why coronary artery disease can seriously disrupt heart function.

Conduction System

Normally electrical impulses arise in the **sinoatrial (SA) node (SA node, sinus node),** the usual *pacemaker of the heart.* The SA

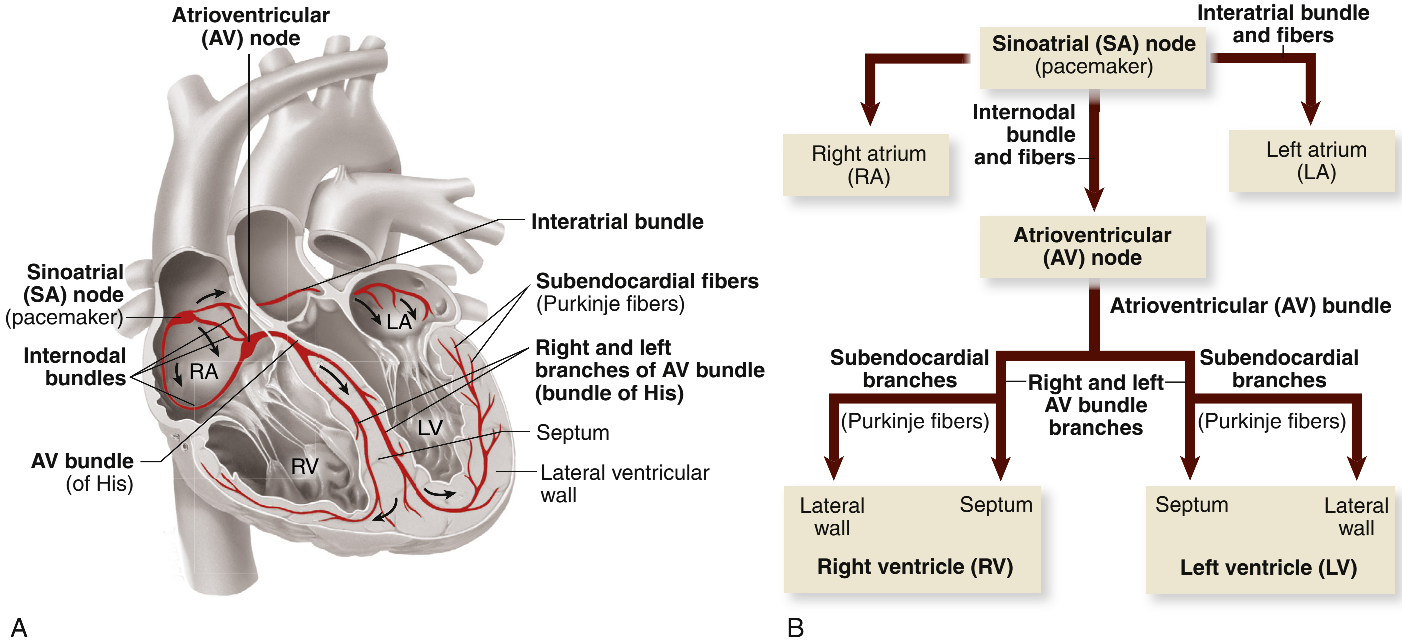

FIGURE 31-9 **Conduction System of the Heart.** Specialized cardiac muscle cells *(boldface type)* in the wall of the heart rapidly initiate or conduct an electrical impulse throughout the myocardium. Both the sketch of the conduction system **(A)** and the flowchart **(B)** show the origin and path of conduction. The signal is initiated by the SA node (pacemaker) and spreads to the rest of the right atrial myocardium directly, to the left atrial myocardium by way of a bundle of interatrial conducting fibers, and to the AV node by way of three internodal bundles. The AV node then initiates a signal that is conducted through the ventricular myocardium by way of the AV bundle (of His) and subendocardial branches (Purkinje fibers). (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

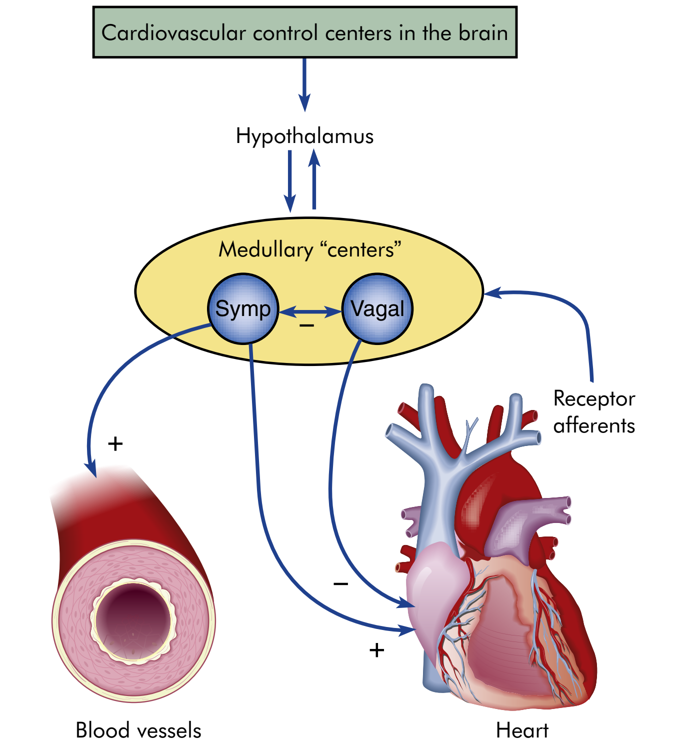

FIGURE 31-10 **Autonomic Innervation of Cardiovascular System.** +, Activation; –, inhibition; *Symp,* sympathetic.

node is located at the junction of the right atrium and superior vena cava, just above the tricuspid valve (see Figure 31-9). The SA node sits only about 1 mm beneath the visceral pericardium, making it vulnerable to injury and disease, especially pericardial inflammation. The SA node is nourished by the sinus node artery, which passes through the center of the node. The SA node is heavily innervated by both sympathetic and parasympathetic nerve fibers. Impulse formation is thought to occur in two cell types found in the node—spindle- and spider-shaped cells.[9]

In the resting adult the SA node generates about 60 to 100 action potentials per minute depending on age and physical condition. Each action potential travels rapidly from cell to cell and through special pathways in the atrial myocardium, causing both atria to contract, beginning systole. The action potential is transmitted from the atrial to the ventricular myocardium through fibers of the conduction system, traveling first to the **atrioventricular (AV) node,** then to the **bundle of His (atrioventricular bundle, common bundle),** and finally through the **bundle branches** of the interventricular septum to Purkinje fibers in the heart wall (see Figure 31-9).

The AV node is well situated for mediating conduction between the atria and ventricles. It is located in the right atrial wall above the tricuspid valve and anterior to the ostium of the coronary sinus. There is variability in the size and length of the AV node fibers. Generally the AV node is thicker and shorter in size than the SA node. Behind the AV node are numerous autonomic parasympathetic ganglia. (The nervous systems are described in Chapter 15.)

Conducting fibers from the AV node converge to form the bundle of His. The bundle of His, which is triangular shaped, lies within the posterior border of the interventricular septum. The two lower ends of the triangle give rise to the right and left bundle branches. The **right bundle branch (RBB)** is thin and travels without much branching to the right ventricular apex. Because of its thinness and relative lack of branches, the RBB is susceptible to interruption by damage to the endocardium.

The **left bundle branch (LBB)** arises perpendicularly from the bundle of His and, in some hearts, divides into two branches, or fascicles. The left anterior bundle branch (LABB) passes the left anterior papillary muscle and the base of the left ventricle and crosses the aortic outflow tract. Damage to the aortic valve or the left ventricle can interrupt this branch. The left posterior bundle branch (LPBB) travels posteriorly, crossing the left ventricular inflow tract to the base of the left posterior papillary muscle. This branch spreads diffusely through the posterior inferior left ventricular wall. Blood flow through this portion of the left ventricle is relatively nonturbulent, so the LPBB is somewhat protected from injury caused by wear and tear. The **Purkinje fibers** are the terminal branches of the right and left bundle branches. They extend from the ventricular apexes to the fibrous rings and penetrate the heart wall to the outer myocardium.

Cardiac Excitation. From the SA node the impulse that begins systole spreads throughout the right atrium at a conduction velocity of about 35 cm/sec.[9] Because impulses from the SA node arrive at the AV node very quickly, investigators have proposed that these nodes are connected by internodal pathways, called the anterior, middle, and posterior internodal pathways. However, the existence of these pathways is controversial; not all experts agree that they exist.[9]

The action potential is delayed in the region of the AV node, possibly because of electrophysiologic differences in the cells that comprise the AV region. Conduction velocity within the node is about 10 cm/sec, markedly slower than conduction through the atria.[9] The delay between atrial and ventricular excitation permits an additional boost to ventricular filling by atrial contraction (atrial kick). From the AV node the impulse travels from the AV bundle and through the bundle branches to the Purkinje fibers. Conduction velocities in the AV and Purkinje fibers are the most rapid in the heart.

Ventricular activation occurs sequentially in three phases: (1) septal activation, (2) apical activation, and (3) basal (upper) and posterior activation. The first areas of the ventricles to be excited are portions of the interventricular septum. The septum is activated from both the RBB and the LBB, although the impulse travels from left to right. The extensive network of Purkinje fibers promotes the rapid spread of the impulse to the ventricular apexes. Activation traverses the heart wall from the inside outward (from the endocardium to the epicardium; see Figure 31-2). The basal and posterior portions of the ventricles are the last to be activated. Deactivation, which begins in diastole, occurs in the opposite direction, spreading from the outside inward (epicardium to endocardium). All areas of the ventricle recover at about the same time.

TABLE 31-2 INTRACELLULAR AND EXTRACELLULAR ION CONCENTRATIONS IN THE MYOCARDIUM

ION	INTRACELLULAR CONCENTRATION	EXTRACELLULAR CONCENTRATION
Sodium (Na^+)	15 mM	145 mM
Potassium (K^+)	150 mM	4 mM
Chloride (Cl^-)	5-30 mM	120 mM
Calcium (Ca^{++})	10^{-7} M	2 mM

Propagation of Cardiac Action Potentials. Electrical activation of the muscle cells, termed **depolarization,** is caused by the movement of ions, including sodium, potassium, calcium, and chloride, across cardiac cell membranes. Deactivation, called **repolarization,** occurs the same way. (Movement of ions across cell membranes is described in Chapter 1; electrical activation of muscle cells is described in Chapter 43.)

Movement of ions into and out of the cell creates an electrical (voltage) difference across the cell membrane called the *membrane potential.* The resting membrane potential of myocardial cells is between −80 and −90 millivolts (mV), whereas the SA node is between −50 and −60 mV and the AV node is between −60 and −70 mV.[9] During depolarization the inside of the cell becomes less negatively charged. In cardiac cells the difference between resting membrane potential (in millivolts) and the decreased negative charge caused by depolarization is the cardiac action potential. Table 31-2 summarizes the intracellular and extracellular ionic concentrations of cardiac muscle. The various phases of the cardiac action potential are related to changes in the permeability of the cell membrane to sodium, potassium, chloride, and calcium. Threshold is the point at which the cell membrane's selective permeability to these ions is temporarily disrupted, leading to depolarization. If the resting membrane potential becomes more negative as a result of a decrease in extracellular potassium concentration (hypokalemia), it is termed *hyperpolarization*.

Normal myocardial cell depolarization and repolarization occur in five phases numbered 0 through 4 (Figure 31-11). Phase 0 consists of depolarization. This phase lasts 1 to 2 milliseconds (ms) and represents rapid sodium entry into the cell. Phase 1 is early repolarization, in which calcium slowly enters the cell. Phase 2, also called the *plateau,* is a continuation of repolarization, with slow entry of calcium and sodium into the cell. Potassium is moved out of the cell during phase 3, with a return to resting membrane potential in phase 4.[9] The time between action potentials corresponds to diastole.

The phases of depolarization and repolarization occur somewhat differently in the SA and AV node cells, a difference that enables these cells to generate cardiac action potentials independently. The cells of the Purkinje fibers, atria, and ventricles begin with a negative resting membrane potential and proceed to a rapid upstroke, or depolarization (phase 0), a rapid early

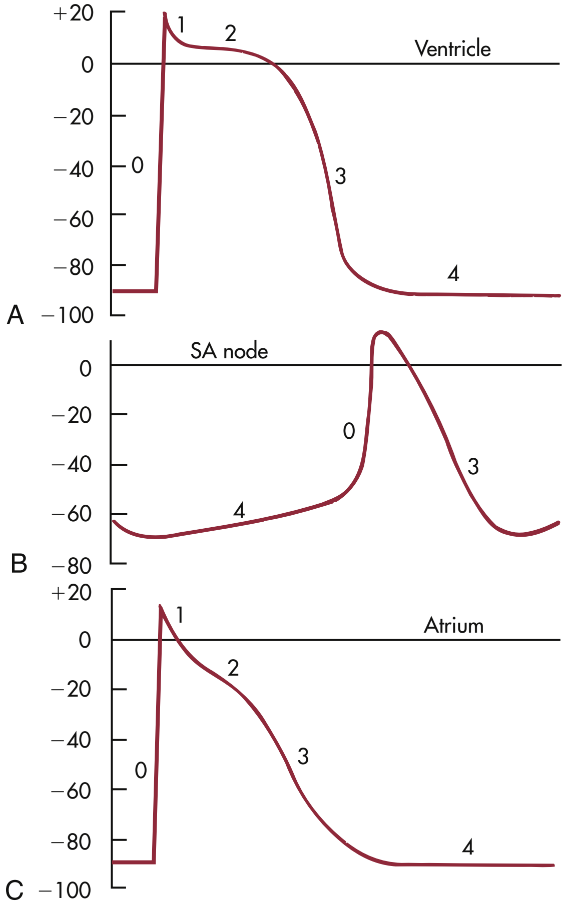

FIGURE 31-11 Cardiac Action Potentials. **A,** Ventricle. **B,** Sinoatrial *(SA)* node. **C,** Atrium. Sweep velocity in **B** is half that in **A** or **C.** (Modified from Koeppen BM, Stanton BA: *Berne and Levy physiology,* ed 6, Philadelphia, 2010, Mosby.)

repolarization (phase 1), a plateau (phase 2), and a rapid later repolarization (phase 3) (see Figure 31-11, *A* and *C*). The fast inward current of phase 0 is mediated by sodium ions flowing through "fast channels" in the cell membrane and causes the rapid upstroke of the action potential in Purkinje fibers, atria, and ventricles. In contrast, the cells of the SA and AV nodes begin with a less negative resting membrane potential, proceed to a slow upstroke (phase 0), and usually lack a plateau (phase 2) (see Figure 31-11, *B*). The slow inward current, mediated by calcium through transient and long-lasting channels and sodium ions flowing through "slow channels" of the cell membrane, is responsible for the action potential of the SA node and the AV node. Hence, drugs that block calcium have profound effects on the slow inward current and can alter heart rate. Slow channel-blocking drugs, such as verapamil, are used to treat a variety of cardiovascular disorders.

A refractory period, during which no new cardiac action potential can be initiated by a stimulus, follows depolarization. This effective or absolute refractory period corresponds to the time needed for the reopening of channels that permit sodium and calcium influx (phase 0 through half of phase 3). A relative refractory period occurs near the end of repolarization, following the effective refractory period. During this time the membrane can be depolarized again but only by a greater than normal stimulus. Abnormal refractory periods as a result of disease can cause abnormal heart rhythms, or dysrhythmias, including ventricular fibrillation and cardiac arrest (see Chapter 32).

Normal Electrocardiogram. The genesis of the normal electrocardiogram is from electrical activity recorded by skin electrodes, that is, the sum of all cardiac action potentials (Figure 31-12). The **P wave** represents atrial depolarization. The **PR interval** is a measure of time from the onset of atrial activation to the onset of ventricular activation; it normally ranges from 0.12 to 0.20 second. The PR interval represents the time necessary to travel from the sinus node through the atrium, AV node, and His-Purkinje system to activate ventricular myocardial cells. The **QRS complex** represents the sum of all ventricular muscle cell depolarizations. The configuration and amplitude of the QRS complex vary considerably among individuals. The duration is normally between 0.06 and 0.10 second. During the **ST interval** the entire ventricular myocardium is depolarized. The **QT interval** is sometimes called the "electrical systole" of the ventricles. It lasts about 0.4 second, but it varies inversely with the heart rate.

Automaticity. Automaticity, or the property of generating spontaneous depolarization to threshold, enables the SA and AV nodes to generate cardiac action potentials without any stimulus. Cells capable of spontaneous depolarization are called **automatic cells.** The automatic cells of the cardiac conduction system can stimulate the heart to beat even when the heart is removed from the body. Spontaneous depolarization is possible in automatic cells because the membrane potential does not "rest" during phase 4. Instead, it slowly creeps toward threshold during the diastolic phase of the cardiac cycle. Because threshold is approached during diastole, phase 4 in automatic cells is called **diastolic depolarization.** The electrical impulse normally begins in the SA node because its cells depolarize more rapidly than other automatic cells. The ionic basis for this diastolic depolarization is the regular rhythmic oscillation of calcium with the automatic cells, a phenomenon known as the "calcium clock."[9]

Rhythmicity. Rhythmicity is the regular generation of an action potential by the heart's conduction system. The SA node sets the pace because normally it has the fastest rate of depolarization, which is why it is called the *natural pacemaker of the heart.* The SA node depolarizes spontaneously 60 to 100 times per minute. If the SA node is damaged, the AV node will become the heart's pacemaker at a rate of about 40 to 60 spontaneous depolarizations per minute. Purkinje fibers also are capable of spontaneous depolarization but at a rate of only 30 to 40 beats/minute; therefore they only function as pacemakers when the SA and AV nodes are diseased or there is interruption to movement of electrical current through the heart.

Cardiac Innervation

Although the heart's nodes and conduction system generate cardiac action potentials independently, the autonomic nervous system influences the rate of impulse generation (firing), depolarization, and repolarization of the myocardium and the strength of atrial and ventricular contraction. Autonomic neural transmission produces changes in the heart and

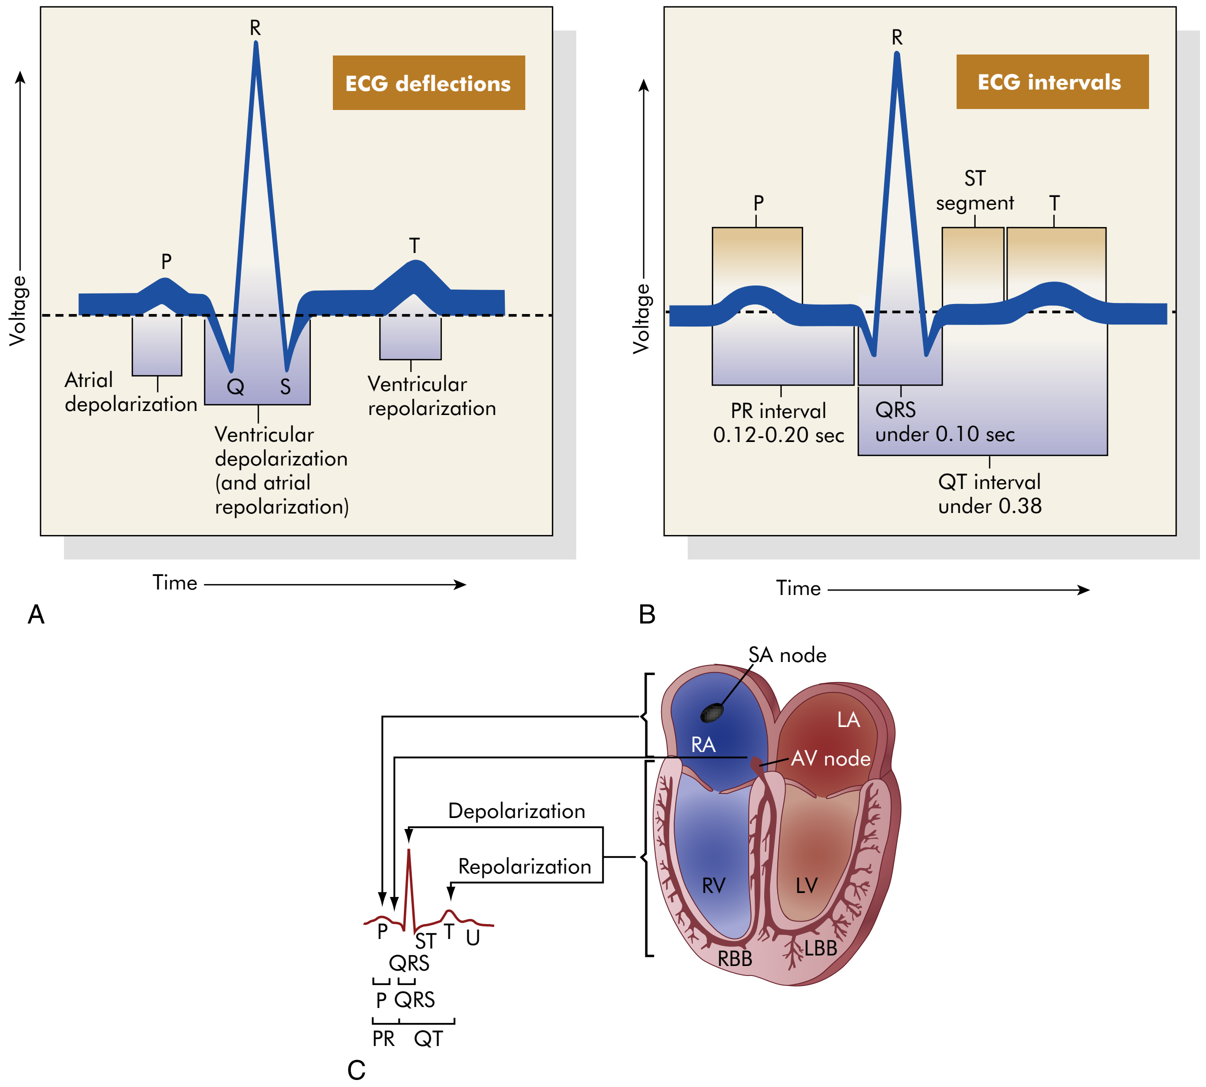

FIGURE 31-12 **Electrocardiogram (ECG) and Cardiac Electrical Activity. A,** Normal ECG. circulatory system faster than metabolic or humoral agents (see Figure 31-10). Speed is important, for example, in stimulating the heart to increase its pumping action during times of stress and fear, the so-called *fight-or-flight response,* or with increased physical activity. Although increased delivery of oxygen, glucose, hormones, and other blood-borne factors sustains increased cardiac activity, the rapid initiation of increased activity depends on the sympathetic and parasympathetic fibers of the autonomic nervous system. (The autonomic nervous system is described and illustrated in Chapter 15.)

Sympathetic and Parasympathetic Nerves. Sympathetic and parasympathetic nerve fibers innervate all parts of the atria and ventricles and the SA and AV nodes. In general, sympathetic stimulation increases electrical conductivity and the strength of myocardial contraction, and vagal parasympathetic nerve activity does the opposite, slowing the conduction of action potentials through the heart and reducing the strength of contraction.

Efferent sympathetic fibers originate in the thoracic spinal cord and branch into the superior middle and inferior cardiac nerves. They join at the **cardiac plexus,** a neural junction located at the root of the aorta in front of the trachea. Sympathetic nervous activity enhances myocardial performance. Catecholamines speed heart rate, shorten the conduction time through the AV node, and increase the rhythmicity of the AV pacemaker fibers. Neurally released norepinephrine or circulating catecholamines interact with β-adrenergic receptors on the cardiac cell membranes. The overall effect is an increased influx of Ca^{++} during the action potential plateau that increases the contractile strength of the heart.

The efferent parasympathetic fibers originate in the medulla oblongata and travel by way of the vagus nerves to join the sympathetic nerves in the cardiac plexus. Parasympathetic (vagal) activity causes the release of acetylcholine. Receptors for these neurotransmitters are found in the myocardium and coronary

vessels of the heart. Acetylcholine decreases heart rate, slows conduction through the AV nodes, and reduces myocardial contraction strength.[9]

Adrenergic Receptor Function. Sympathetic neural stimulation of the myocardium and coronary vessels depends on the presence of G-protein–coupled adrenergic receptors, which bind specifically with neurotransmitters of the sympathetic nervous system. (Receptor physiology is discussed in Chapter 1.) The effects of sympathetic stimulation depend on whether (1) the α- or β-adrenergic receptors are most plentiful on cells of the effector tissue, (2) the neurotransmitter is norepinephrine or epinephrine, and (3) the extent to which the individual variations in receptor structure caused by single nucleotide polymorphisms (SNPs) influence receptor responsiveness.[10,11]

There are five types of adrenergic receptors: β_1, β_2, β_3, α_1, and α_2 (see Table 15-7). Each of the α-adrenergic receptors also has three subtypes, so some sources indicate that there are nine types of adrenergic receptors.[11,12] Overall, cardiovascular structures have more β than α receptors; therefore, effects mediated by the β receptors predominate. Norepinephrine is released by postsynaptic sympathetic nerve endings in the heart while epinephrine is mainly released by the adrenal medulla and reaches the heart through the bloodstream.

The β_1 receptors are found mostly in the heart, specifically the conduction system (AV and SA nodes, Purkinje fibers) and the atrial and ventricular myocardium. The β_2 receptors are found in the heart and also on vascular smooth muscle. Stimulation of both the β_1 and β_2 receptors results in an increase in heart rate (chronotropy) and force of myocardial contraction (inotropy).[13] In addition, stimulation of the β_2 receptors results in vasodilation because of the location of the receptors on vascular smooth muscle. Overall β_1 and β_2 stimulation enables the heart to pump more blood and β_2 stimulation also increases coronary blood flow, and β_3 receptors are also found in the myocardium and coronary vessels. In the heart, stimulation of these receptors opposes the effects of β_1- and β_2-receptor stimulation and decreases myocardial contractility (negative inotropic effect).[13] Thus β_3 receptors may provide a "safety mechanism" to prevent overstimulation of the heart by the sympathetic nervous system.

Norepinephrine binding with α_1 receptors, all of which are postsynaptic in the systemic and coronary arteries, causes smooth muscle contraction and thus vasoconstriction. One of the three subtypes of α_2 receptors, α_{2a}, is located on the sympathetic ganglia and nerve terminals. The effect of norepinephrine on these receptors is to inhibit release of more norepinephrine, which promotes vasodilation, thus providing another safety mechanism to prevent excess blood pressure elevation.[13] Dysfunction of α- and β-adrenergic receptors can occur in many conditions (e.g., diabetes, hypertension) and has been implicated in the pathogenesis of many cardiac diseases, including heart failure, myocardial ischemia, and dysrhythmias.[10,11,13]

Myocardial Cells

The cells of cardiac muscle (the myocardium) and of skeletal muscle are nearly identical in structure, function, and microscopic appearance. (The properties of skeletal muscle are described in detail in Chapter 43.) Both types of muscle tissue are composed of long, narrow cells, called *fibers,* that contain basically the same structures: bundles of longitudinally arranged myofibrils; a single nucleus (cardiac muscle) or many nuclei (skeletal muscle); mitochondria; an internal membrane system (the sarcoplasmic reticulum); cytoplasm (sarcoplasm); and a plasma membrane (the sarcolemma), which encloses the cell. Cardiac and skeletal muscle cells also have an "external" membrane system made up of transverse tubules (T tubules) formed by invaginations of the sarcolemma. The sarcoplasmic reticulum forms a network of channels that surround the muscle fiber.

The microscopic appearance of cardiac and skeletal muscle is somewhat similar as well (see Chapter 1, Table 1-8). Because the myofibrils in both types of fibers consist of alternating light and dark bands of protein, the fibers appear striped, or striated. The dark and light bands of the myofibrils comprise longitudinal repeating units called *sarcomeres.* The length of the sarcomeres, normally between 1.6 and 2.2 mm, is important because it determines the limits of myocardial stretch at the end of diastole and subsequently the force of contraction during systole.

Cardiac muscle differs from skeletal muscle in several respects that reflect heart function. Cardiac cells are arranged in branching networks throughout the myocardium, whereas skeletal muscle cells tend to be arranged in parallel throughout the length of the muscle. Cardiac fibers have only one nucleus, whereas skeletal muscle cells have many nuclei. Other differences enable cardiac fibers to (1) transmit action potentials quickly from cell to cell, (2) maintain high levels of energy synthesis, and (3) gain access to more ions, particularly sodium and potassium, in the extracellular environment.

Rapid transmission of electrical impulses from cardiac fiber to cardiac fiber is possible because the network of fibers is connected at specialized intercellular junctions called *intercalated disks.* **Intercalated disks** are thickened portions of the sarcolemma that enable electrical impulses to spread quickly in a continuous cell-to-cell (syncytial) fashion. The intercalated disks contain three junctions: desmosomes, or macula adherens; the fascia adherens, which mechanically attach one cell to another; and gap junctions, also known as tight junctions or the nexus, which allow the electrical impulse to spread from cell to cell (see Chapter 1). Changes in the function of these junctional elements have been associated with an increased risk of dysrhythmias.[9]

Unlike skeletal muscle, the heart cannot rest and is in constant need of energy that is supplied by molecules such as adenosine triphosphate (ATP). Therefore, the cytoplasm surrounding the bundles of myofibrils in each cardiac muscle cell contains a larger number of mitochondria (25% of the cellular volume) than that found in skeletal muscle cells. The large numbers of mitochondria provide the necessary respiratory enzymes for aerobic metabolism and supply quantities of ATP sufficient for the constant action of the myocardium.

The third major difference between cardiac and skeletal muscle cells involves the T tubule system. Cardiac fibers contain more T tubules than skeletal muscle fibers. This increased proximity to the T tubules gives each myofibril in the myocardium faster access to molecules it needs for the continuous

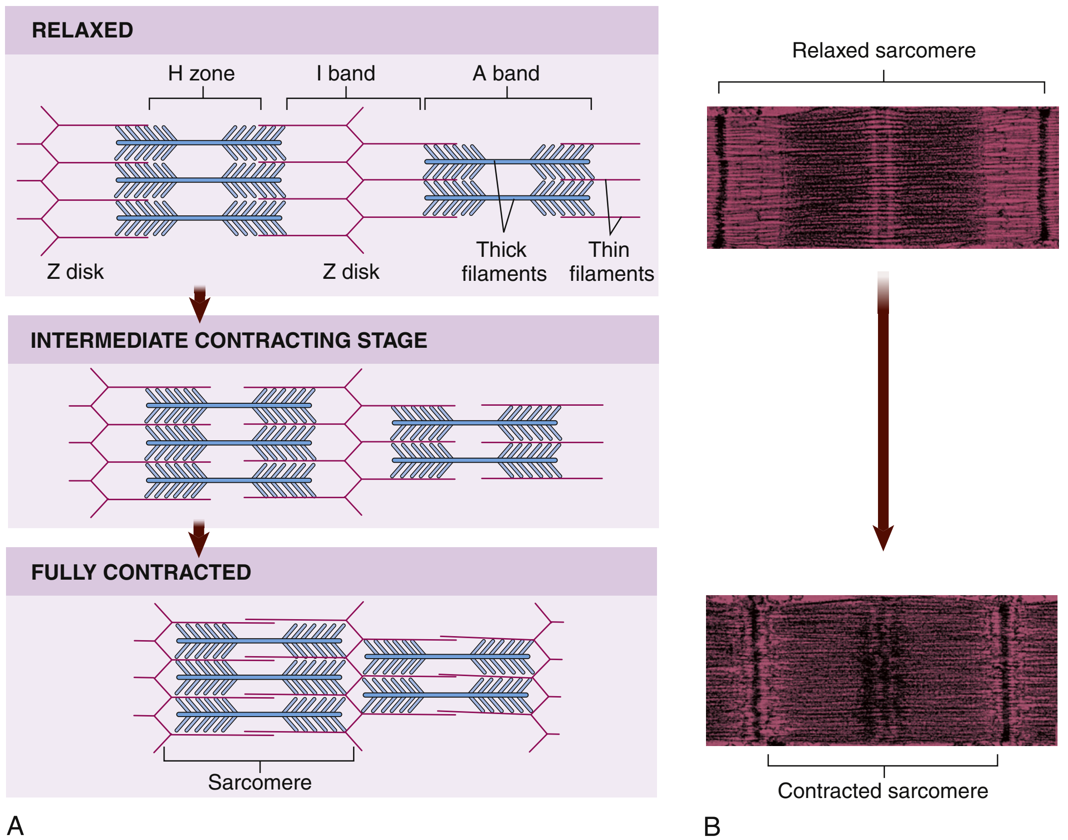

FIGURE 31-13 Sliding-Filament Model. **A,** During contraction, myosin cross-bridges pull the thin filaments toward the center of each sarcomere, thus shortening the myofibril and the entire muscle fiber. **B,** Color-enhanced transmission electron micrographs (TEMs) showing the shortening of a sarcomere caused by the sliding of filaments during muscle contraction. (**A** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby. **B** courtesy H.E. Huxley, Brandeis University, Waltham, MA.)

transmission of action potentials, a process that involves transport of sodium and potassium through the walls of the T tubules. (The mechanisms by which sodium and potassium transport causes transmission of cardiac action potentials are described in Chapters 1 and 43.) Because the T tubule system is continuous with the extracellular space and the interstitial fluid, it facilitates the rapid transmission of electrical impulses from the surface of the sarcolemma to the myofibrils inside the fiber. This activates all the myofibrils of one fiber simultaneously. The sarcoplasmic reticulum is located around the myofibrils. When an action potential is transmitted through the T tubules, it induces the sarcoplasmic reticulum to release its stored calcium, which activates the contractile proteins, actin and myosin, within the sarcomere at the same time. T tubule loss, disruption, and dysregulation are associated with heart failure and atrial fibrillation.[14]

Actin, Myosin, Troponin-Tropomyosin Complex, and Titin. Within each myocardial sarcomere the thick filaments of **myosin** constitute the central dark band called the **anisotropic,** or **A, bands** (Figure 31-13). The myosin molecule resembles a golf club with two large bulbous heads protruding from one end of a straight shaft (Figure 31-14). The bilobed heads contain an actin-binding site and a site of ATPase activity. A thick filament called myosin microfilament is composed of about 200 myosin

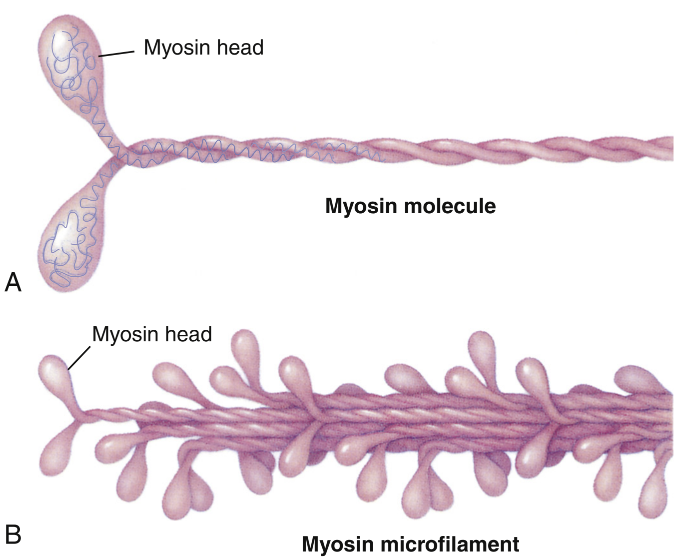

FIGURE 31-14 Structure of Myosin. **A,** Each myosin molecule is a coil of two chains wrapped around each other. At the end of each chain is a globular region, much like a golf club, called the *head.* **B,** Myosin molecules usually are combined into filaments, which are stalks of myosin from which the heads protrude at regular intervals.

molecules bundled together with outward-facing molecule heads called *cross-bridges* because with activation of contraction they will form force-generating bridges with exposed actin molecules (see Figure 31-14, *B*).The actin molecules are part of the thin filaments (Figure 31-15). The light bands are called **isotropic,** or **I, bands** (see Figure 31-13). The thin filaments of actin appear light and extend from the **Z line,** a dense fibrous line that crosses the center of each I band. A sarcomere is the area from one dark Z line to an adjacent Z line with a length that varies from 1.6 to 2.2 mm. In the center of a sarcomere is the H zone, a somewhat less dense region. A thin, dark **M line** travels the center of the H zone. A single tropomyosin molecule (a relaxing protein) lies alongside seven actin molecules. **Troponin,** another relaxing protein, associates with the tropomyosin molecule, forming the **troponin-tropomyosin complex** (see Figure 31-15). The troponin complex itself has three components. **Troponin T** aids in binding of the troponin complex to actin and tropomyosin; **troponin I** inhibits the ATPase of actomyosin; and **troponin C** contains binding sites for the calcium ions involved in contraction. Troponin and tropomyosin are referred to as relaxing proteins because when they cover the myosin-binding sites on the actin, the cross-bridges release and the myocardium relaxes. Also within the sarcomere is a giant elastic protein called **titin** (or connectin), which acts as a spring and is one of the factors responsible for myocardial stiffness and thus impacts diastolic filling of the myocardium.[15]

Myocardial Metabolism. Cardiac muscle, like other muscle tissue, depends on the constant production of ATP for energy. ATP is produced within the mitochondria mainly from glucose, fatty acids, and lactate. If the myocardium is inadequately perfused because of coronary artery disease, anaerobic metabolism must be used as a source of energy (see Chapter 1). The energy produced by metabolic processes is used for muscle contraction and relaxation, electrical excitation, membrane transport, and synthesis of large molecules. Normally, the amount of ATP produced supplies sufficient energy to pump blood systemically.

Cardiac work often is expressed in terms of **myocardial oxygen consumption ($M\dot{V}O_2$).** Because oxidative metabolism is the main process of cardiac energy generation, the rate of oxygen consumption correlates closely with total cardiac energy requirements. $M\dot{V}O_2$ is determined by three major factors: (1) the amount of wall stress during systole, which can be estimated by measuring the systolic blood pressure; (2) the duration of systolic wall tension, which is measured indirectly by the heart rate; and (3) the contractile state of the myocardium, for which no clinical measurement exists.

The oxygen supply to the myocardium is delivered exclusively by the coronary arteries. From 70% to 75% of the oxygen from the coronary arteries is used immediately by cardiac muscle, leaving little oxygen in reserve. Therefore, increased energy needs can be met only by increasing coronary blood flow. Myocardial oxygen consumption can increase several-fold with exercise and decrease moderately under conditions such as hypotension and hypothermia. As myocardial metabolism and consumption of oxygen increases, the concentration of local vasoactive metabolic factors increases. Some of these, such as adenosine, nitric oxide, and prostaglandins, dilate coronary arterioles, thus increasing coronary blood flow.[16]

Myocardial Contraction and Relaxation

Myocardial contractility is a change in developed tension at a given resting fiber length. In functional terms, contractility is the ability of the heart muscle to shorten. On a molecular basis, thin filaments of actin slide over thick filaments of myosin, called the **cross-bridge cycle of muscle contraction.**[17] It is the cycling of cross-bridges that is the molecular basis for myocardial force generation and thus ultimately the heart's ability to pump blood through the circulation. Anatomically, contraction occurs when the sarcomere shortens, causing adjacent Z lines to move closer together (Figure 31-16). The width of the A band, which contains the thick myosin filaments, is unchanged while the I band becomes narrower as the overlap between the thick and thin filaments increases. The degree of shortening of the muscle fibers depends on how much the thin filaments overlap the thick filaments. Maximal contraction occurs when the sarcomere length is 2.2 mm. At 2.2 mm the number of cross-bridge attachments between actin and myosin is maximal.

Cross-Bridge Cycling. The globular head-end of the myosin contains a binding site for actin and a separate enzymatic site that catalyzes the breakdown of ATP to adenosine diphosphate (ADP) and inorganic phosphate (P_i) (see Figure 31-16). This reaction releases the chemical energy stored in ATP. Magnesium is required for the binding of ATP to the myosin site. The splitting of ATP occurs on the myosin molecule before it attaches to actin, but the ADP and inorganic phosphate released remain bound to the active site on myosin. The chemical energy released is transferred to myosin (m), producing a high-energy form of myosin (M):

$$M \bullet ATP \rightarrow M \bullet ADP + P_i$$

The binding of this high-energy myosin-actin form to a cross-bridge releases the energy stored in myosin (e.g., ADP and P_i), producing the force necessary for movement of the cross-bridge. With the attachment of actin to myosin at the cross-bridge, the myosin head molecule undergoes a position change, exerting traction on the rest of the myosin bridge, causing the thin filaments to slide past the thick filaments (see Figure 31-16). During contraction each cross-bridge undergoes several cycles of attachment, movement, and dissociation from the thin filaments.[17]

Calcium and Excitation-Contraction Coupling. **Excitation-contraction coupling** is the process by which an action potential in the plasma membrane of the muscle fiber triggers the cycle of events leading to cross-bridge activity and contraction. Activation of this cycle depends on the availability of calcium.

Calcium is stored in the tubule system and the sarcoplasmic reticulum. It enters the myocardial cell from the interstitial fluid after electrical excitation, which increases the membrane permeability to calcium. Two types of calcium channels (L-type and T-type) are identified in cardiac tissues. The L-type, or long-lasting, channels are the predominant type of calcium channels and are the channels blocked by **calcium channel–blocking drugs** (verapamil, nifedipine, diltiazem). The major

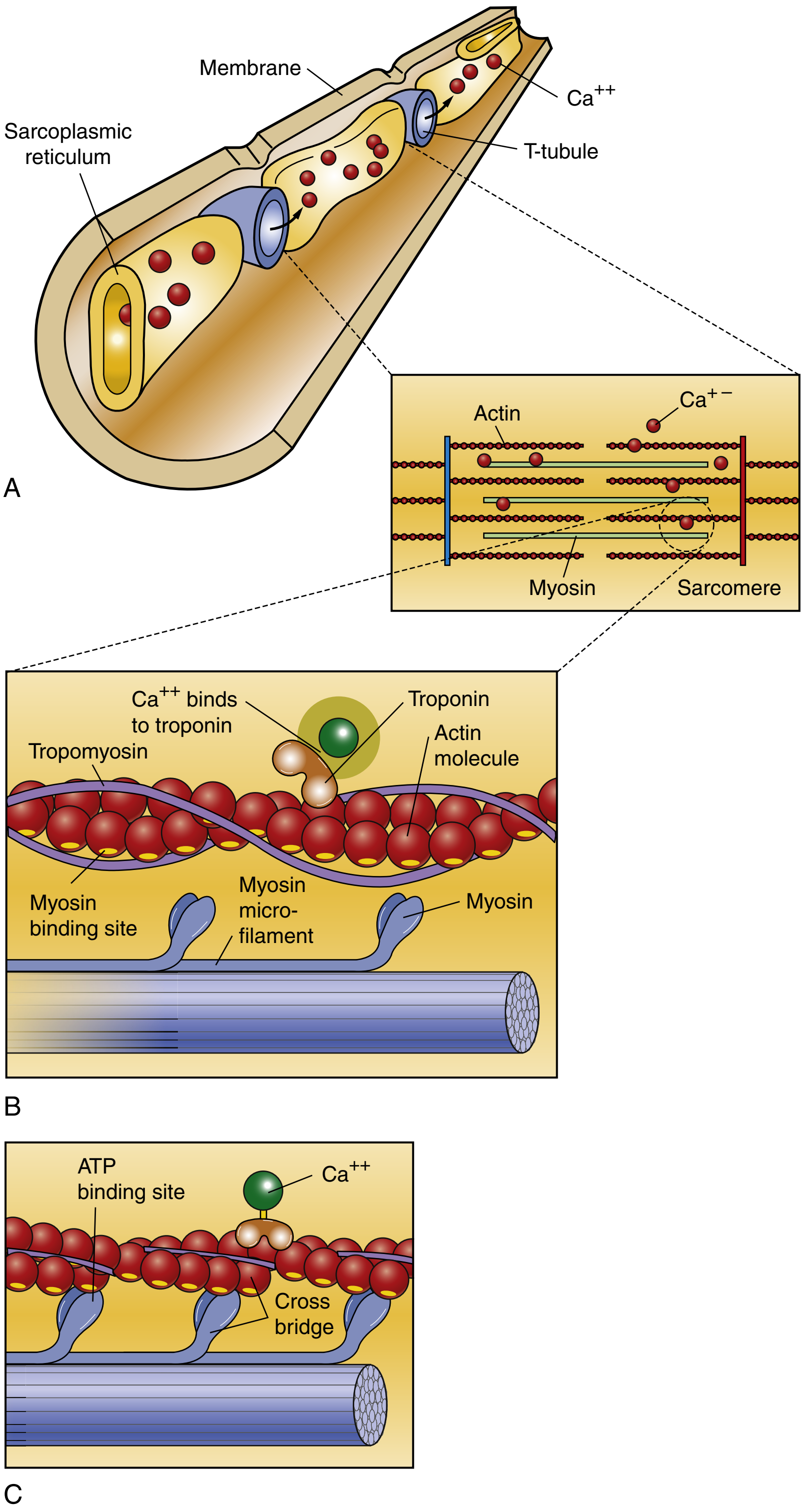

FIGURE 31-15 Myofilaments and Mechanisms of Muscle Contraction. **A,** Thin and thick myofilaments. In resting muscle, calcium ions are stored in the sarcoplasmic reticulum. When an action potential reaches the muscle cell, the T tubules carry the action potential deep into the sarcoplasm. The action potential causes the sarcoplasmic reticulum to release the store of calcium ions. **B,** In resting muscle the myosin-binding sites are covered by troponin and tropomyosin. The calcium ions released into the sarcoplasm as a result of the action potential bind to the troponin. This binding causes the tropomyosin and troponin to move out of the way of the myosin-binding sites, leaving the myosin heads free to bind to the actin microfilament. **C,** ATP is used as an energy molecule to the myosin cross-bridge. (Adapted from Raven PH, Johnson GB: *Understanding biology,* ed 3, Dubuque, IA, 1995, Brown.)

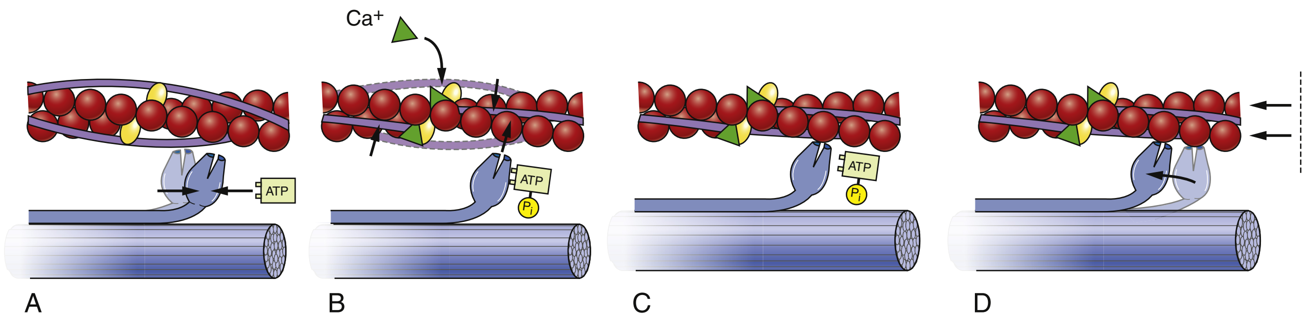

FIGURE 31-16 Cross-Bridge Theory of Muscle Contraction. **A,** Each myosin cross-bridge in the thick filament moves into a resting position after an adenosine triphosphate (ATP) molecule binds and transfers its energy. **B,** Calcium ions released from the sarcoplasmic reticulum bind to troponin in the thin filament, allowing tropomyosin to shift from its position blocking the active sites of actin molecules. **C,** Each myosin cross-bridge then binds to an active site on a thin filament, displacing the remnants of ATP hydrolysis—adenosine diphosphate (ADP) and inorganic phosphate (P_i). **D,** The release of stored energy from step **A** provides the force needed for each cross-bridge to move back to its original position, pulling actin along with it. Each cross-bridge will remain bound to actin until another ATP molecule binds to it and pulls it back into its resting position **(A).** (Adapted from Thibodeau GA, Patton KT: *Anatomy & physiology,* ed 4, St Louis, 1999, Mosby.)

effect of these medications is to decrease the strength of cardiac contraction. The T-type, or transient, channels are much less abundant in the heart and are not blocked by currently available calcium channel–blocking drugs. Calcium that enters the cell from the interstitial fluid triggers release of calcium from the storage sites. The storage sites most important for contraction are from the sarcoplasmic reticulum. Calcium from these sites diffuses toward the myofibrils, where it binds with troponin.

The calcium-troponin complex facilitates the contraction process. In the resting state, troponin I is bound to actin and the configuration of the tropomyosin molecule is such that it covers the sites where the myosin heads bind to actin, thus preventing interaction between actin and myosin. Calcium binding to troponin inhibits troponin C (which enhances troponin I–actin binding) and results in tropomyosin moving troponin I, which uncovers the binding sites on the myosin heads. Myosin and actin can then form cross-bridges, and ATP can be dephosphorylated to ADP. Sliding of the thick and thin filaments can then occur, and the myocardium contracts.

Myocardial Relaxation

Relaxation is just as vital to optimal cardiac function as contraction, and calcium, troponin, and tropomyosin also facilitate relaxation. After contraction, free calcium ions are actively pumped out of the cell back into the interstitial fluid or taken up again by the sarcoplasmic reticulum and stored. As the concentration of calcium within the sarcomere subsequently falls, troponin releases its bound calcium. The tropomyosin complex blocks the active sites on the actin molecule, preventing cross-bridges with the myosin heads. Each tropomyosin molecule is held in this blocking position by a molecule of troponin. Troponin is bound to both tropomyosin and actin (see Figure 31-15).

Factors Affecting Cardiac Output

Cardiac output is the volume of blood flowing through either the systemic or the pulmonary circuit and is expressed in liters per minute. Cardiac output is calculated by multiplying heart rate in beats per minute by **stroke volume** in liters per beat. Normal adult cardiac output at rest is about 5 L/min. The ventricles do not eject all of the blood they contain with each heartbeat and the amount ejected is called the **ejection fraction.** The ejection fraction is calculated by dividing the stroke volume by the end-diastolic volume. The end-diastolic volume (EDV) of the normal ventricle is about 70 to 80 ml/m^2 and the normal ejection fraction of the resting heart is 55% or higher. Ejection fraction is a valuable clinical indicator of ventricular function.[18]

Four factors affect cardiac output directly: preload, afterload, myocardial contractility, and heart rate (Figure 31-17). **Preload** (pressure generated at the end of diastole) and **afterload** (resistance to ejection during systole) depend on the heart as well as the vascular system. Contractility and heart rate are characteristics of the cardiac tissue per se and are influenced by neural and humoral mechanisms. To understand the role of these factors in cardiac performance, it is first necessary to understand two physical laws that explain the mechanisms of heart action: the Frank-Starling law of the heart and Laplace's law.

Frank-Starling Law of the Heart

Cardiac muscle, like other muscle, increases its strength of contraction when it is stretched. This relationship was described in 1914 by a British physiologist, Ernest Starling, and was based on the earlier work of a German physiologist, Otto Frank. The **Frank-Starling law of the heart,** or the length-tension relationship of cardiac muscle, relates resting sarcomere length, expressed as the volume of blood in the heart at the end of diastole **(end-diastolic volume),** to tension generation, described as development of left ventricular pressure. Thus the volume of blood in the heart at the end of diastole (the length of its muscle fibers) is directly related to the force of contraction during the next systole. Although the change in pressure is related to the volume of the ventricle and, consequently, to the length of the ventricular muscle fibers, preload (i.e., filling pressure) is commonly used as an index of ventricular volume. The length-tension mechanism is the main mechanism by which the normal right and left ventricles maintain equal minute outputs even though their stroke outputs may vary considerably during

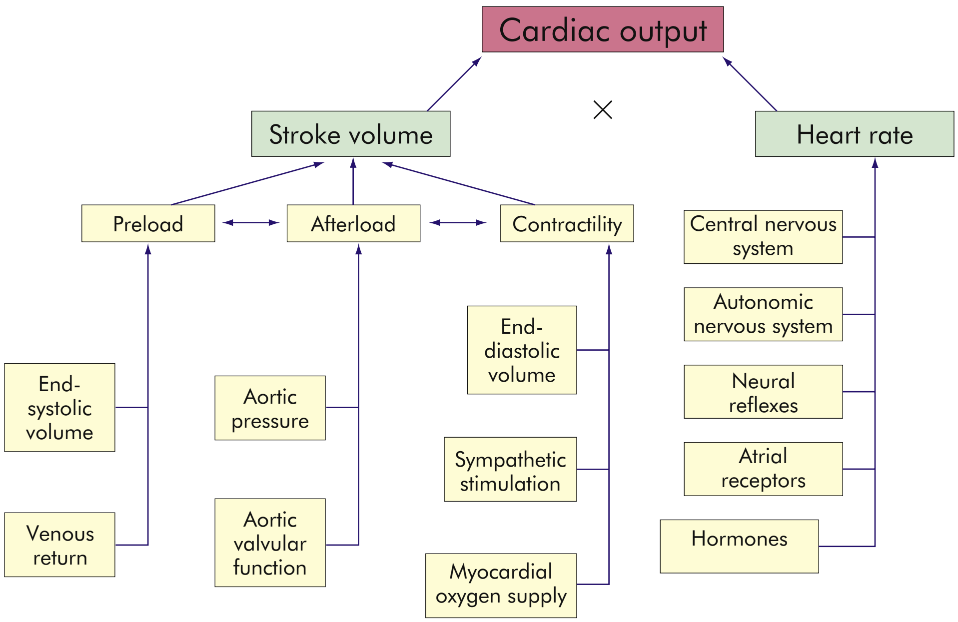

FIGURE 31-17 Factors Affecting Cardiac Performance. Cardiac output, which is the amount of blood (in liters) ejected by the heart per minute, depends on heart rate (beats per minute) and stroke volume (milliliters of blood ejected during ventricular systole).

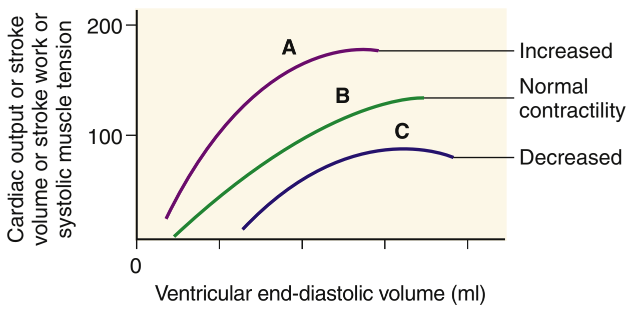

FIGURE 31-18 Frank-Starling Law of the Heart. Relationship between length and tension in the heart. End-diastolic volume determines end-diastolic length of ventricular muscle fibers and is proportional to tension generated during systole, as well as to cardiac output, stroke volume, and stroke work. A change in myocardial contractility causes the heart to perform on a different length-tension curve. *A,* Increased contractility; *B,* normal contractility; *C,* heart failure or decreased contractility. (See text.)

normal respiration. For example, changes in volume occur when an individual assumes a reclining position after being in a standing position; the volume of blood returning to the heart temporarily increases. The right ventricle stretches to accommodate this increase in volume and thereby increases its force of contraction. A larger stroke volume (i.e., the amount of blood ejected per beat) is pumped to the lungs, generating higher pressures. Pulmonary vascular pressure increases, causing a rise in the left ventricular filling pressure or preload. Left ventricular volume and pressure increase. The left ventricle pumps a larger stroke volume, and arterial vascular pressure rises.

The mechanical function of the heart is characterized by a number of length-tension curves (Figure 31-18). Factors that increase contractility (i.e., positive inotropic), such as sympathetic nerve stimulation, cause the heart to operate on a higher length-tension curve (curve *A* in Figure 31-18). A higher tension or increase in ventricular stroke volume is generated without a necessary change in left ventricular end-diastolic volume or fiber length. Heart failure (curve *C* in Figure 31-18) is characterized by a lower length-tension curve (see Chapter 32). The Frank-Starling law of the heart may not apply to dilated or failing hearts because their fibers are already stretched beyond their optimal length. The failing heart responds to increased filling or stretch with a progressive decline in the force of contraction. Thus at the same left ventricular end-diastolic volume as curves *A* and *B* (see Figure 31-18), the force of contraction of stroke volume is decreased.

The cross-bridge arrangement with the sarcomere partially accounts for the length-tension mechanism of cardiac muscle. According to the Frank-Starling law, the longer the initial resting length of the cardiac muscle fiber (optimal length is between 2.2 and 2.4 mm), the greater the strength of contraction. At 2.2 mm an optimal number of active cross-bridges exist between actin and myosin. However, if the fibers are stretched beyond 2.2 to 2.4 mm, the force of contraction decreases because actin and myosin become partially disengaged, disrupting many of the cross-bridges. Excessive stretching, to about 3.65 mm, causes actin and myosin to become completely disengaged so that tension (force of contraction) drops to zero. The relationship between stretch and contraction can be compared with that of a rubber band. Up to a certain point, the more the rubber band is stretched the farther it will fly when one end is released; beyond that point, however, the rubber band will break but, of course, the myocardium does not actually break!

Laplace's Law

Laplace's law states that wall tension is related directly to the product of intraventricular pressure and internal radius and

inversely related to the wall thickness as shown in the Laplace equation:

$$T = (p \times r)/\mu m$$

where T = wall tension, p = intraventricular pressure, r = internal radius of the sphere, and μm = wall thickness. In other words, the amount of tension generated in the ventricular wall (or any chamber or vessel) to produce a given intraventricular pressure depends on the size (radius and wall thickness) of the ventricle.

Laplace's law is useful for understanding aneurysm formation, distensibility in blood vessels, and the effects of ventricular dilation on myocardial contraction. Dilation is an important factor in heart failure (see Chapter 32). With a dilated ventricle, myocardial fibers in the wall must develop greater tension to produce a given pressure within the ventricle. The disadvantage of dilation is that the increased force, or tension, in the myocardial fibers required to develop a given pressure inside a dilated ventricle decreases the rate of fiber shortening, thereby decreasing the ability of the ventricle to eject blood.

Preload

Left ventricular preload is the pressure generated in the left ventricle at the end of diastole, or **left ventricular end-diastolic pressure (LVEDP).** It is determined by the **left ventricular end-diastolic volume (LVEDV),** which stretches the cardiac muscle fibers and in turn develops tension, or force, for contraction according to the Frank-Starling law. Preload is determined by two primary factors: (1) the amount of venous return to the ventricle, and (2) the blood left in the ventricle after systole or end-systolic volume (see Figure 31-17). End-systolic volume is dependent on the strength of ventricular contraction and the resistance to ventricular emptying. Within a physiologic range of muscle stretching (2.2 to 2.4 mm), increased preload increases cardiac output. When preload exceeds the physiologic range, further muscle stretching causes a decline in cardiac output (see Frank-Starling law, p. 1101). In monitoring preload the clinician measures indexes of left ventricular end-diastolic pressure. Pressure changes are important because increased left ventricular filling pressures "back up" into the pulmonary circulation, where they force plasma out through vessel walls, causing fluid to accumulate in lung tissues that can cause pulmonary edema (see Chapter 35). Treatment goals in heart failure management are to maintain an end-diastolic volume and pressure that will maintain or increase cardiac output.

Afterload

Ventricular afterload is the resistance to ejection of blood from the ventricle. Aortic systolic pressure is a good index of afterload for the left ventricle. Low aortic pressures (decreased afterload) enable the heart to contract more rapidly, whereas high aortic pressures (increased afterload) slow contraction and cause higher workloads against which the heart must function to eject blood. Pressure in the ventricle must exceed aortic pressure before blood can be pumped out during systole. Increased aortic pressure is usually the result of increased peripheral vascular resistance (PVR), also called total peripheral resistance (TPR). In individuals with hypertension, increased PVR means that afterload is chronically elevated, resulting in increased ventricular workload and hypertrophy of the myocardium. The situation is similar for the right ventricle except the pressures are much lower and the afterload for the right ventricle is pulmonary arterial pressure.

Myocardial Contractility

Stroke volume, or the volume of blood ejected during systole, depends on the force of contraction, which is a function of myocardial contractility, the degree of myocardial fiber shortening. In healthy persons, three major factors determine the force of contraction: (1) changes in the stretching of the ventricular myocardium caused by variations in ventricular volume (preload), (2) alterations in nervous system input to the ventricles, and (3) adequacy of myocardial oxygen supply (see Figure 31-17). As discussed previously, increased blood flow from the veins into the heart distends the ventricle by increasing preload, which, within the physiologic range, increases the stroke volume and, subsequently, cardiac output.

Chemicals affecting contractility are called **inotropic agents.** The most important positive inotropic agents produced by the body are norepinephrine released from the sympathetic nerves supplying the heart and epinephrine released by the adrenal cortex. Other positive inotropes include thyroid hormone and dopamine. The most important negative inotropic agent is acetylcholine released from the vagus nerve. Many medications have positive or negative inotropic properties that can have profound effects on cardiac function.

Myocardial contractility is dependent on oxygen supply with hypoxia contributing to a decrease in contractility. However, because hypoxia also stimulates coronary artery dilation, the impact of hypoxia will vary with activity level and the actual level of hypoxia. Preload, afterload, and contractility all interact with one another to determine stroke volume and cardiac output. Changes in any one of these factors can result in deleterious effects on the others, resulting in heart failure (see Chapter 32). In persons with sepsis, a variety of cytokines, including tumor necrosis factor-alpha (TNF-α), interleukin-beta, lysozyme C and endothelin-1, have been shown to impair myocardial contractility.[19]

Heart Rate

The average heart rate in healthy adults is about 70 beats/min. The average heart rate is significantly greater in children. Heart rate diminishes by 10 to 20 beats/min during sleep and can accelerate to more than 100 beats/min during muscular activity or emotional excitement. In well-conditioned athletes the resting heart rate is about 50 to 60 beats/min. In highly trained or elite athletes the resting heart rate can be less than 50 beats/min. The low resting heart rate is the result of increased vagal stimulation and lower sympathetic stimulation.

Neural factors, including neural reflexes, and hormonal and chemical factors influence the heart rate. Neural control is exerted by the central and autonomic nervous systems. Hormonal factors include the catecholamines (i.e., norepinephrine and epinephrine), thyroid hormones, growth hormones, and

endocannabinoids, such as anandamide.[20] (Hormonal function is described in Chapter 21.) Stimulation by the sympathetic nervous system increases the frequency of the cardiac pacemaker (SA node), whereas parasympathetic stimulation has a **bradycardic effect** (heart rate less than 60 beats/min).

Cardiovascular Control Centers in the Brain. The major **cardiovascular control center** is in the brainstem in the medulla with secondary areas in the hypothalamus, the cerebral cortex, the thalamus, and complex networks of exciting or inhibiting interneurons (connecting neurons) throughout the brain. The hypothalamic centers regulate cardiovascular responses to changes in temperature; the cerebral cortex centers adjust cardiac reaction to a variety of emotional states; and the medullary control center regulates heart rate and blood pressure (see page 1114 for blood pressure regulation). The medullary neurons often are classified as cardiac and vasomotor

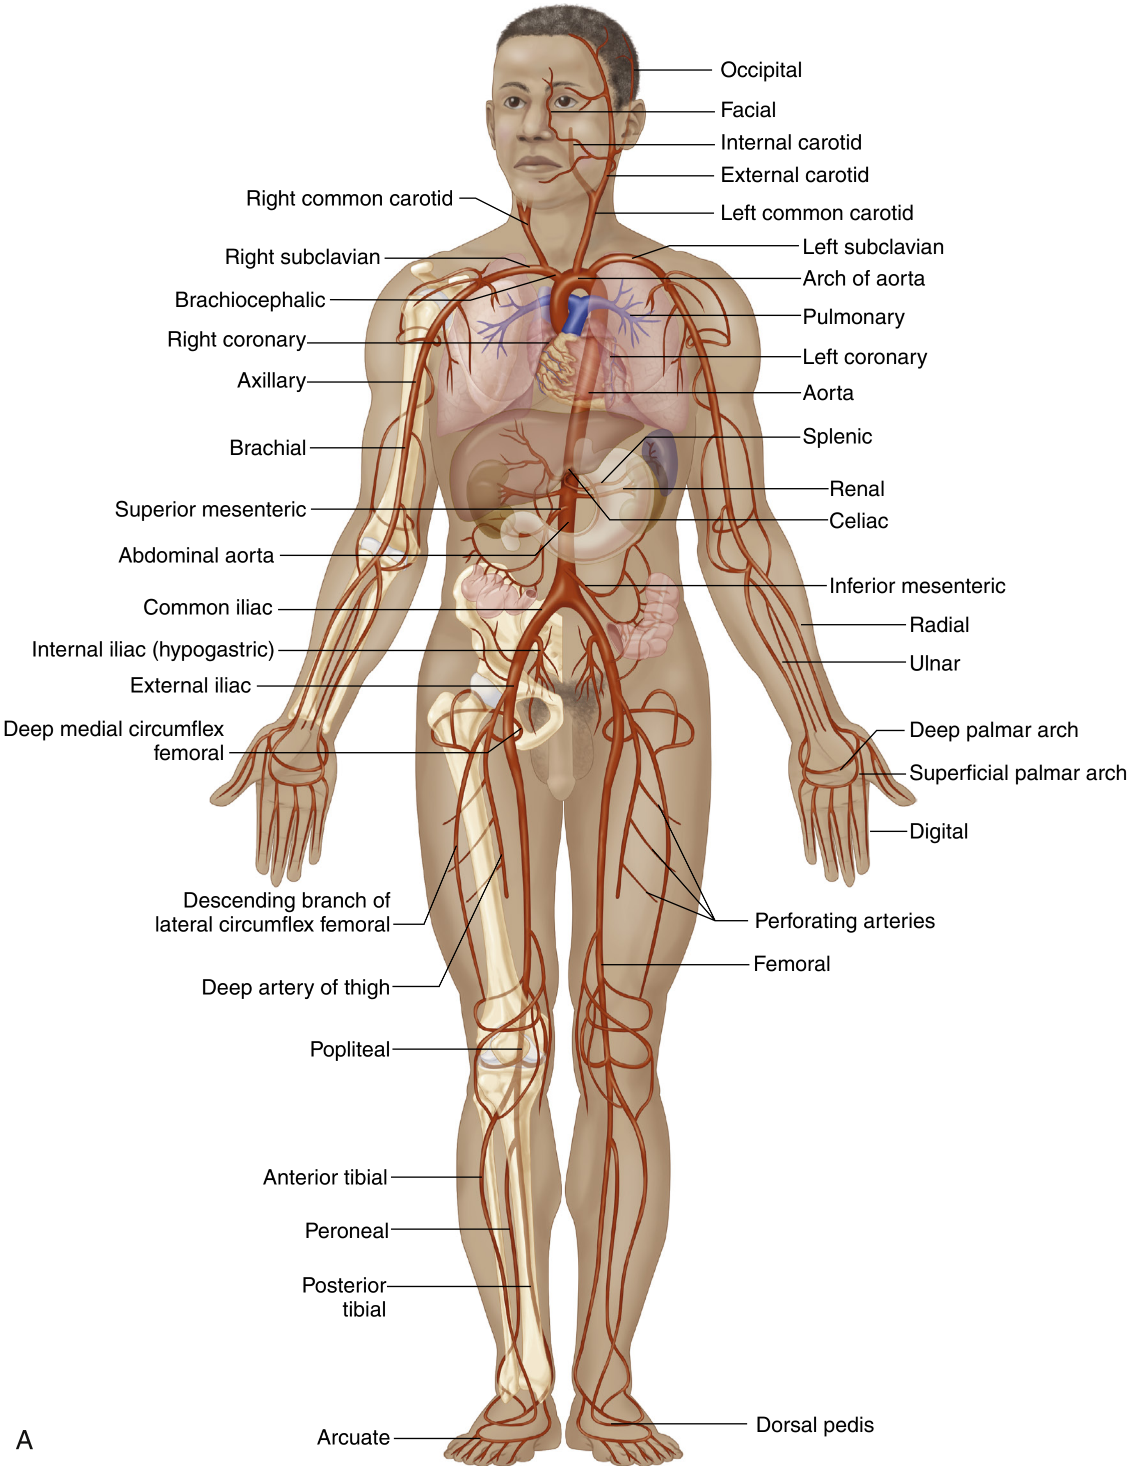

FIGURE 31-19 Circulatory System. **A,** Principal arteries of the body.

(vasoconstrictor or vasodilator) centers; however, because these centers are not discrete anatomic areas and actually constitute diffuse networks of interneurons, it is preferable to call the entire area the cardiovascular control center.

The nerve fibers from the cardiovascular control center synapse with the autonomic neurons (see Chapter 15 and Table 15-7). When the parasympathetic nerves to the heart are stimulated, the sympathetic nerves to the heart, arterioles, and veins usually are inhibited. The opposite also is true: when the sympathetic nerves are stimulated, the parasympathetic nerves usually are inhibited. Because parasympathetic excitation and simultaneous sympathetic inhibition generally depress cardiac function (e.g., decrease the heart rate), these interneurons often are referred to as the **cardioinhibitory center.** Excitation occurs

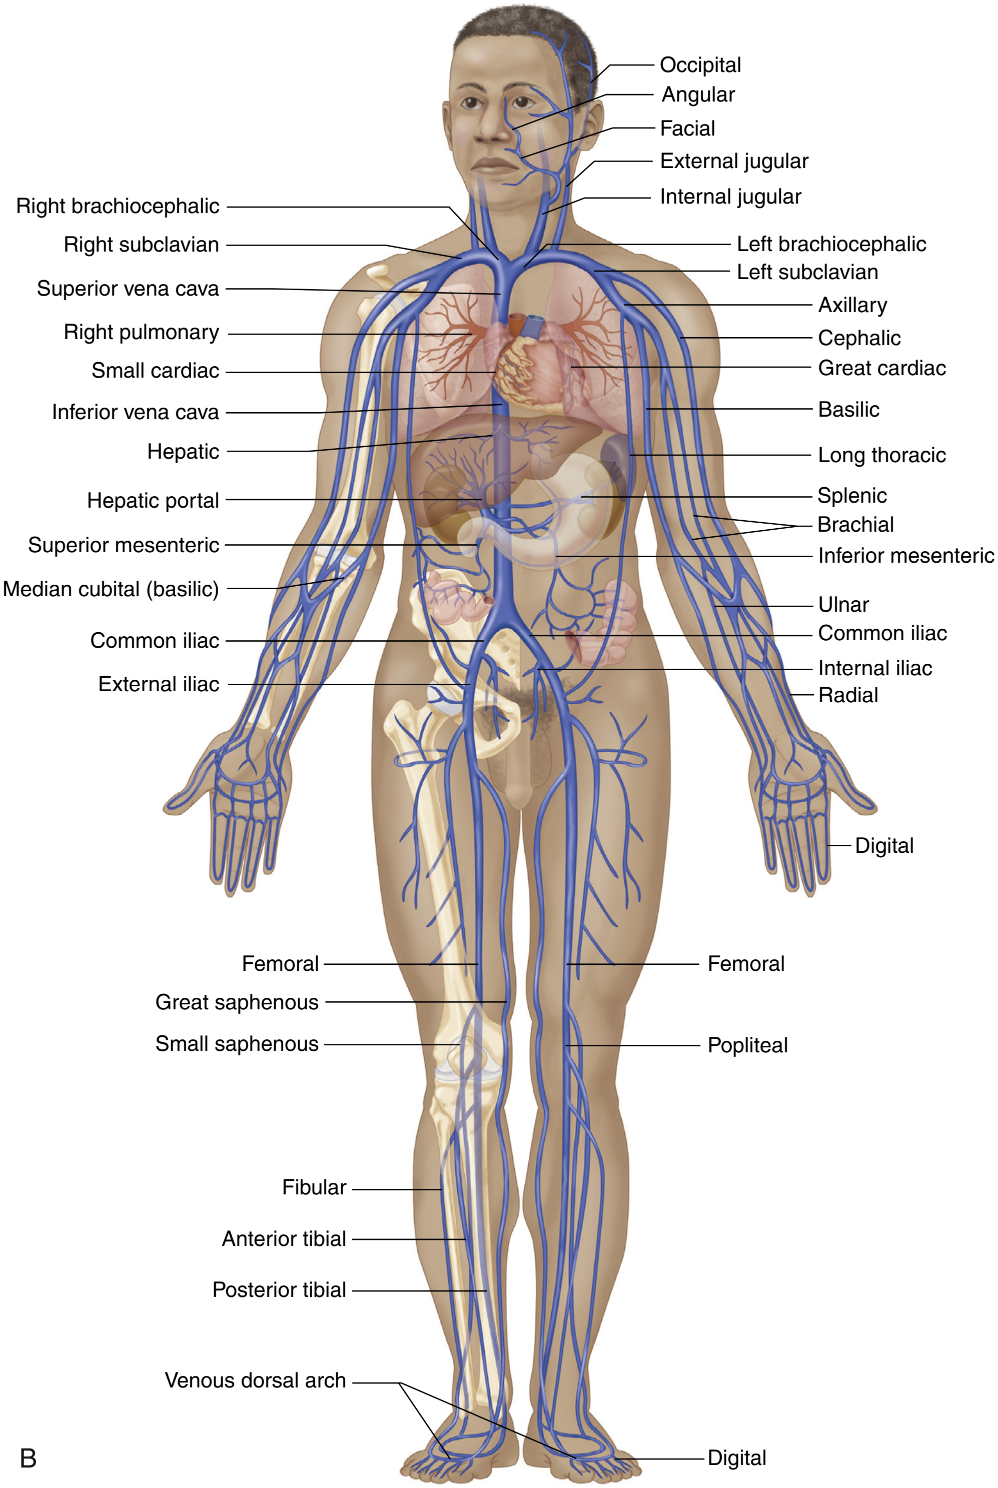

FIGURE 31-19, cont'd B, Principal veins of the body. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

with parasympathetic inhibition and sympathetic stimulation, and these interneurons are collectively called the **cardioexcitatory center.** Therefore, heart rate can be slowed by two simultaneous events that begin in the cardiovascular control center: (1) inhibition of sympathetic stimulation of the SA node, and (2) activation of parasympathetic stimulation of the SA node. Conversely, heart rate can be increased by activation of sympathetic nerves and inhibition of parasympathetic nerves.

The resting heart rate in healthy individuals is primarily under the control of parasympathetic stimulation. While the individual is at rest, parasympathetic effects from the vagus nerves override sympathetic effects in the SA node. Interruption of the vagus nerves causes significant tachycardia (abnormally fast heart rate) because the inhibitory parasympathetic influence is lost.

Neural Reflexes. Heart rate varies naturally with respiration, the rate increasing with inspiration and decreasing with expiration. This normal alteration in rhythm pattern, called **sinus arrhythmia,** is caused by changes that occur within the chest cavity because of respiration. Inspiration results in stretch and an associated increase in firing of the SA node that increases heart rate. With expiration the stretch is reduced and the SA node firing rate slows, resulting in a decrease in heart rate.[21]

Two neural reflexes that can affect heart rate and rhythm are the baroreceptor reflex and the Bainbridge reflex. The **baroreceptor reflex** is important in blood pressure control and is mediated by stretch receptors in the aortic arch and carotid arteries. (Because the receptors respond to mechanical factors, they are also called *aortic and carotid mechanoreceptors.*) When blood pressure falls, the baroreceptor reflex accelerates heart rate and causes constriction of arterioles in the systemic circulation. These responses raise blood pressure back toward normal and are critical to maintaining adequate tissue perfusion. Aging is associated with dysfunction of the baroreceptor reflex (baroreflex) and can result in postural hypotension (orthostatic hypotension, see p. 1140).[22]

The baroreflex also can reduce high blood pressure. The mechanoreceptors increase their rate of discharge when stretched by blood pressure elevations. Neural impulses are then transmitted over the glossopharyngeal nerve (ninth cranial nerve) from the carotid artery and through the vagus nerve from the aorta to the cardiovascular control centers in the medulla. These centers initiate an increase in parasympathetic activity and a decrease in sympathetic activity, causing blood vessels to dilate and heart rate to decrease. Responses to the baroreceptor reflex return the blood pressure to its previous level, which may or may not have been normal.

Bainbridge reflex is the name for the changes in the heart rate that occur after intravenous infusions of blood or other fluids.[23] The change in heart rate is thought to be caused by a reflex mediated by volume receptors in the atria that are innervated by the vagus nerves (volume receptors are thought to respond to increased plasma volume). Although this reflex can be elicited in humans, its relevance is uncertain at this time.[23]

Hormones and Biochemicals. Hormones and biochemicals affect the arteries, arterioles, venules, capillaries, and contractility of the myocardium. Norepinephrine increases heart rate, enhances myocardial contractility, and constricts blood vessels. Epinephrine dilates vessels of the liver and skeletal muscle and causes an increase in myocardial contractility. Some adrenocortical hormones, such as hydrocortisone, potentiate the effects of the catecholamines.

Thyroid hormone, specifically triiodothyronine, causes increases in both heart rate and contractility, resulting in an increase in cardiac output; it also decreases systemic vascular resistance. Triiodothyronine acts directly on the cardiac myocytes to cause gene transcription and cellular changes that result in more calcium release from the sarcoplasmic reticulum.[24] Awareness of these changes helps to understand the cardiovascular changes that occur with thyroid diseases. Growth hormone, working together with insulin-like growth factor 1 (IGF-1), also has been shown to increase myocardial contractility.[25] Decreases in levels of growth hormone or thyroid hormone may result in bradycardia, reduced cardiac output, and low blood pressure.

SYSTEMIC CIRCULATION

The arteries and veins of the systemic circulation are illustrated in Figure 31-19. Oxygenated blood from the left side of the heart flows through the aorta and into the systemic arteries. The **arteries** branch into small **arterioles** that branch into the smallest vessels, the **capillaries,** where nutrient exchange between the blood and tissues occurs. Blood from the capillaries then enters tiny **venules** that join to form the larger **veins,** which return venous blood to the right heart. **Peripheral vascular system** is the term used to describe the part of the systemic circulation that supplies the skin and the extremities, particularly the legs and feet.

Structure of Blood Vessels

Blood vessel walls are composed of three layers: the **tunica intima** (innermost or intimal layer), the tunica media (middle or medial layer), and the tunica externa or adventitia (outermost or external layer). These structures are illustrated in Figure 31-20. The tunica intima is composed of a layer of squamous epithelium or endothelium, a layer of connective tissue, and a basement membrane. (These cellular structures are described in Chapter 1.) The **tunica media** is composed of smooth muscle fibers mixed with elastic fibers. The **tunica externa,** or **adventitia,** is an active layer of connective tissue containing nerves, lymphatic vessels that influences both vessel development, and muscle tone (see What's New? New Roles for the Arterial Adventitia). Blood vessel walls vary in thickness depending on the thickness or absence of one or more of these three layers. Cells of the larger vessels are nourished by the **vasa vasorum,** small vessels located in the tunica externa, and innervated by perivascular nerves. The vasa vasorum arise from the blood vessel itself or from other vessels nearby. In the large elastic vessels the tunica media is separated from the adventitia by the **external elastic lamina.**

Adults are capable of growing new blood vessels through three processes, all of which are important in wound healing but also contribute to tumor growth. The three processes are angiogenesis, arteriogenesis, and vasculogenesis. Both

WHAT'S NEW?

New Roles for the Arterial Adventitia

The adventitia or tunica externa, once thought to be a simple fibrous sheath, is now recognized as a dynamic player in the life of the vessel and the surrounding tissues. The adventitia has roles in vessel response to injury, immune function, and vascular tone. Some of the cell types found include fibroblasts, stem/progenitor cells, mast cells, macrophages, B cells, T cells, and dendritic cells. Other components of this layer include the vasa vasorum, perivascular nerves (nervi vasorum), lymphatic vessels, and extracellular matrix (see Figure 31-20). Studies of labeled cells after arterial injury have shown that new cells migrate from the adventitia into the media and intima to repair and maintain the vessel. It is also possible that, in some cases, these migrating cells may contribute to arterial disease. The vasa vasorum, which forms a miniature circulatory system that supplies blood to walls or larger arteries and veins, also provides a means for transporting cells of the inflammatory response, such as macrophages, across the blood vessel walls. Adventitia fibroblasts have the capacity to become myofibroblasts, which can then influence the vascular tone of the vessel. Research continues on the roles of the adventitia both in health and in a wide variety of vascular diseases such as atherosclerosis and pulmonary hypertension.

Data from Hu Y, Xu Q: *Arterioscler Thromb Vasc Biol* 31(7):1523–1529; Majesky MW et al: *Arterioscler Thromb Vasc Biol* 31(7):1530–1539; Majesky MW et al: *Cells Tissues Organs* 195(1-2):73–81, 2012; Stenmark KR et al: *Ann Rev Physiol* 2012 Dec 3. [Epub ahead of print.].

angiogenesis and arteriogenesis occur by growth of new vessels that branch from existing vessels. **Angiogenesis** is branching of small vessels, such as capillaries, whereas **arteriogenesis** occurs by branching from larger vessels, such as arterioles. **Vasculogenesis** is a term that refers to the growth of vessels from progenitor or stemlike cells that originate in the bone marrow and other body tissues.[26]

Arterial Vessels

Arterial walls are composed of elastic connective tissue, fibrous connective tissue, and smooth muscle. There are two types of arteries: elastic and muscular. The **elastic arteries** have a very thick tunica media that contains more elastic fibers than smooth muscle fibers. Elastic arteries include the aorta and its major branches and the pulmonary trunk. Elasticity enables the vessel to absorb energy imparted to the blood by ventricular contraction and they stretch as blood is ejected from the heart during systole. During diastole, elasticity promotes recoil of the arteries, which is important for maintaining blood pressure within the vessels, and retransfers the energy from the elastic artery walls to the blood.

The **muscular arteries** are medium and small size arteries farther from the heart than the elastic arteries. They contain fewer elastic fibers and more muscle fibers than the elastic arteries and their function is to distribute blood to arterioles throughout the body. Because their smooth muscle can be stimulated to contract or relax, they play a role in controlling blood flow and in directing flow to the parts of the body with the highest need at any time. During exercise more blood is sent to the skeletal muscles, while after a meal more blood is directed to the gut and liver. Contraction narrows the vessel **lumen** (the internal cavity of the vessel), which diminishes flow through the vessel. This condition is termed **vasoconstriction.** When the smooth muscle layer relaxes, more blood flows through the vessel lumen, a state called **vasodilation.**

An artery becomes an arteriole at the point where the diameter of its lumen narrows to less than 0.5 mm. The arterioles are composed almost exclusively of smooth muscle, with little elastic tissue. Arterioles regulate the flow of blood into the capillaries by vasoconstriction, which retards the flow of blood into the capillaries, and vasodilation, which permits blood to enter the capillaries freely (Figure 31-21). The thick, smooth muscle layer of the arterioles is a major determinant of the resistance blood encounters as it flows through the systemic circulation.

The capillary network is composed of connective channels called **metarterioles,** and "true" capillaries (see Figure 31-21). Metarterioles have discontinuous smooth muscle cells in their tunica media whereas capillaries lack any smooth muscle cells. The capillaries branch from the metarterioles, meeting at a ring of smooth muscle called the **precapillary sphincters.** As the sphincters contract and relax, they regulate blood flow through the capillaries. Appropriately stimulated, the precapillary sphincters help maintain arterial pressure and regulate selective flow to vascular beds.

Capillaries are composed solely of a layer of endothelial cells surrounded by a basement membrane. Their thin walls and unique structure make possible the rapid exchange of water; small (low molecular weight) soluble molecules; some larger molecules, such as albumin; and cells of the innate and adaptive immune system between the blood and the interstitial fluid.[1] Based on their structure, three types of capillaries have been described: continuous, sinusoid, and fenestrated. In the renal glomerulus, for example, the endothelial cells contain oval windows or pores termed **fenestrations,** which are covered by a thin diaphragm.[27] Sinusoid capillaries are found in the liver and bone marrow.

Substances pass between the capillary lumen and the interstitial fluid in several ways: (1) through junctions between endothelial cells, (2) through fenestrations in endothelial cells, (3) in vesicles moved by active transport across the endothelial cell membrane, or (4) by diffusion through the endothelial cell membrane. (Movement across cell membranes is described in Chapter 1.) A single capillary may be only 0.5 to 1 mm in length and 0.01 mm in diameter, but the capillaries are so numerous that their total surface area may be more than 600 m^2.

Endothelium

Once thought to be simply the cellular layer lining blood vessels, the vascular **endothelium** is now recognized as important to several body functions and is considered by some to be a separate organ (Figure 31-22). In addition to substance transport, the vascular endothelium has important roles in coagulation, antithrombogenesis, and fibrinolysis; immune system function; tissue growth and wound healing; and **vasomotion,** the contraction and relaxation of vessels. The endothelium performs these vital functions through synthesis and release of vasoactive chemicals. Figures 31-23 and 31-24 and Box 31-1 summarize some of the more important functions. Because of its varying roles, the actual structure

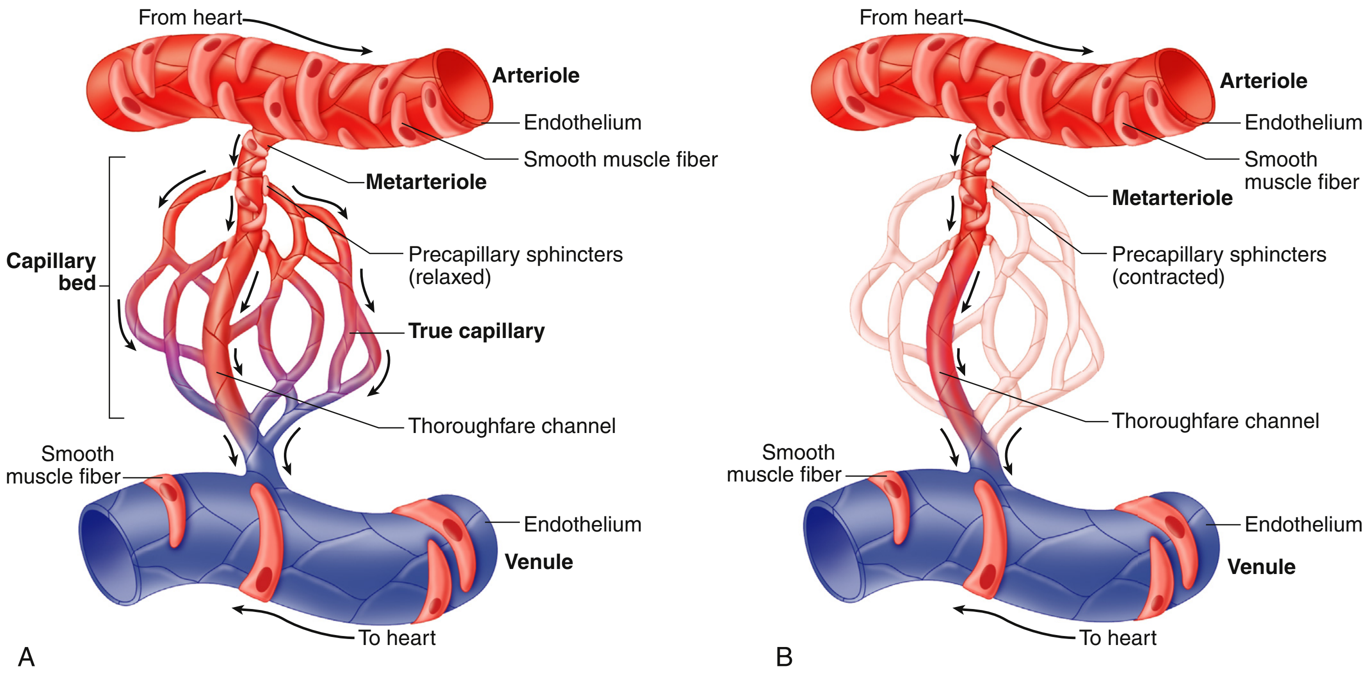

FIGURE 31-21 Capillary Wall and Microcirculation. Control of blood flow through a capillary network is regulated by the relative contraction of precapillary sphincters surrounding arterioles and metarterioles. **A,** Sphincters are relaxed, permitting blood flow to enter the capillary bed. **B,** With sphincters contracted, blood flows from the metarteriole directly into the thoroughfare channel, bypassing the capillary bed. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

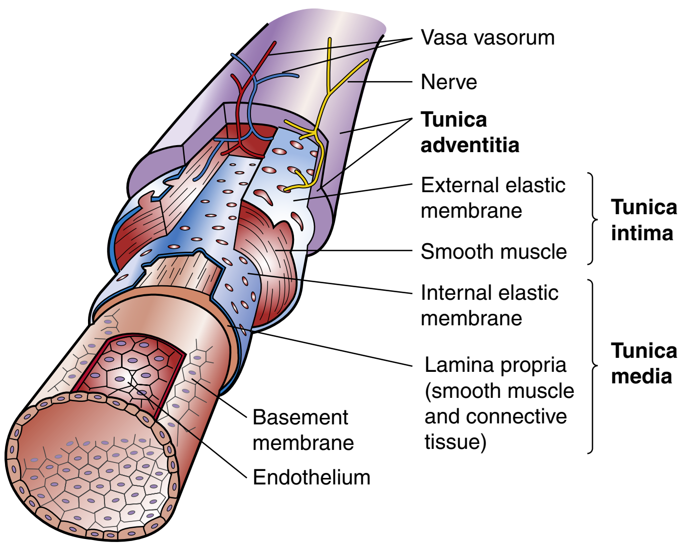

FIGURE 31-22 Endothelium. This schematic shows the endothelium in context with the entire blood vessel. Practically imperceptible, the endothelial cells arrange themselves as a fine lining that has numerous life support functions.

of the endothelium may vary in different vascular beds. For example, within lymph nodes the **endothelial cells** of specialized venules, called "high endothelial venules," are uniquely structured to support the movement of lymphocytes from the blood into the lymph node.[28] Endothelial injury and dysfunction are central processes in many of the most common and serious cardiovascular disorders including hypertension and atherosclerosis (see Chapter 32).

Veins

The smallest venules downstream from the capillaries have an endothelial lining surrounded by fibrous tissue. The largest venules, those farthest from the capillaries, are surrounded by a few smooth muscle fibers comprising a thin tunica media.

Compared with arteries, veins are thin walled and fibrous with a larger diameter (see Figure 31-20). A given vein is larger than the artery that lies within the same sheath. Veins are more numerous than arteries. In veins the tunica externa has less elastic tissue than in arteries, so veins do not recoil after distention as quickly as arteries. Like arteries, veins receive nourishment from the tiny vasa vasorum. Some veins, typically in the legs, contain valves that regulate the one-way flow of blood toward the heart (Figure 31-25). These valves are folds of the tunica intima and are structurally similar to the semilunar valves of the heart. Backflow in veins of the legs is stopped as the flaps of the valves fill with blood and block the vessel. The position of the valves also facilitates blood flow in the proper direction during venous compression. When a person stands up, contraction of the skeletal muscles of the legs compresses the deep veins of the legs and assists the flow of blood toward the heart. This important mechanism of venous return is called the *muscle pump* (see Figure 31-25).

Factors Affecting Blood Flow

Blood flow, the amount of fluid moved per unit of time, is usually expressed as liters or milliliters per minute (ml/min). The factors that influence blood flow include pressure, resistance, velocity, turbulent vs. laminar flow, and compliance.

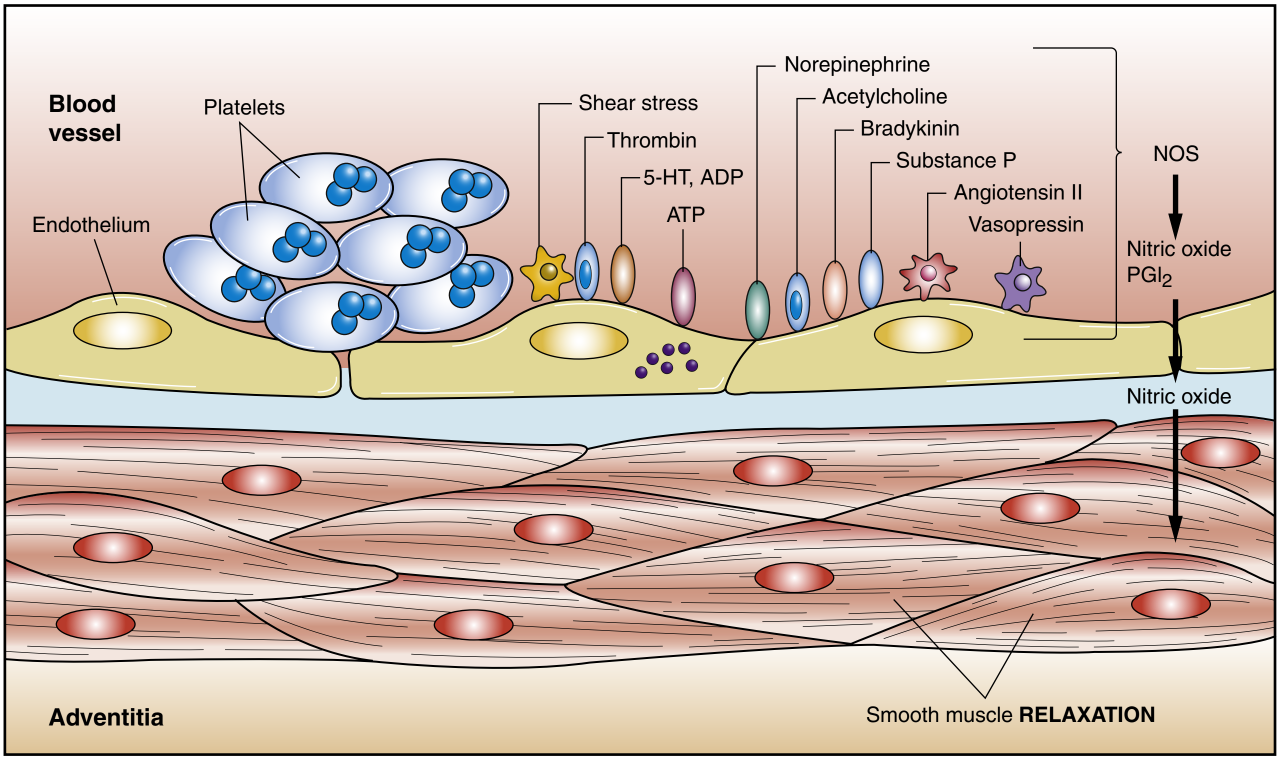

FIGURE 31-23 **Factors Causing Endothelium-Dependent Vasodilation.** A variety of exogenous pharmacologic substances, platelet-derived factors, and shear stress can promote release of nitric oxide by stimulating nitric oxide synthase (NOS). Prostacyclin (PGI_2) causes relaxation of vascular smooth muscle cells by a cyclic adenosine monophosphate (cAMP)–dependent mechanism, and both nitric oxide and PGI_2 inhibit platelet aggregation. *5-HT,* Serotonin; *ADP,* adenosine diphosphate; *ATP,* adenosine triphosphate.

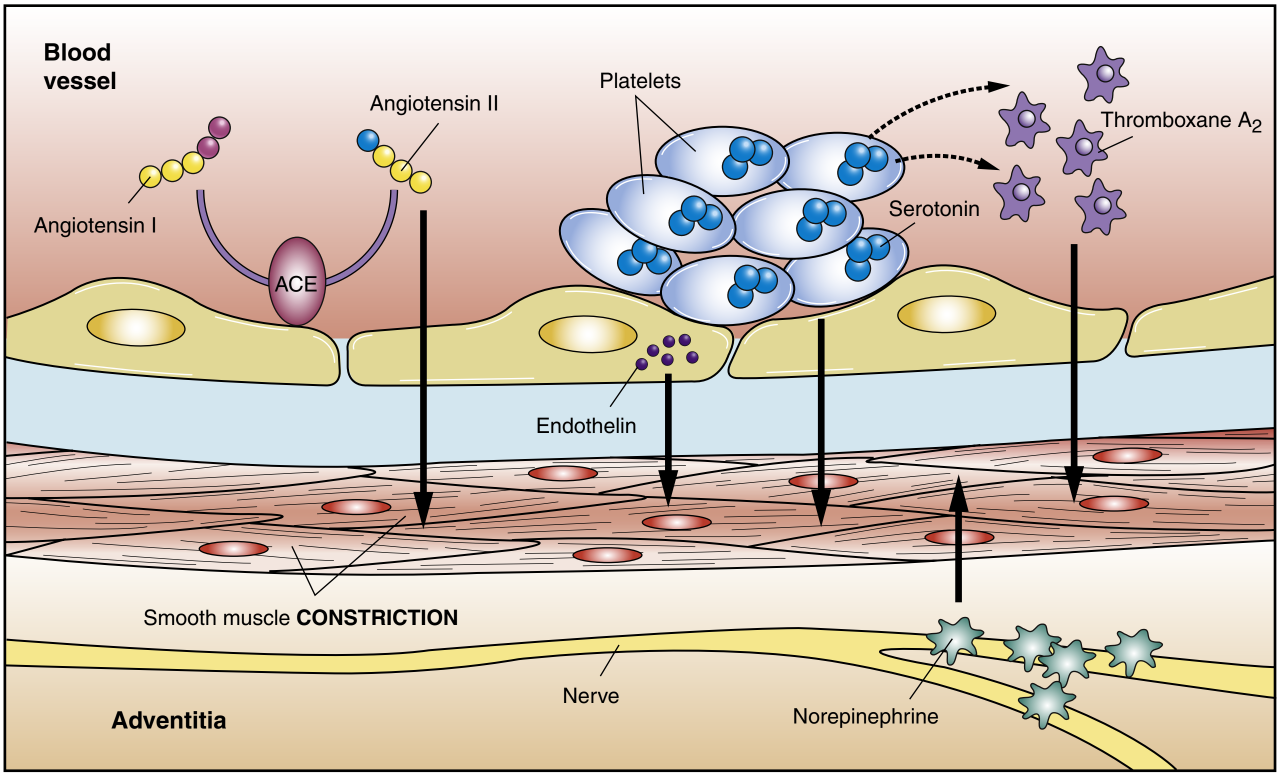

FIGURE 31-24 **Endothelium Regulation of Vasomotion (Constriction and Dilation) and Platelet Aggregation by Release of a Variety of Constricting and Dilating Substances.** Constricting factors include arachidonic acid and metabolites, such as thromboxane A_2 (which aspirin inhibits), and a potent amino acid peptide called *endothelin.* The endothelium also converts angiotensin I into angiotensin II by the membrane-bound angiotensin-converting enzyme that also metabolizes the endogenous endothelium-dependent vasodilator bradykinin. *ACE,* Angiotensin-converting enzyme.

BOX 31-1 ENDOTHELIUM FUNCTIONS AND VASOACTIVE SUBSTANCES

Dilators

Prostacyclin: A prostaglandin formed from arachidonic acid that can relax vascular smooth muscle through increases in cAMP. The primary function is to inhibit platelet adherence to the endothelium.

Nitric oxide (NO): Bradykinin and shear stress prompt the endothelium to synthesize and release NO, a potent vasodilator. NO is also anti-inflammatory and antithrombotic.

C-type natriuretic hormone: Made throughout the vasculature and works with NO and prostacyclin as a vasodilator.

Insulin: Insulin increases endothelial cell production of nitric oxide.

Estrogen: Triggers enzyme activation and release of NO.

Endothelium-derived relaxing factor: A potent vasodilator made by vascular endothelial cells.

Constrictors

Endothelin: A potent endothelium-derived constrictor.

Urotensin II: Is another potent endothelium-derived constrictor.

Angiotensin II (Ang II): Is a potent vasoconstrictor produced both hormonally via the renin-angiotensin-aldosterone system and locally in vascular tissues. Ang II blocks the release of NO and prostacyclin. Ang II is also proinflammatory: it increases vascular permeability, recruits infiltrating monocytes, increases expression of adhesion molecules, and stimulates release of growth factors.

Thromboxane: Causes vasoconstriction and platelet adhesion.

Prostaglandins: Cause vasoconstriction especially during states of chronic inflammation.

Other Endothelial Functions

Platelet and monocyte adhesion: The endothelium helps regulate clotting and inflammation by modulating the number of platelets and inflammatory cells (monocytes and macrophages) that bind to the vessel wall. Endothelial-derived substances include von Willebrand factor, platelet-activating factor, heparan sulfate, t-PA, thrombomodulin, and others.

Filtration and permeability: The endothelium facilitates movement of large molecules through intercellular junctions and small molecules via vesicles and junctions.

Cell growth and inhibition: NO and prostacyclin inhibit cellular growth; Ang II stimulates growth.

Pressure and Resistance

The two main factors influencing blood flow are pressure and resistance, whereas viscosity, type of flow pattern, and compliance have a lesser impact. **Pressure** in a liquid system is the force exerted on the liquid per unit area and is expressed as dynes per square centimeter (dynes/cm^2), millimeters of mercury (mmHg), or torr (1 torr = 1 mmHg). Blood flow to a specific organ depends partly on the pressure difference between the arterial and venous vessels supplying that organ. Fluid moves from the arterial "side" of the capillaries, a region of greater pressure, to the venous side, a region of lesser pressure. Blood flow varies directly with pressure; that is, the greater the pressure differential across a vascular bed, the greater will be the blood flow.

Resistance is the opposition to blood flow. In the cardiovascular system most opposition to blood flow is a result of the diameter and length of the blood vessels. Changes in blood flow through an organ, therefore, result from changes in the vascular resistance within the organ. The major mechanisms causing changes in vascular resistance are increases or decreases in vessel diameter and the opening or closing of vascular channels. The mathematical description of this resistance in a tube is known as the Hagen-Poiseuille equation, sometimes also referred to as Poiseuille's law. This equation indicates that resistance is directly related to tube length and fluid viscosity (blood viscosity) and inversely related to the radius of the tube to the fourth power (r^4). Blood flow is inversely related to resistance so that the greater the resistance in a vascular bed or tissue, the lower the blood flow.

Clinically the most important factor determining resistance in a single vessel is the caliber of the vessel's lumen, which can be measured either as its radius or, as in Figure 31-26, as its diameter. Small changes in the lumen's radius lead to large changes in vascular resistance. Clinically, vasoconstriction will contribute to an increase in resistance whereas vasodilation will cause a decrease that may be reflected by a decrease in blood pressure. Because vessel length is relatively constant and lumen size is quite variable, length is not as important as lumen size in determining flow through a single vessel. Because viscosity is relatively constant, except in the following circumstances,

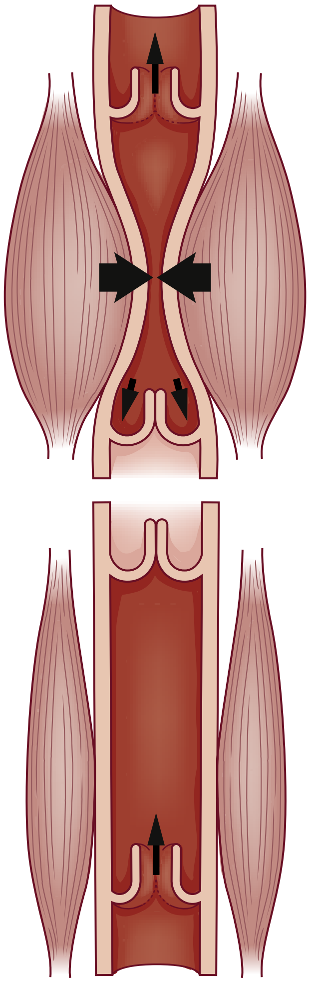

FIGURE 31-25 Muscle Pump. As blood returns from downstream and the surrounding muscles contract, the venous valves only allow blood to flow in one direction, back towards the heart.

blood vessel radius is usually the key factor in determining total peripheral resistance.

Generally, resistance to flow is greater in longer tubes because resistance increases with length. That resistance increases with increased length is demonstrated by comparing flow of the same amount of blood under the same pressure through vessels arranged in different configurations. Blood flowing through the distributing arteries, beginning with branches off the aorta and ending at arterioles in the capillary bed, encounters more resistance than blood flowing through the capillary bed itself, where flow is distributed among many short, tiny branches arranged in parallel. This is because the distributing arteries comprise a long system of tubes connected in series (end-to-end), whereas the arterioles and capillaries comprise a short system of many vessels arranged in parallel (side-by-side) (see Figure 31-26). Although the arterioles are arranged in series with the distributing arteries and the capillaries, they are arranged in parallel with other arterioles. Similarly, the capillaries are in series with the metarterioles, but they are in parallel with other capillaries.

Resistance to flow through a system of vessels, or **total resistance,** depends not only on characteristics of individual vessels but also on whether the vessels are arranged in series or in parallel. For vessels arranged in series, total resistance equals the sum obtained by adding all the individual resistances. For vessels arranged in parallel, total resistance equals the sum of the reciprocals *(I/R)* of the individual resistances.

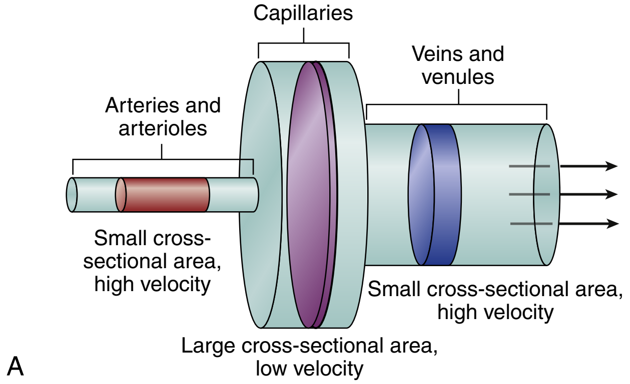
Total resistance is related to the total cross-sectional area of a system of vessels in parallel and to the number of vessels in parallel that make up the total cross-sectional area. The larger the total cross-sectional area, as in the capillary system, the lower the resistance. However, if a cross-sectional area consists of a very large number of parallel vessels, the overall resistance will be greater than it would be if the cross-sectional area were made up of only two or three parallel vessels. Therefore, resistance is greater in smaller vessels than in larger vessels. The total cross-sectional area of the arteriolar system is greater than that of the arterial system (see Figure 31-26); the greater number of arterioles arranged in parallel, however, leads to greater resistance to flow in the arteriolar system. The pressure drop is greatest across the arterioles. Many capillaries arise from each arteriole so that the total cross-sectional area of the capillary bed is very large and resistance is low, despite the fact that the cross-sectional area of each capillary is less (which normally increases resistance) than that of each arteriole. As a result, blood flow becomes quite slow in the capillaries, analogous to water flow in a river. A narrow river whose bed widens flows more slowly through the wide section than through the narrow section. The slow velocity of flow in each vessel is optimal for capillary-tissue exchange.

Both pressure and resistance impact the velocity of the blood within a vessel. **Blood velocity** is the distance blood travels in a unit of time, usually centimeters per second (cm/sec). Blood velocity is directly related to blood flow (amount of blood moved per unit of time) and inversely related to the cross-sectional area of the vessel in which the blood is flowing.

The relationship between velocity and flow can again be understood by thinking of a river. The volume of water flowing in a river is the same whether the river is narrow or wide. Where the river narrows, the water flows quickly; where it widens, the water flows slowly. The volume of water moving between the riverbanks does not change. In the body, as blood moves from the aorta to the capillaries, the total cross-sectional area of the vessels increases and the velocity of flow decreases.

Viscosity

Flow varies inversely with the **viscosity**—thick, sticky consistency of the fluid. Thick fluids move more slowly and cause greater resistance to flow than thin fluids—just think of honey as compared to water. The viscosity of blood depends on red cell content. The greater the percentage of red cells in the blood, the more viscous the blood. This relationship is expressed as the **hematocrit**—the ratio of the volume of red blood cells to the volume of whole blood (see Chapter 27). A high hematocrit value reduces flow through the blood vessels, particularly the microcirculation (arterioles, capillaries, venules). Conditions in which the hematocrit value is elevated, such as a lack of body water, cyanotic congenital heart disease (see Chapter 33), or polycythemia (see Chapter 27), can lead to increased cardiac work as a result of increased vascular resistance.



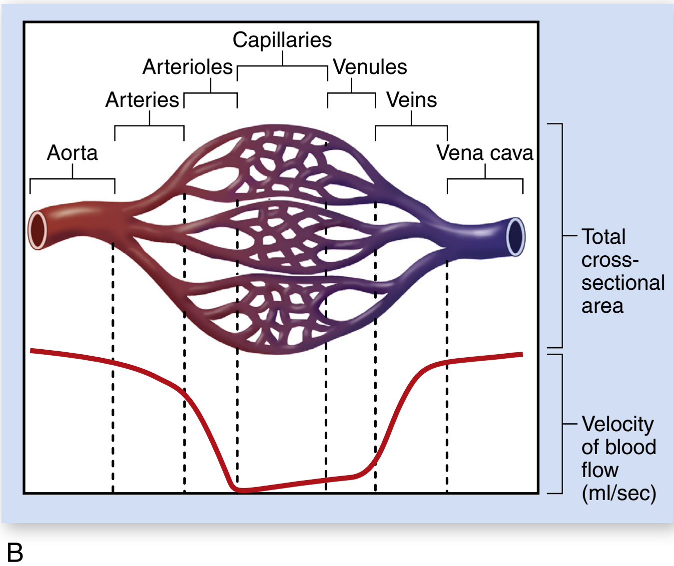


FIGURE 31-26 **Relationship Between Cross-Sectional Area and Flow Rate of Blood.** As can be seen in the simple diagram **(A)** and the blood vessel chart **(B),** blood flows with great speed in the large arteries. However, branching of arterial vessels increases the total cross-sectional area of the arterioles and capillaries, reducing the flow rate. When capillaries merge into venules and venules merge into veins, the total cross-sectional area decreases, causing the flow rate to increase. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Laminar Versus Turbulent Flow

Flow through any tubular system can be either laminar or turbulent. Blood flow through the vessels, except where vessels split or branch, is mainly laminar. In **laminar flow,** concentric layers of molecules move "straight ahead." Each concentric layer flows at a different velocity (Figure 31-27). The cohesive attraction between the fluid and the vessel wall prevents the molecules of blood that are in contact with the wall from moving. The next thin layer of blood is able to slide slowly past the stationary layer and so on until, at the center, the blood velocity is greatest. The centermost concentric layer of fluid is not slowed by friction against the vessel wall. Large vessels have room for a large center layer; therefore, they have less resistance to flow and greater flow and velocity than smaller vessels.

Where flow is obstructed, the vessel turns, or blood flows over rough surfaces, it becomes **turbulent** with whorls or eddy currents that produce noise, causing a murmur to be heard on auscultation, such as occurs during blood pressure measurement with a sphygmomanometer. Resistance increases with turbulence. Arterial areas of turbulence also are places where atherosclerotic plaques are found (see Chapter 32).

Vascular Compliance

Vascular compliance is the increase in volume a vessel is able to accommodate for a given increase in pressure. Compliance depends on the factors related to the nature of a vessel wall, such as the ratio of elastic fibers to muscle fibers in the vessel wall. Elastic arteries are more compliant than muscular arteries; the veins are more compliant than either type of artery because they have less smooth muscle. Because they are more compliant, veins serve as storage areas for the circulatory system.

Compliance determines a vessel's response to pressure changes. For example, with a very small increase in pressure, a large volume of blood can be accommodated by the venous system. In the less compliant arterial system, where smaller volumes and higher pressures are normal, small variations in pressure cause little or no change in the volume of blood within the arterial vessels.

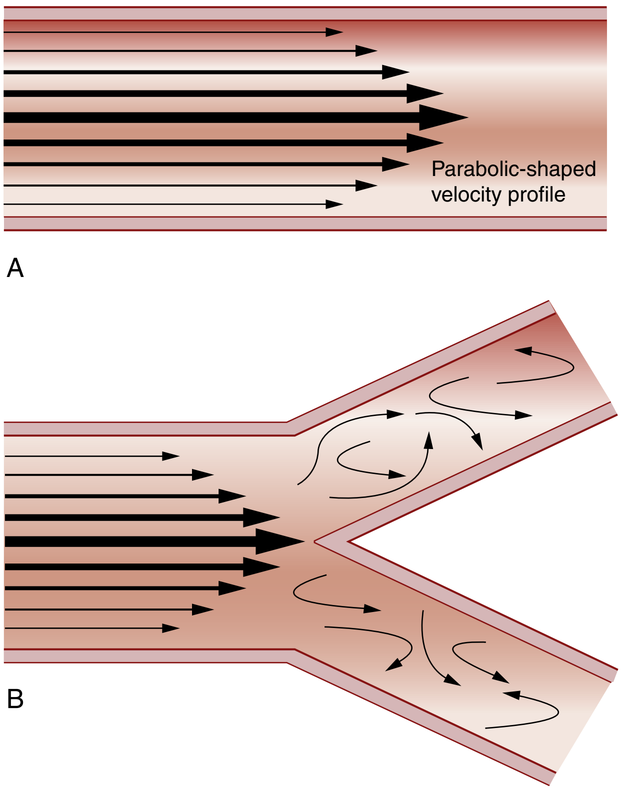

FIGURE 31-27 Laminar and Turbulent Flow. **A,** Laminar flow. Fluid flows in long smooth-walled tubes as if it is composed of a large number of concentric layers. **B,** Turbulent flow is caused by numerous small currents flowing crosswise or oblique to the long axis of the vessel, resulting in flowing whorls and eddy currents. (Adapted from Seeley RR, Stephens TD, Tate P: *Anatomy and physiology,* ed 3, St Louis, 1995, Mosby.)

Stiffness is the opposite of compliance. Several conditions and disorders can increase vascular stiffness, with the most common being aging and arteriosclerosis (see Chapter 32 and section on aging at the end of this chapter). Arteriosclerosis increases the rigidity or stiffness of arterial walls, which in turn increases peak arterial pressure at a given volume of blood.

Regulation of Blood Pressure (Arterial Pressure)

During a wide range of physiologic conditions, including changes in body position, muscular activity, and circulating blood volume, arterial pressure is regulated within a fairly narrow range to maintain tissue **perfusion,** or blood supply to the capillary beds, Systemic arterial blood pressure is a *regulated variable,* which means that the cardiovascular control systems are designed to maintain blood pressure within these limits. Very low pressures are not consistent with survival because body tissues will not be perfused whereas very high pressures increase the risk of stroke and damage to other organs, such as the kidneys, heart, and retinas. Arterial pressure is a function of and varies directly with both cardiac output (heart rate × stroke volume) and peripheral resistance. Increases in one or both will raise arterial pressure, and decreases in one or both will lower the arterial pressure (Table 31-3). The major factors and relationships that regulate arterial blood pressure are summarized in Figure 31-28.

TABLE 31-3 FACTORS THAT AFFECT MEAN ARTERIAL PRESSURE AND CAPILLARY FLOW

	MEAN ARTERIAL PRESSURE	CAPILLARY FLOW
Peripheral Resistance*		
Increased	Increased	Decreased
Decreased	Decreased	Increased
Heart Rate†		
Increased	Increased	Increased
Decreased	Decreased	Decreased
Stroke Volume‡		
Increased	Increased	Increased

*Cardiac output maintained constant.
†Peripheral resistance and stroke volume constant.
‡Peripheral resistance and heart rate constant.

The **mean arterial pressure (MAP),** which is the average pressure in the arteries throughout the cardiac cycle, depends on the elastic properties of the arterial walls and the mean volume of blood in the arterial system. MAP can be approximated from the measured values of the systolic *(Ps)* and diastolic *(Pd)* pressures by means of the following formula:

$$MAP = Pd + \frac{1}{3}(Ps\text{-}Pd)$$

The difference between the systolic pressure and diastolic pressure *(Ps − Pd)* is called the **pulse pressure.** Pulse pressure is directly related to arterial wall stiffness and stroke volume.

Effects of Cardiac Output

The cardiac output (minute volume) of the heart can be changed by alterations in heart rate, stroke volume (volume of blood ejected during each ventricular contraction), or both. An increase in cardiac output without a decrease in peripheral resistance will cause mean blood pressure and flow rate to increase. The higher arterial pressure increases blood flow through the arterioles. On the other hand, a decrease in the cardiac output causes an immediate drop in mean arterial blood pressure and flow rate (see Table 31-3).

Effects of Total Peripheral Resistance and Blood Volume

Total resistance in the systemic circulation, often referred to as either systemic vascular resistance (SVR) or *total peripheral resistance (TPR),* is primarily a function of the diameter of the arterioles. If cardiac output remains constant, arteriolar constriction raises mean arterial pressure by reducing the flow of blood into the capillaries and arteriolar dilation has the opposite effect.

Neural Control of Total Peripheral Resistance. Reflex control of cardiac output and peripheral resistance includes: (1) sympathetic stimulation of heart, arterioles, and veins;

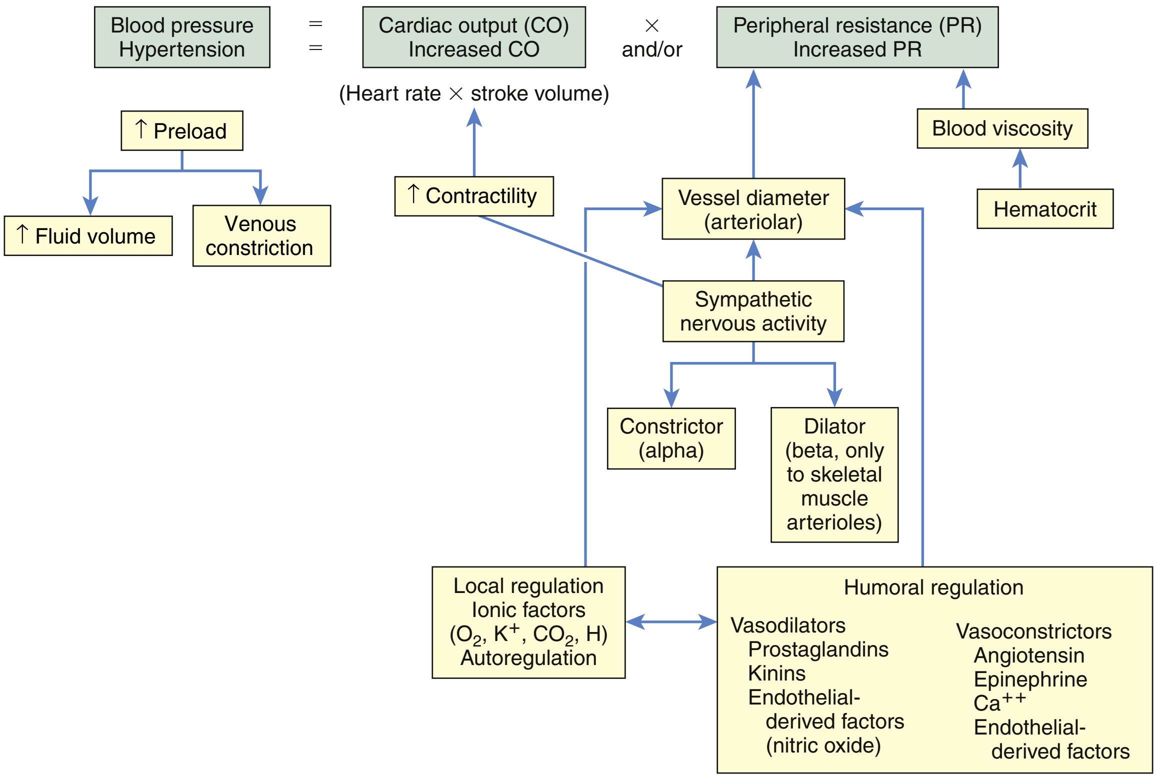

FIGURE 31-28 Factors Regulating Blood Flow.

and (2) parasympathetic stimulation of the heart. The cardiovascular center in the medulla receives input from pressure and blood composition sensors throughout the vascular system and then modifies vagal and sympathetic output to control heart rate and contractility, plus vascular diameter (see Figure 31-10). Another input to the system comes from hypothalamic centers that regulate vascular (and cardiac) responses to changes in temperature. When the body's core temperature exceeds normal, the hypothalamus reflex initiates dilation of arterioles and veins in the skin. This vasodilation shunts blood to the skin, where heat is lost through sweating, radiation, conduction, and/or convection. When body core temperature decreases below normal, surface vessels constrict, shunting blood to the vital organs. Vasoconstriction is regulated by an area of the brainstem that maintains a constant (tonic) output of norepinephrine from sympathetic fibers in the peripheral arterioles. This tonic activity is essential for maintenance of blood pressure.

During exercise and stress, the sympathetic fibers that stimulate vasodilation of skeletal muscle arterioles are thought to be under the direct control of the cerebral cortex and hypothalamus and not the medullary centers. Information about pressure, resistance, and blood composition is sensed by neural receptors (baroreceptors and chemoreceptors) in arterial walls and delivered to the medullary centers.

Baroreceptors. **Baroreceptors** (stretch receptors), located in the aorta, the carotid sinus (Figure 31-29), as well as other locations in the vasculature, influence both heart rate and vascular resistance, and therefore blood pressure. Baroreceptors respond to changes in smooth muscle fiber length by altering their rate of discharge and supply sensory information to the cardiovascular center that regulates blood pressure.[29] (Technically they are mechanoreceptors but they usually are called *baroreceptors* or *pressoreceptors*.) The rate of firing of the baroreceptors increases and decreases with changes in blood pressure. An increase in arterial pressure increases the rate of firing of the carotid sinus and aortic arch baroreceptors. These impulses travel up the afferent nerves to the medulla (e.g., the cardiac control center) and (1) slow heart rate by decreasing sympathetic discharge and increasing parasympathetic discharge (vagus nerve), (2) decrease myocardial contractility by inhibiting sympathetic discharge, and (3) increase arteriolar and venous dilation by decreasing sympathetic discharge to smooth muscle. The net effect of this major blood pressure–regulating reflex is to reduce blood pressure to normal by decreasing cardiac output (heart rate and stroke volume) and peripheral resistance. Conversely, the baroreceptor response to decreased blood pressure results in an increase in heart rate, an increase in myocardial contractility, and peripheral vasoconstriction, thus raising the blood pressure. (Postural changes and the baroreceptor reflex are discussed in Chapter 32.)

Arterial Chemoreceptors. Specialized areas within the medulla oblongata and aortic and carotid arteries are sensitive to concentrations of oxygen (Pao_2), carbon dioxide ($Paco_2$), and hydrogen ions (pH) in the blood. Although these receptors, called *chemoreceptors*, are more important for respiratory control, they also transmit impulses to the medullary cardiovascular centers that regulate blood pressure. A decrease in arterial oxygen concentration or an increase in $Paco_2$ causes

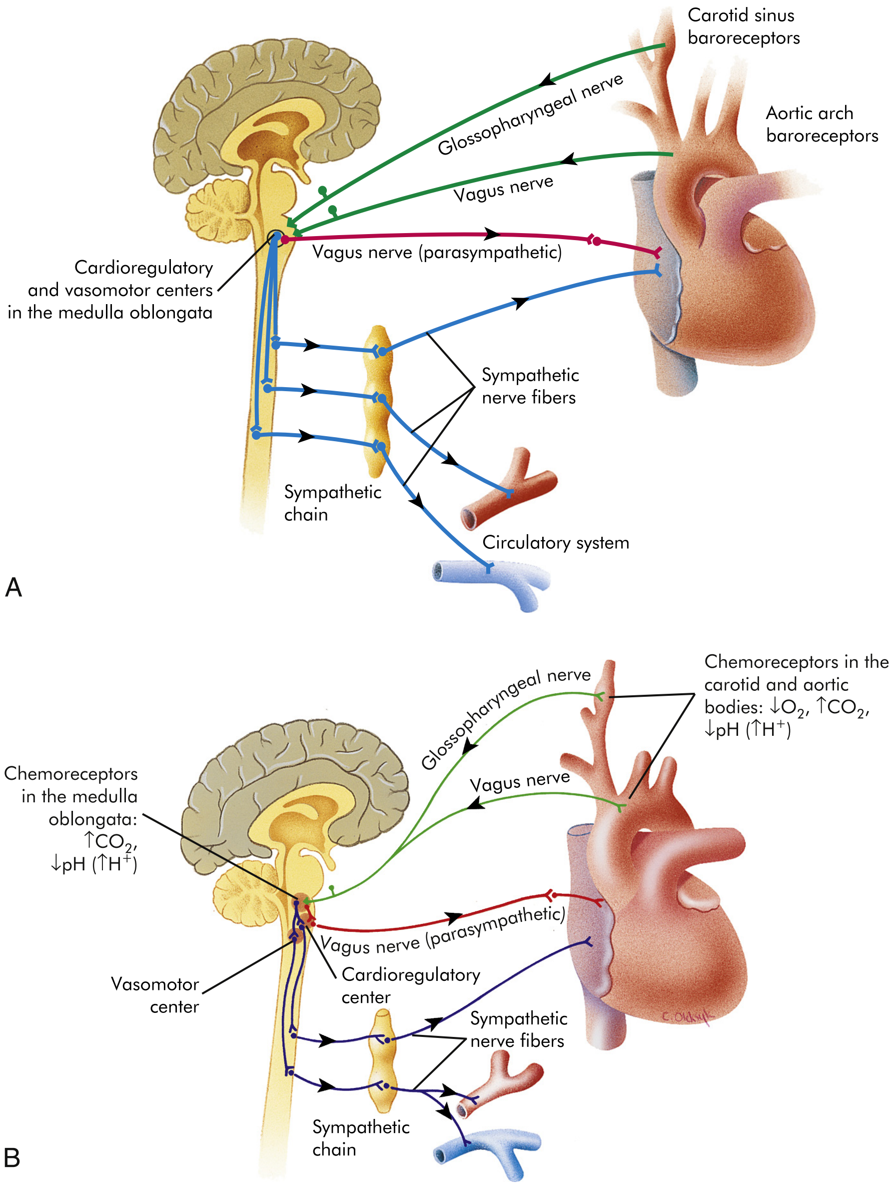

FIGURE 31-29 Baroreceptor and Chemoreceptor Reflex Control of Blood Pressure. **A,** Baroreceptor reflexes. Baroreceptors located in the carotid sinuses and aortic arch detect changes in blood pressure. Action potentials are conducted to the cardioregulatory and vasomotor centers. The heart rate can be decreased by the parasympathetic system; the heart rate and stroke volume can be increased by the sympathetic system. The sympathetic system also can constrict or dilate blood vessels. **B,** Chemoreceptor reflexes. Chemoreceptors located in the medulla oblongata and in the carotid and aortic bodies detect changes in levels of blood oxygen, carbon dioxide, or pH. Action potentials are conducted to the medulla oblongata. In response, the vasomotor center can cause vasoconstriction or dilation of blood vessels by the sympathetic system, and the cardioregulatory center can cause changes in the pumping activity of the heart through the parasympathetic and sympathetic systems. (From Seeley RR, Stephens TD, Tate P: *Anatomy & physiology,* ed 3, St Louis, 1995, Mosby.)

a reflexive increase in heart rate, stroke volume, and blood pressure, whereas an increase in carbon dioxide concentration causes decreases in these variables. The major chemoreceptive reflex is caused by alterations in arterial oxygen concentration. The effects of altered pH or carbon dioxide levels are minor.

Effect of Hyperemia. When metabolic activity is increased in the heart, skeletal muscle, and other muscular organs, it causes an increase in blood flow termed **hyperemia.** For example, the blood flow to exercising skeletal muscle increases in proportion to the activity of the muscle. This condition, known as *active (exercise) hyperemia,* is the result of arteriolar dilation and autoregulation of blood flow within the active organ. *Reactive hyperemia* refers to vasodilation in response to restoration of blood flow after a period of tissue ischemia and results from a buildup of vasodilatory metabolic byproducts in the ischemic tissue. After an infarction in a vascular bed, the subsequent reactive hyperemia that may occur has been associated with damage known as *ischemia reperfusion injury*.[30]

Effects of Hormones. Hormones influence total peripheral resistance and blood volume by changing either vascular

tone or blood volume. Certain hormones cause contraction or relaxation of arteriolar smooth muscle. By constricting or dilating arterioles in specific vascular beds, hormones can (1) increase the blood supply to vital organs that require more blood flow in times of stress, (2) redistribute blood volume during hemorrhage or shock, and (3) regulate heat loss.

The **vasoconstrictor hormones** include angiotensin II, vasopressin (also known as antidiuretic hormone), epinephrine, and norepinephrine. **Epinephrine,** the catecholamine hormone released from the adrenal medulla, causes vasoconstriction in most vascular beds except the coronary, liver, and skeletal muscle circulations. **Norepinephrine** mainly acts as a neurotransmitter; however, some is also released from the adrenal medulla and is actually a more potent vasoconstrictor than epinephrine. Both **angiotensin II** and **vasopressin** are vasoconstrictors but they are not thought to have a major role in blood pressure control in normal circumstances.

Both vasopressin and aldosterone influence blood pressure by increasing blood volume through their influence on fluid reabsorption in the kidney and by stimulating thirst. Vasopressin causes the reabsorption of water from tubular fluid in the distal tubule and collecting duct of the nephron. **Aldosterone,** part of the renin-angiotensin-aldosterone system, stimulates the reabsorption of sodium, chloride, and water from the same locations. The natriuretic hormones, which include **brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP),** and **urodilatin,** all cause loss of sodium, chloride, and water through their effects on kidney function.[31]

Adrenomedullin (ADM) is a recently discovered, widely dispersed peptide present in numerous tissues with powerful vasodilatory activity, and is a member of the calcitonin gene–related peptide family. Although it has been found to have numerous cardiovascular effects in animals, including a role in fetal cardiovascular system development and vasodilation, its exact role in adult human cardiovascular function has not been identified. It is likely that it has a role in cardiovascular disease but those links remain to be explored.[32]

Effects of Other Mediators. Several mediators produced by the vascular endothelium have been demonstrated to cause arteriolar vasodilation. These mediators include nitric oxide (NO), prostaglandins, endothelium-derived relaxing factor, and possibly other molecules. The velocity of blood movement within the arterioles causes shear stress at the vascular endothelial surface that in turn is the stimulus that causes the endothelial cells to produce these vasodilator substances. The flow-mediated dilation (FMD) test is used to evaluate endothelial function and to predict the risk of cardiovascular disease. A reduction in FMD is predictive of increased risk.[33]

Venous Pressure

The main determinants of venous blood pressure are: (1) the volume of fluid within the veins, and (2) the compliance (distensibility) of the vessel walls. Veins have much thinner walls than arteries and are more distensible. Typically, the venous system accommodates approximately 66% of the total blood volume with venous pressure averaging less than 10 mmHg. The systemic arteries accommodate about 11% of the total blood volume, with an average arterial pressure (blood pressure) of about 100 mmHg, whereas the rest of the blood volume is within the heart, capillaries, and pulmonary circulation.[18]

The sympathetic nervous system controls compliance. The walls of the veins are highly innervated by sympathetic fibers that control venous smooth muscle. When the sympathetic nerves to the veins fire, the result is an increase in smooth muscle tone rather than vasoconstriction, which would be the result in arterial vessels. This increased smooth muscle tone stiffens the walls of the veins, reducing distensibility and increasing venous blood pressure, thus forcing more blood through the veins and into the right heart.

Two other mechanisms that increase venous pressure and venous return to the heart are: (1) the skeletal muscle pump, and (2) the respiratory pump. During skeletal muscle contraction the veins within the muscles are partially compressed, causing a decrease in venous capacity and increased return to the heart. The respiratory pump acts during inspiration, when the veins of the abdomen are partially compressed by the downward movement of the diaphragm. Increased abdominal pressure moves blood toward the heart.

Regulation of Coronary Circulation

Flow of blood in the coronary circulation, as in all vascular beds, is directly proportional to the perfusion pressure and inversely proportional to the vascular resistance of the bed. **Coronary perfusion pressure** is the difference between pressure in the aorta and pressure in the coronary vessels. Thus aortic pressure is the driving pressure that propels the perfusion of myocardial vessels. Mechanisms of vasodilation and vasoconstriction normally maintain coronary blood flow despite stresses imposed by the constant contraction and relaxation of the heart muscle and despite shifts (within a physiologic range) of coronary perfusion pressure.

Several unique anatomic factors influence coronary blood flow. Because of their location, the aortic valve cusps can obstruct coronary blood flow by pushing against the openings of the coronary arteries during systole. Also during systole, the coronary arteries are compressed by ventricular contraction. These anatomic factors have a **systolic compressive effect,** which is particularly evident in the subendocardial layers of the left ventricular wall and can greatly increase resistance to coronary blood flow. Therefore, most coronary blood flow in the left ventricle occurs during diastole. During the period of systolic compression, when flow is slowed or stopped, oxygen is supplied by **myoglobin,** a protein in heart muscle (also smooth and skeletal muscle) that binds oxygen during contraction, diastole in the heart, and then releases it when blood levels of oxygen fall during relaxation or systole. Myoglobin is structurally different than hemoglobin although both contain a heme group.[34]

Autoregulation

Autoregulation (automatic self-regulation) enables organs to regulate blood flow by altering the resistance in their arterioles. Autoregulation in the coronary circulation maintains the blood flow at a nearly constant rate at perfusion pressures (mean arterial pressure) between 60 and 180 mmHg when

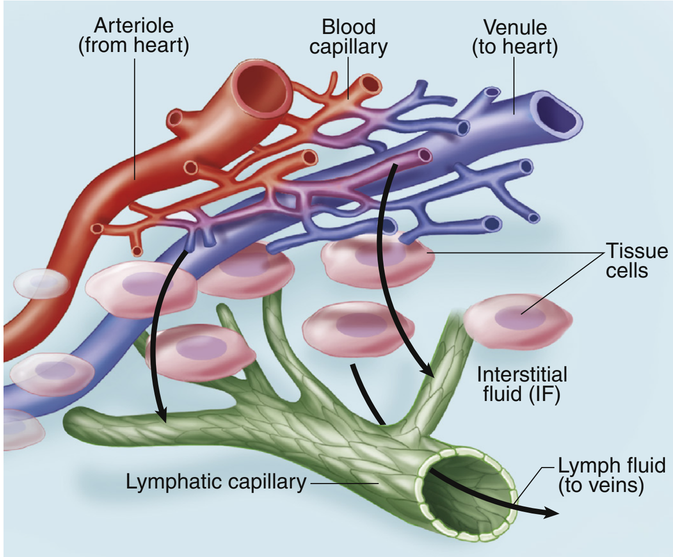

FIGURE 31-30 Role of the Lymphatic System in Fluid Balance. Fluid from plasma flowing through the capillaries moves into interstitial spaces. Although *most* of this interstitial fluid is either absorbed by tissue cells or resorbed by blood capillaries, *some* of the fluid tends to accumulate in the interstitial spaces. As this fluid builds up, it usually drains into lymphatic vessels *(green)* that eventually return the fluid to the venous blood. Lymphatic structures are not actually green. Green is used in diagrams to contrast lymphatic structures with nearby blood vessels *(red, blue)*. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

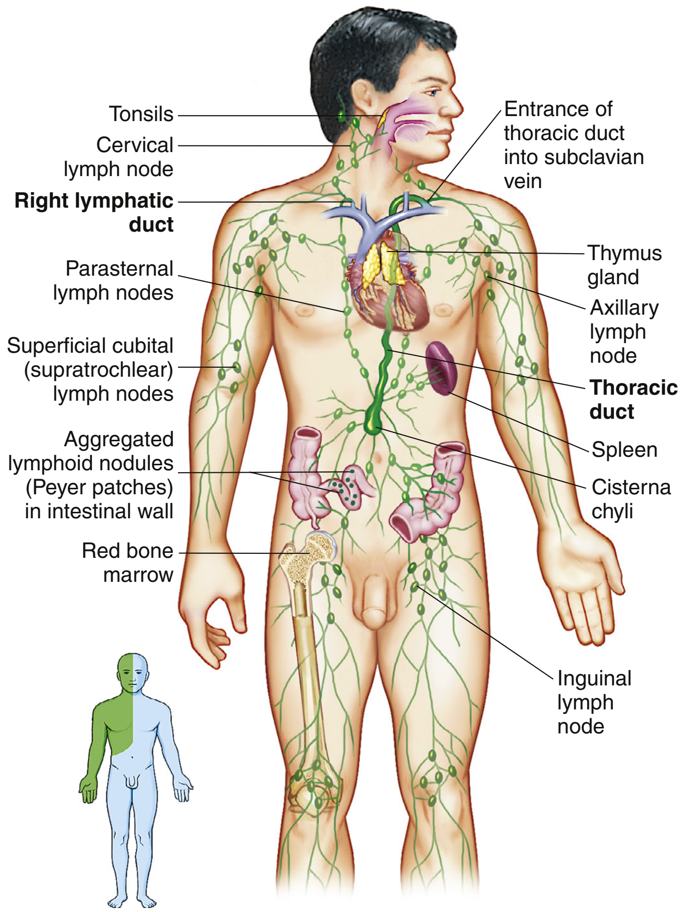

FIGURE 31-31 Principal Organs of the Lymphatic System. The inset shows the areas drained by the right lymphatic duct *(green)* and the thoracic duct *(blue)*. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

other influencing factors are held constant. Thus autoregulation helps to ensure constant coronary blood flow despite shifts in the perfusion pressure within the stated range. Given that blood flow is directly related to pressure and inversely related to resistance, we know that for flow to stay constant as pressure decreases, resistance also has to decrease; thus the mechanism(s) underlying autoregulation must relate to control of smooth muscle contraction in the arteriolar walls. Although the exact mechanisms underlying autoregulation are not known, some research has indicated that G-protein–coupled receptors that influence calcium release with the myocardium are involved.[35]

LYMPHATIC SYSTEM

The **lymphatic system** is a one-way network of vessels that is important for fluid balance, immune function, and transport of lipids, hormones, and cytokines. Every day about 3 liters of fluid filters out of venous capillaries in body tissues and is not reabsorbed. This fluid becomes the lymph that is carried by the lymphatic vessels to the chest where it enters the venous circulation. The lymphatic vessels run in the same sheaths with the arteries and veins (Figure 31-30). The lymphatic system consists of lymphatic vessels and the lymph nodes (Figure 31-31). (Lymph nodes and lymphoid tissues are described in Chapters 7 and 27.) In this pumpless system a series of valves ensures one-way flow of the excess interstitial fluid (then called *lymph*) toward the heart. The lymphatic capillaries are closed at the distal ends (Figure 31-32).

Lymph consists primarily of water and small amounts of dissolved proteins, mostly albumin, that are too large to be reabsorbed into the less permeable blood capillaries. Lymph also carries two types of cells—lymphocytes and antigen-presenting cells. The antigen-presenting cells are carried to the next lymph node in the system whereas lymphocytes traffic between lymph nodes. Once within the lymphatic system, lymph travels through **lymphatic venules** and **veins** that drain into one of two large ducts in the thorax—the right lymphatic duct and the thoracic duct. The **right lymphatic duct** drains lymph from the right arm and the right side of the head and thorax, whereas the larger thoracic duct receives lymph from the rest of the body (see Figure 31-31). The right lymphatic duct and the **thoracic duct** drain lymph into the right and left subclavian veins, respectively.

The lymphatic veins are thin walled, like the veins of the cardiovascular system. In the larger lymphatic veins, endothelial flaps form valves similar to those in the circulatory veins. The valves permit lymph to flow in only one direction because lymphatic vessels are compressed intermittently by contraction of skeletal muscles, pulsatile expansion of an artery in the same sheath, and contraction of the smooth muscles in the walls of the lymphatic vessel.

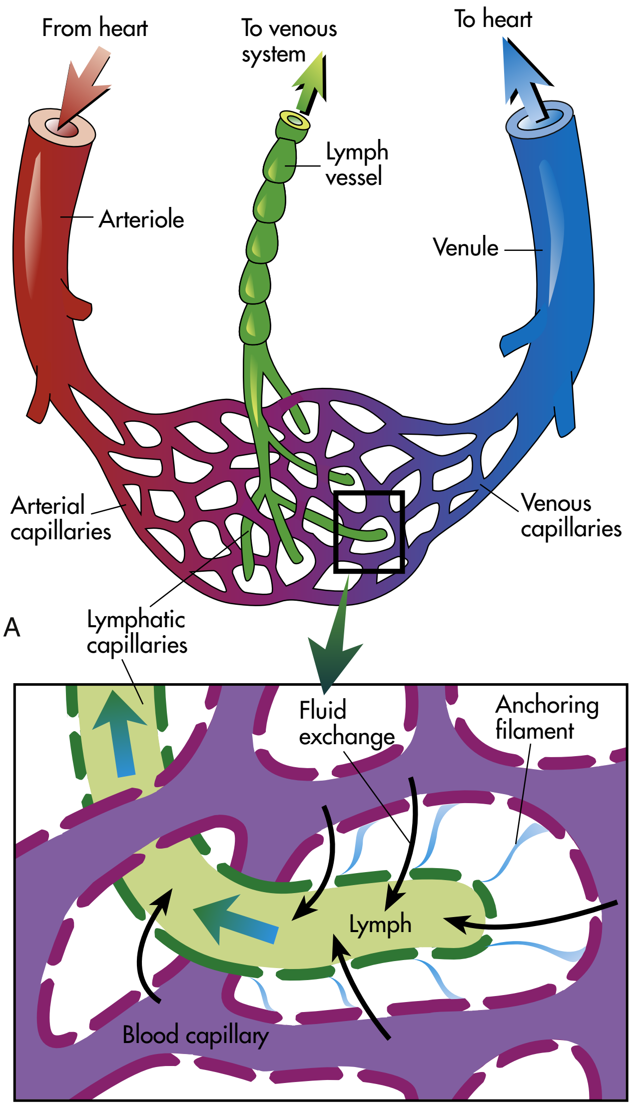

FIGURE 31-32 Lymphatic Capillaries. **A,** Schematic representation of lymphatic capillaries. **B,** Anatomic components of microcirculation.

As lymph is transported toward the heart, it is filtered through thousands of bean-shaped lymph nodes clustered along the lymphatic vessels (see Figure 31-31). Lymph enters the nodes through several **afferent lymphatic vessels,** filters through the sinuses in the nodes, and leaves by way of **efferent lymphatic vessels.** Lymph flows slowly through a node, which facilitates the phagocytosis of foreign substances within the node by antigen-presenting cells and the entry of mature but naïve B and T lymphocytes, which then circulate through the body, moving from one lymph node to the next while waiting for a chance encounter with the antigen to which they are programmed to respond (see What's New? Growth of New Lymphatic Vessels from Macrophages). (Phagocytosis is described in Chapter 7.)

TESTS OF CARDIOVASCULAR FUNCTION

Assessment of the individual with suspected cardiovascular disorders begins with a thorough history for determination of risk factors and symptoms. A careful physical examination looking for evidence of tissue ischemia, pulmonary congestion, and cardiac dysfunction is next. Blood samples are taken and sent for a variety of tests. For many individuals, these basic steps will be complemented with methods that measure heart and vascular function with greater specificity. Cardiac function can be evaluated using indicators calculated from pressures and flow rates in the heart and vessels. Table 31-4 defines the indicators most often used in the clinical setting. The normal values for several testing methods are different for men and women.[36,37] This textbook's inside back cover includes normal blood values for common laboratory tests.

WHAT'S NEW?

Growth of New Lymphatic Vessels from Macrophages

During inflammation and wound healing in adults, new lymphatic vessels sprout from existing vessels in the affected area, a process known as lymphangiogenesis. When inflammation occurs, inflammatory cytokines, such as vascular endothelial growth factors A and C (VEGF-A and VEGF-C), bind to receptors, such as the VEGF receptor 3 (VEGFR-3), on macrophages and stimulate the division of lymphatic endothelial cells and the formation of new lymphatic capillaries that will drain the affected tissue. Some macrophages in the area differentiate into a new subtype, known as a macrophage-derived lymphatic endothelial cell progenitor, that is capable of working with the lymphatic endothelial cells to create the new lymphatic capillaries. Understanding the factors that stimulate and control this growth of new lymphatic vessels may allow treatment of conditions such as lymphedema, as well as some heart conditions, impaired wound healing, and some types of cancer.

Cardiac and Coronary Artery Evaluation

Many sophisticated tests are used to evaluate and diagnose cardiac or coronary artery diseases, and new ones are being tested each year. Some of the more commonly used modalities include chest x-ray, electrocardiography, echocardiography, stress testing, computed tomography (CT) and magnetic resonance imaging (MRI), technetium scanning, electrophysiology studies, and catheterization with angiography.

Chest Radiograph Examination

Chest x-rays allow for the examination of the size and contour of the heart and related structures. Evidence of chamber enlargement, pericardial disease, pulmonary edema, valvular calcification, ventricular hypertrophy, and pathology of the great vessels may be visualized. Chest x-ray also is useful to assess for appropriate placement of invasive cardiac conduction devices and for any complications caused by these devices (e.g., pneumothorax or hemothorax; see Chapter 35). A chest x-ray examination is a routine part of a cardiac examination. The most commonly obtained views are posteroanterior (PA) and lateral, with the individual standing upright and the lungs fully expanded. In those individuals confined to bed, an anteroposterior (AP) view may be obtained but is usually of lesser quality than the PA view.

TABLE 31-4 INDICATORS OF CARDIAC FUNCTION

INDICATOR	DEFINITION*	COMMON CAUSE OF ABNORMALITY
Heart rate (HR)	Number of heartbeats (cardiac cycles) per minute Normal adult value: 70 beats/min	Ischemia, electrolyte disturbances, drug toxicity
Cardiac output (CO)	Amount of blood (in L) moved by the heart in 1 min Normal range: 4-8 L/min	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
Cardiac index (CI)	Relationship between cardiac output and body surface area (BSA, in m^2) Normal range: 2.8-4.2 L/min/m^2	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
Stroke volume (SV)	Amount of blood (in ml) ejected by the left ventricle during systole (i.e., per beat) Normal range: 60-100 ml/beat	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
Stroke volume index (SVI)	Relationship between stroke volume and body surface area Normal range: 33-47 ml/beat/m^2	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
Oxygen consumption index ($\dot{V}O_2$)	Amount of oxygen (in ml) consumed per minute in relation to BSA	Decrease: sedation, anesthesia, hypothermia Increase: elevated temperature, sepsis, seizures
Stroke work index (SWI)	Amount of work (expressed as done) by the left or right ventricle per systole per square meter of BSA Normal value: 35 g/m^2	Decreases within specific ranges indicate cardiogenic or hypovolemic shock (see Chapter 48) Increase: elevated systemic vascular resistance
Systemic mean arterial pressure (MAP)	Mean blood pressure (in mmHg) in the systemic arteries Normal range: 70-100 mmHg	Elevated: epinephrine release, diseases of arteries, primary hypertension Decreased: cardiac failure, decreased vascular resistance of sepsis
Pulmonary vascular resistance (PVR)	Relationship among cardiac output, preload, and afterload, expressed as units of force of resistance per second per centimeter of water Normal value: less than 250 dynes/sec/cm^{-5}	Increased: acute respiratory distress syndrome (ARDS), pneumonia, primary pulmonary hypertension, congestive heart failure Decreased: late shock
Systemic vascular resistance (SVR)	Same definition as for PVR Normal range: 770-1500 dynes/sec/cm^{-5}	Increased: epinephrine release Decreased: inflammatory response

*Values given are for adults at rest.

Electrocardiography

Electrocardiography, typically a 12-lead electrocardiogram (ECG), gives information about heart rate and rhythm; the effects of activities of daily life, exercise, electrolytes, drugs, and disease on electrical activity in the heart; and the electrical orientation of the cardiac muscle. An ECG provides no direct information about the contractile state or mechanical performance of the heart.

Serial 12-lead ECGs are of primary importance in establishing the presence of myocardial ischemia and infarction or conduction defects and dysrhythmias. This examination has become part of the routine hospital preadmission/admission assessment, even when the admitting diagnosis is not cardiac in nature, because it establishes baseline information about the electrical function of the heart. Also, recent ECGs can be compared with ECGs obtained from the same individual in the past. Changes in the ECG over time assist in determining the cause, amount, or nature of changes in cardiac anatomy and physiology. Ambulatory electrocardiographic or Holter monitoring is used to evaluate rhythm changes that may occur in persons during activities of daily living. Cell phone technology also is rapidly advancing to enable ECG recording and relaying to healthcare providers.

Echocardiography

Echocardiography is the most effective and widely used noninvasive modality for evaluating the structures of the heart. Ultrasound beams reflected by cardiovascular structures produce shapes that can be visualized and allow for recognition of altered cardiac anatomy.[38] It is used to evaluate for suspected coronary artery disease, heart failure, valvular disease, infective endocarditis, cardiomyopathies, pericardial disease, prosthetic valve function, congenital heart disease, and aortic diseases. Through the use of M-mode, two- and three-dimensional techniques with Doppler and color flow imaging, accurate assessments of cardiac output, ejection fraction, and valvular function can be obtained.[38,39] Advances in technology now allow both intracardiac and transesophageal echocardiography for evaluation of the heart anatomy, although anesthesia is required for the transesophageal technique.[40]

Exercise or Stress Testing

Cardiac activity during exercise is examined during a stress test when an intervention is used to increase myocardial work. Stress testing elicits signs and symptoms of heart disease and coronary artery disease that may not appear at rest. Echocardiography or continuous 12-lead ECG and blood pressure measurements are obtained before, during, and after the study. Cardiac stress from exercise is usually induced by having the individual walk on a treadmill. Other, less frequently used forms of exercise include static exercise (hand ergometry or chemical stress), stair climbing (the Stairmaster's double two-step), arm ergometry, and bicycle ergometry. The individual exercises until the maximal heart rate for gender and age is reached or

until other subjective or objective indicators of cardiac dysfunction or distress appear. Subjective indicators include chest pain, extreme fatigue, extreme dyspnea, leg pain, or the individual's request to stop the test. Objective criteria are ST-segment elevation or depression, SA node or atrial dysrhythmias, AV node dysrhythmias, ventricular dysrhythmias, elevated or decreased blood pressure, signs of cerebral hypoxia, and signs of circulatory insufficiency. One limitation of this test is that it cannot be used in persons whose capacity for exercise is limited.

Stress testing also may be used to evaluate either fitness for noncardiac surgery or progress in recovery after myocardial infarction or cardiac surgery. Graded exercise in individuals with low- to moderate-risk chest pain evaluated in an emergency department can be used as a prognostic indicator of adverse cardiac events. When a differential diagnosis for chest pain has been difficult to determine, stress testing may help distinguish coronary artery insufficiency from other causes of pain. The risks associated with stress testing include dysrhythmias, myocardial infarction, and death. The risk is greater when the test is performed soon after an acute ischemic event.

Stress testing with ECG monitoring may not be sensitive enough to detect and localize areas of the myocardium at risk for ischemia and infarction. Currently, most stress testing includes the injection of a radiotracer that is absorbed by active heart cells. When the heart is scanned, during and after stress testing, areas where the radiotracer is not taken up by ischemic cells can be seen and those locations indicate areas of myocardial damage.

Single-Photon Emission Computed Tomography

Single-photon emission computed tomography (SPECT) is typically used to evaluate individuals for coronary artery disease and myocardial ischemia during stress testing. A radiotracer (usually thalium-201) is injected intravenously and is absorbed and retained for a while by healthy myocytes.[41] Photons are emitted from the radiotracer in the myocardium in proportion to perfusion of the tissue. A gamma camera visualizes the photons, and views are taken from 360 degrees by CT, which digitizes the information and provides a three-dimensional view of myocardial perfusion. Data about where the myocardium absorbs the tracer normally, slowly, or not at all can be correlated with existing myocardial disease and can help quantify ischemic risk. A new development, high-speed SPECT, has the advantage of taking less time and, thereby, requiring less radiotracer, which decreases radiation exposure for the person being examined.[41]

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

Computed tomography (CT) and magnetic resonance imaging (MRI) are used to evaluate cardiac anatomy and physiology. New techniques, including ECG gating (timing of data gathering to the cardiac cycle), electron beam CT, and spiral CT, have improved the ability of tomography to visualize cardiac structures. The high resolution of CT can provide information about calcification of coronary vessels and cardiac valves. Information about coronary artery calcification is being used to improve risk classification for coronary artery disease.[42] It also is a tool for evaluating large-vessel disease. Concerns and debate continue, however, about the radiation risks and use of variable protocols. The International Commission on Radiological Protection (ICRP) recently released a report on radiological protection in cardiology.[43]

MRI is based on the principle that the frequency of energy (resonant frequency) given up by a nucleus is exactly proportional to the surrounding magnetic field (see Chapter 15). The anatomy and physiology of the great blood vessels and myocardium are depicted in three dimensions with excellent resolution. Ventricular function can be evaluated using indexes of ventricular function, such as ejection fraction. Rapidly moving sequences (MRI) can determine regional wall motion and myocardial deformation. Flow direction and velocity also can be quantitatively determined. Stress testing also can be done with MRI using the drug dobutamine to increase the cardiac workload instead of exercise.[44]

Technetium Scanning

Radiopharmaceuticals labeled with ^{99m}technetium preparations, such as sestamibi, teboroxime, and tetrofosmin, are used to image the coronary arteries and myocardium. Technetium pyrophosphate (^{99m}TcPYP) is injected intravenously into a resting individual during a "hot spot" imaging examination. Two hours after injection the distribution pattern of the radioactive solution is recorded by nuclear scan. During the 2-hour delay, the injected material will have been taken up by infarcted areas of the myocardium, particularly 1 to 3 days after the onset of symptoms. This type of scanning also is done with stress testing using exercise or dobutamine.[45] Study results are not definitive during the first 12 hours after an infarct.

Technetium scanning is used when (1) there is a conflicting history for myocardial infarction, (2) there are equivocal ECG abnormalities, or (3) an individual's cardiac enzymes have been elevated because of surgery or trauma. Ongoing research is determining any risks associated with radioactive substances.

Electrophysiology Studies

In-depth evaluation of electrical conduction within the heart can provide important information about the nature and causes of dysrhythmias, such as atrial and ventricular tachycardias and heart block. This evaluation is often referred to as *electrophysiologic mapping* of the myocardium. There are many types of electrophysiology studies that are specific to certain conduction disorders but they have the common goal of documenting abnormal conduction pathways. Furthermore, the techniques used may also allow for ablation of unwanted pathways or the appropriate placement of pacemakers and implantable defibrillators. Mapping can include the use of echocardiography and CT scanning.[46]

One example of an electrophysiology study is AV bundle electrocardiography. Two electrode-tipped catheters are inserted percutaneously into the femoral vein, floated up the inferior vena cava, and positioned in or near the right atrium during AV bundle (His bundle) electrocardiography. AV bundle electrocardiography can detect secondary sites of impulse generation (ectopic foci), as well as accessory pathways of conduction. Other conduction defects and the effects of drugs on conduction also can be illuminated. Risks related to this procedure can be grave and include dysrhythmias, death, vessel or heart perforation, clot or plaque embolization, and kidney failure.

Cardiac Catheterization and Angiography

One or both sides of the heart can be examined using **cardiac catheterization.** This invasive procedure requires the use of fluoroscopy and strict sterile techniques and takes place in a specially equipped catheterization laboratory. Local anesthetic is administered, and a catheter is introduced percutaneously into the vasculature and passed caudally into the atrium and ventricle. For a right-heart catheterization, the catheter is placed in either the jugular, subclavian, brachial, or femoral veins. The femoral artery is commonly used for a left-heart study. Once the catheter has been guided into the heart chambers, pressures are recorded, blood samples are obtained to examine oxygen content, and a contrast medium is injected to visualize chamber function and valve patency.

Cardiac catheterization provides a means to visualize the chambers of the heart continuously, although for a short time. A great deal of information can be obtained about heart structure and function. Pressures in each chamber and across heart valves can be precisely measured, along with timing of events in the cardiac cycle. Of particular value is the ability to compare the oxygen content of blood in each heart chamber. Risks for this procedure that have decreased over time include the development of dysrhythmias. Death can occur secondary to cardiac arrest after ventricular fibrillation.

Fluoroscopic visualization of the coronary arteries and left-heart structures using contrast dye is called **coronary angiography** or arteriography. Like cardiac catheterization, this study takes place in a catheterization laboratory using local anesthesia and a sterile field. A catheter is threaded into the left ventricle through the femoral artery. A ventriculogram generally is performed first. Contrast dye is injected into the apex of the ventricle, and the next few cardiac cycles are visualized and filmed. Like cardiac catheterization, coronary angiography is used to gain information about the structure and function of the ventricles and related valves. After the ventriculogram, catheters are introduced individually into the ostia of the coronary arteries. When the catheter is in position, a small volume of contrast dye is mechanically and rapidly injected into the artery and the results are visualized and filmed. Dye injection is repeated with the individual tilted at various angles to afford views of the artery other than the anteroposterior view.

The risks of for coronary angiography are similar to those of cardiac catheterization, with exceptions. Because the blood supply to the cardiac muscle is briefly interrupted when dye is introduced into the coronary arteries, angina (chest pain) caused by ischemia (lack of oxygen) is much more common. Coronary artery spasms also can occur. Interrupted flow also causes decreased heart rate (bradycardia), as well as some tachydysrhythmias, hypotension, and ST-segment depression.

Systemic Vascular Evaluation

The systemic vascular system can be studied by a variety of techniques in order to evaluate for adequate flow rates, vascular obstruction, and structural defects. These techniques include Doppler ultrasonography, CT and MRI, venography, and arteriography.

Arterial Pressure Pulse Waveform Analysis

Pulsation, described by the flow of blood through an artery during the cardiac cycle, can be drawn as a waveform plotting pressure against time (Figure 31-33). The waveform can be obtained noninvasively by placing a transducer on the skin over the carotid artery while the individual's head is turned slightly away from the transducer. The amplitude and shape of arterial waveforms can provide information about the elasticity of the arterial wall, or its inverse—the stiffness of the wall.

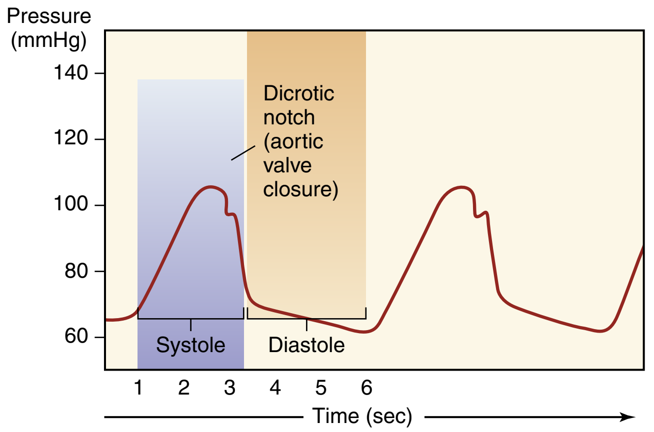

FIGURE 31-33 Arterial Pressure Pulse Waveforms.

Doppler Ultrasonography Studies

A Doppler study is done using a microphone that amplifies and records the sounds made by blood flowing in peripheral vessels. The Doppler microphone is placed over the vessel to be studied, and sounds related to obstructions to flow, vessel wall mobility, and heart murmurs are transmitted through a lubricating gel to the microphone. The audio findings can be digitized into visual findings that can be analyzed for flow velocity and volume. These studies are useful in the evaluation for abnormalities of venous flow (e.g., deep venous thrombosis) and arterial flow (e.g., embolism). Ultrasound also is used to calculate the thickness of arterial walls, yielding a reading called *intimal-medial thickness*. Carotid intimal-medial thickness is used to assess for atherosclerosis.[47] Many people are familiar with ultrasound measurements because they are commonly used to assess fetal growth and development.

Computed Tomography and Magnetic Resonance Imaging

CT and MRI are used to evaluate the systemic circulation, providing information about the structure of the great vessels. Either can be used to evaluate for aneurysms and dissections of the thoracic or abdominal aorta. CT also is used to assess for vessel calcification and provide some insights into the risk for stroke and myocardial infarction through evaluation of the carotid and coronary vessels.

Venography and Arteriography

Radiopaque dye can be injected through intravenous or intra-arterial catheters to allow for visualization of the internal structure, diameter, and patency of veins and arteries. Venography is performed primarily in the lower extremity to assess for the presence of thrombi in the large veins of the leg. Arteriography (angiography) can be used in almost any vascular system,

TABLE 31-5 **CARDIOVASCULAR FUNCTION IN OLDER ADULTS**

DETERMINANT	RESTING CARDIAC PERFORMANCE	EXERCISE CARDIAC PERFORMANCE
Cardiac index	Unchanged or slightly decreased in women only	Declines because of a decrease in heart rate and stroke volume
Heart rate	Slight decrease	Increases less than in younger people, possibly because of decreased cardiovascular response to catecholamines; overall slight decrease
Stroke volume	Slight increase	Slight increase
Ejection fraction	Unchanged	Increases less from rest to exercise in older people than in younger people
Afterload	Increased	Uncertain
End-diastolic volume	Unchanged	Unchanged
End-systolic volume	Unchanged	Higher in older people than in younger people
Contraction	Increased because of prolonged relaxation	Decreases with vigorous exercise*
Cardiac dilation	No change	Increases at end-diastole and end-systole
O_2 max	Not applicable	Declines because of a decline in skeletal muscle mass and increase in body fat

Data from Najjar SS, Gerstenblith G, Lakatta EG: Aging and the cardiovascular system. In Willerson JT et al, editors: *Cardiovascular medicine,* ed 3, London, 2007, Springer-Verlag.
*As measured by end-systolic volume/systolic blood pressure (ESV/SBP), an index of contractility.

including the great vessels and the pulmonary, coronary (see previously in this chapter), cerebral, mesenteric, renal, hepatic, and peripheral arteries. Risks include rupture, dissection, thrombosis, embolization, or organ infarction involving the arterial system being studied.

AGING AND THE CARDIOVASCULAR SYSTEM

Cardiovascular disease is the most common cause of morbidity and mortality in older adults in Western society and in much of the rest of the world.[48] In addition, age is a key driver of cardiovascular risk, which explains why it is the primary cause of death in persons older than age 65.[49] The most common cardiovascular disease condition is hypertension followed by coronary atherosclerosis for which hypertension is a risk factor.

It is challenging to determine the normal physiologic changes in cardiac function with aging because many pathologic changes are usually present and physical fitness is variable in older people as well. Studies of the effect of age on cardiovascular function must be rigorous in their distinction between persons who are free of disease and those who have disease that may be evident only during testing. There is a wide range in the older population for nearly every cardiovascular variable. These variations are related to an increase in the prevalence of hypertension and coronary disease with advancing age; the growth in the segment of the population older than age 65; and major age-associated changes in lifestyle (e.g., fitness status).[49] The most relevant age-associated physiologic changes in cardiovascular performance include myocardial and blood vessel stiffening, changes in neurogenic control over vascular tone, increased occurrence of atrial fibrillation, and loss of exercise capacity plus left ventricular hypertrophy and fibrosis.[49,50] These changes pose considerable consequences with increased demand for flow, changes in posture, or with disease.

Arterial stiffening occurs with aging even in the absence of clinical hypertension. It can, however, be an important contributor to systolic hypertension and its associated risks for cardiovascular events, dementia, and death. These changes result from alterations within the vascular media, including age-associated changes in cross-linking of collagen, an increase in the amount of collagen, deposition of calcium, and changes in the nature of elastin, the extracellular matrix, inflammatory molecules, endothelial cell function, and reactive oxygen species.[26] The increased arterial stiffness may not be related strictly to an age-associated change in vascular structure but may be caused by changes in baroreceptor activity. Baroreceptor activity may decrease with age, slowing physiologic adjustment to changes in blood pressure, and posture. In persons older than age 60, pulse pressure, which is directly influenced by arterial stiffness, is a better predictor of cardiovascular disease than either diastolic or systolic blood pressure.[51]

Left ventricular hypertrophy and fibrosis also are more common in the aging population, even in the absence of high blood pressure. As the arterial system becomes stiffer the ventricles must work harder to pump blood throughout the body, thus contributing to hypertrophy. Fibrosis, calcification, and increase in stiffness also impact valvular function, particularly the function of the atrioventricular valves. These changes make valvular disease a greater risk for the elderly, along with an increased risk of heart failure related to the left ventricular hypertrophy and stiffness.

The advent of genomic medicine and a deeper exploration of molecular changes with aging continue to enhance our understanding of the myriad changes in our bodies as we age.[49,50] The ongoing hope is that as we better understand the causative factors related to cardiovascular decline with aging, we may be able to develop therapeutics that arrest or slow these changes.

Stress testing is used to uncover functional capacity losses that are not apparent at rest. In contrast to the subtle age effects on resting cardiac tests, more dramatic changes occur during exercise. Table 31-5 summarizes age-associated changes at rest and during exercise. Overall, long-term exercise conditioning in older individuals increases aerobic capacity and decreases arterial stiffness and left ventricular function so that cardiovascular diseases may be prevented or delayed in older adults. Although the risks and benefits of pharmacologic and invasive strategies must always be assessed carefully, many older adults can live longer and healthier lives if appropriate preventive and treatment regimens are offered, even quite late in life.

SUMMARY REVIEW

Circulatory System

1. The circulatory system is the body's transport system and a part of its communication system. It delivers oxygen, nutrients, metabolites, hormones, neurochemicals, proteins, and blood cells, including lymphocytes and leukocytes, throughout the body and carries metabolic wastes to the kidneys and lungs for excretion.
2. The circulatory system consists of the heart, blood vessels, and the lymphatic vessels and is made up of two separate but conjoined, serially connected pump systems: the pulmonary circulation and the systemic circulation, plus the lymphatics.
3. The low-pressure pulmonary circulation is driven by the right side of the heart. The function of the pulmonary circulation is to deliver blood to the lungs for oxygenation.
4. The higher pressure systemic circulation is driven by the left side of the heart, and its function is to move oxygenated blood to body tissues and to deliver waste products to the lungs, kidneys, and liver.
5. The lymphatic vessels collect fluids from the interstitium and return the fluids to the circulatory system. Another important function of the lymphatic system is the movement of lymphocytes and leukocytes between different components of the immune system.

The Heart

1. The heart consists of four chambers (two atria and two ventricles), four valves (two AV valves and two semilunar valves), a muscular wall, a fibrous skeleton, a conduction system, nerve fibers, systemic vessels (the coronary circulation), and openings where the great vessels enter the atria and ventricles.
2. The heart wall, which encloses the heart and divides it into chambers, is made up of three layers: the epicardium (outer layer), the myocardium (muscular layer), and the endocardium (inner lining). The heart is contained within the pericardium, a double-walled sac.
3. The myocardial layer of the two atria, which receive blood entering the heart, is thinner than the myocardial layer of the ventricles, which is stronger because it generates the pressure that causes the blood to circulate through the lungs or the systemic circulation.
4. The right and left sides of the heart are separated by portions of the heart wall called the *interatrial septum* and the *interventricular septum.*
5. Unoxygenated (venous) blood from the systemic circulation enters the right atrium through the superior and inferior venae cavae. From the right atrium the blood passes through the right AV (tricuspid) valve into the right ventricle. In the ventricle the blood flows from the inflow tract to the outflow tract and then through the pulmonic semilunar valve (pulmonary valve) into the pulmonary artery, which delivers it to the lungs for oxygenation.
6. Oxygenated blood from the lungs enters the left atrium through the four pulmonary veins (two from the left lung and two from the right lung). From the left atrium the blood passes through the left AV valve (mitral valve) into the left ventricle. In the ventricle the blood flows from the inflow tract to the outflow tract and then through the aortic semilunar valve (aortic valve) into the aorta, which delivers it to systemic arteries of the entire body.
7. The heart valves that ensure the one-way flow of blood from the atria to the ventricles are called the atrioventricular valves. The valves that ensure one-way flow from the ventricles to either the pulmonary artery or the aorta are called semilunar valves.
8. Oxygenated blood enters the coronary arteries through openings within the semilunar valves at the entrance to the aorta, and deoxygenated blood from the coronary veins enters the right atrium through the coronary sinus.
9. The pumping action of the heart consists of two phases: diastole, during which the myocardium relaxes and the chambers fill with blood; and systole, during which the myocardium contracts, forcing blood out of the ventricles. A cardiac cycle consists of one systolic contraction and the diastolic relaxation that follows it. Each cardiac cycle makes up one heartbeat.
10. The sinoatrial (SA) node generates electrical impulses and the conduction system of the heart transmits these electrical impulses (cardiac action potentials) that stimulate systolic contraction. The autonomic nerves (sympathetic and parasympathetic fibers) can adjust heart rate and systolic force, but they do not stimulate the heart to beat.
11. The normal ECG is the sum of all cardiac action potentials. The P wave represents atrial depolarization; the QRS complex is the sum of all ventricular cell depolarizations. The ST interval occurs when the entire ventricular myocardium is depolarized.
12. Cardiac action potentials are generated by the SA node at the rate of between 60 to 100 impulses per minute. The impulses travel through the conduction system of the heart, stimulating myocardial contraction as they travel.
13. Cells of the cardiac conduction system possess the properties of automaticity and rhythmicity. Automatic cells return to threshold and depolarize rhythmically without an outside stimulus. The cells of the SA node depolarize faster than other automatic cells, making it the natural pacemaker of the heart. If the SA node is disabled, the next fastest pacemaker, the AV node, assumes control.
14. Each cardiac action potential travels from the SA node to the AV node to the bundle of His (AV bundle), through the bundle branches, and finally to the Purkinje fibers and the ventricular myocardium. There the impulse is stopped. It is prevented from reversing its path by the refractory period of cells that have just been polarized. The refractory period ensures that diastole (relaxation) will occur, thereby completing the cardiac cycle.
15. Adrenergic receptor number, type, and function govern autonomic (sympathetic) regulation of heart rate, contractile force, and dilation or constriction of coronary arteries.

SUMMARY REVIEW—cont'd

The presence of specific receptors (α_1, α_2, β_1, β_2, β_3) in the myocardium and coronary vessels determines the effects of the neurotransmitters norepinephrine and epinephrine.

16. Unique features that distinguish myocardial cells from skeletal cells enable myocardial cells to transmit action potentials faster (through intercalated disks), synthesize more ATP (because of a large number of mitochondria), and have readier access to ions in the interstitium (because of an abundance of transverse tubules). These combined differences enable the myocardium to work constantly, which is not required of skeletal muscle.
17. Cross-bridges between actin and myosin enable contraction to occur. Calcium and its interaction with the troponin complex facilitate the contraction process. With troponin release of calcium, myocardial relaxation begins.
18. Cardiac performance is affected by preload, afterload, heart rate, and myocardial contractility.
19. Preload, or pressure generated in the ventricles at the end of diastole, depends on the amount of blood in the ventricle. Afterload is the resistance to ejection of the blood from the ventricle. Afterload depends on pressure in the aorta.
20. Contractility is the potential for myocardial fiber shortening during systole. It is determined by the amount of stretch during diastole (i.e., preload) and by sympathetic stimulation of the ventricles.
21. The Frank-Starling law of the heart states that the myocardial stretch determines the force of myocardial contraction (the greater the stretch, the stronger the contraction).
22. Laplace's law states that the amount of contractile force generated within a chamber depends on the radius of the chamber and the thickness of its wall (the smaller the radius and the thicker the wall, the greater the force of contraction).

Systemic Circulation

1. Blood flows from the left ventricle into the aorta and from the aorta into arteries that eventually branch into arterioles and capillaries, the smallest of the arterial vessels. Oxygen, nutrients, and other substances needed for cellular metabolism pass from the capillaries into the interstitium, where they are available for uptake by the cells. Capillaries also absorb products of cellular metabolism from the interstitium.
2. Venules, the smallest veins, receive capillary blood. From the venules the venous blood flows into larger and larger veins until it reaches the venae cavae, through which it enters the right atrium.
3. Vessel walls consist of three layers: the tunica intima (inner layer), the tunica media (middle layer), and the tunica externa (outer layer).
4. Layers of the vessel wall differ in thickness and composition from vessel to vessel, depending on the vessel's size and location within the circulatory system. In general, the tunica media of arteries close to the heart contains a greater proportion of elastic fibers because these arteries must be able to distend during systole and recoil during diastole. Distributing arteries farther from the heart contain a greater proportion of smooth muscle fibers because these arteries must be able to constrict and dilate to control blood pressure and volume within specific capillary beds.
5. Blood flow into the capillary beds is controlled by the contraction and relaxation of smooth muscle bands (precapillary sphincters) at junctions between metarterioles and capillaries. The endothelium is probably a source of prostaglandins that control vasomotion.
6. Blood flow through the veins is assisted by the contraction of skeletal muscles (the muscle pump), and backwards flow in the lower body is prevented by one-way valves, particularly in the deep veins of the legs.
7. Blood flow is affected by blood pressure; resistance to flow within the vessels; blood consistency (which affects velocity); anatomic features that may cause turbulent or laminar flow; and compliance (distensibility) of the vessels.
8. Poiseuille's law describes the relationship of blood flow, pressure, and resistance as the difference between pressure at the inflow end of the vessel and pressure at the outflow end divided by resistance within the vessel.
9. Resistance to blood flow depends on vessel length and radius and on the viscosity of the blood. The greater a vessel's length and the blood's viscosity and the narrower the radius of the vessel's lumen, the greater the resistance within the vessel.
10. Total peripheral resistance, or the resistance to flow within the entire systemic circulatory system, depends on the combined lengths and radii of all the vessels within the system and on whether the vessels are arranged in series (greater resistance) or in parallel (lesser resistance).
11. Blood flow is influenced also by neural stimulation (of vasoconstriction or vasodilation) and by autonomic features that cause turbulence within the vascular lumen (e.g., protrusions from the vessel wall, twists and turns, bifurcations).
12. Arterial blood pressure is influenced and regulated by factors that affect cardiac output (heart rate and stroke volume), total resistance within the system, and blood volume.
13. Many hormones and other endothelial mediators alter vasomotion including epinephrine, norepinephrine, antidiuretic hormone, renin-angiotensin system, natriuretic peptides, adrenomedullin, nitric oxide, prostaglandins, and endothelium-derived relaxing factor.
14. Venous pressure is influenced by blood volume within the venous system and compliance of the venous walls.
15. Blood flow through the coronary circulation is governed not only by the same principles as flow through other vascular beds but also by two adaptations dictated by cardiac dynamics. First, blood flows into the coronary arteries during diastole rather than systole because during systole, the cusps of the aortic semilunar valve block the openings of the coronary arteries. Second, systolic contraction inhibits coronary artery flow by compressing the coronary arteries.
16. Autoregulation enables the coronary vessels to maintain optimal perfusion pressure despite systolic effects, and

SUMMARY REVIEW—cont'd

myoglobin in heart muscle stores oxygen for use during the systolic phase of the cardiac cycle.

Lymphatic System

1. The vessels of the lymphatic system run in the same sheaths as those of the arteries and veins.
2. Lymph (interstitial fluid plus cells of the immune system) is absorbed by lymphatic venules in the capillary beds and travels through ever larger lymphatic veins until it empties into the right lymphatic duct and the thoracic duct, which drain into the right and left subclavian veins, respectively.
3. As lymph travels toward the thoracic ducts, it passes through lymph nodes clustered around the lymphatic vessels. The lymph nodes are sites of immune function and are ideally placed to sample fluid and cells moving from the periphery into the central circulation.

Tests of Cardiovascular Function

1. The evaluation of an individual with known or suspected cardiovascular disease must include a careful history and physical examination including assessment of risk factors, symptoms, vital signs, level of consciousness, mucous membrane color, and cardiopulmonary functioning.
2. Important tests for cardiac disorders are ECG and Holter monitoring, which detect disturbances of impulse generation or conduction.
3. Stress tests elicit clinical manifestations of cardiovascular disease that might not be present at rest.
4. The sensitivity of stress testing is improved by the use of radiotracer imaging techniques such as SPECT.
5. Echocardiography detects structural and functional cardiac abnormalities over time.
6. Cardiac catheterization is used to measure the oxygen content and pressure of blood in the heart's chambers and to inject contrast media for x-ray examination of the size and shape of the chambers and valves. Injection of contrast medium into the coronary arteries (coronary angiography), on the other hand, permits visualization of the coronary circulation and every tissue perfused by the coronary arteries.
7. Evaluation of the systemic vascular system can include arterial pressure pulse waveform analysis, Doppler ultrasonography, venography, and arteriography.

Aging and the Cardiovascular System

1. Controversy exists regarding the effects of normal aging on the cardiovascular system. Separating the physiologic from the pathologic alterations is difficult because of the wide range of physical fitness in the elderly and the presence of arteriosclerosis in a majority of older adults.
2. Studies have documented no change in cardiac output, a slight decrease in heart rate, and a slight increase in stroke volume in healthy (lack of ischemic heart disease) older adults at rest. No changes were noted at rest in ejection fraction. A slight increase in afterload (e.g., as systolic blood pressure) and prolonged left ventricular relaxation was noted.
3. The most relevant age-associated changes in cardiovascular performance are myocardial and blood vessel stiffening, changes in neurogenic control over vascular tone, and left ventricular hypertrophy and fibrosis.
4. With active risk reduction, physical activity, and disease management, older adults can have markedly improved cardiovascular health.

CHAPTER OUTLINE

Cardiovascular disease is the leading cause of death worldwide (Table 32-1).[1] The pathophysiology of heart disease is much more complicated than just structural and hemodynamic changes. Today the focus is on the genetic, neurohumoral, and inflammatory mechanisms that underlie tissue and cellular processes, such as endothelial injury, remodeling, stunning, reperfusion injury, and autoimmune disease.

DISEASES OF THE VEINS

Varicose Veins and Chronic Venous Insufficiency

Varicose veins are a common condition affecting more than 25 million Americans, women nearly twice as often as men.[2] A varicose vein is a superficial vein in which blood has pooled. Varicose veins typically involve the saphenous veins of the legs and are distended, tortuous, and palpable (Figure 32-1). Varicose veins are caused by (1) trauma to the saphenous veins that damages one or more valves, or (2) gradual venous distention caused by the action of gravity on blood in the legs.

Veins are thin-walled, highly distensible vessels. Normally the muscular pump in the legs moves venous blood up toward the heart, and valves prevent backflow and pooling of blood (see Figures 31-35 and 31-31). In individuals who habitually stand for long periods, wear constricting garments, or cross the legs at the knees, distention progresses until the pressure in the vein damages venous valves, rendering the valves incompetent. Damaged valves cannot maintain normal venous pressure, which causes hydrostatic pressure in the vein to increase. As the

TABLE 32-1 **DEATH RATES AND PERCENT OF TOTAL DEATHS FOR THE 15 LEADING CAUSES OF DEATH IN THE UNITED STATES ALL RACES, BOTH SEXES, ALL AGES (FINAL DATA REPORT 2010)**

RANK ORDER*	CAUSE OF DEATH	RATE†	PERCENT OF TOTAL DEATHS
1	Diseases of the heart	194	24.2
2	Malignant neoplasms	186	23.3
3	Chronic lower respiratory diseases	45	5.6

FIGURE 32-1 Varicose Veins of the Leg *(arrow)*. (Courtesy of Dr. Magruder C. Donaldson, Brigham and Women's Hospital, Boston. From Kumar V et al: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders.)

vein distends further, it becomes tortuous, and edema develops in the extremity.

Evidence has been emerging that varicose veins are not just the result of mechanical pressures. Altered connective tissue proteins, increased proteolytic enzyme activity, and decreased transforming growth factor-beta (TGF-β) in vein walls probably precede the development of valvular damage and the development of varicosities.[2] Inflammatory changes that affect autonomic innervation of veins has also been implicated.[3]

Varicose veins can progress to **chronic venous insufficiency (CVI),** which is defined as sustained inadequate venous return. Venous hypertension, circulatory stasis, and tissue hypoxia lead to an inflammatory reaction in vessels and tissue. This causes fibrosclerotic remodeling of the skin and then ulceration. Symptoms include edema of the lower extremities and hyperpigmentation of the skin of the feet and ankles.

Circulation to the extremities can become so sluggish that the metabolic demands of the cells for oxygen, nutrients, and waste removal are barely met. Any trauma or pressure can therefore lower the oxygen supply and cause cell death and necrosis (**venous stasis ulcers**). Infection can occur because poor circulation impairs the delivery of the cells and biochemicals for the immune and inflammatory responses. This same sluggish circulation makes infection following reparative surgery a significant risk. Treatment of varicose veins and CVI begins conservatively, and wound healing often occurs following noninvasive treatments, such as leg elevation, compression stockings, and physical exercise. New management techniques include endovenous ablation (radiofrequency and laser) and ultrasound-guided foam sclerotherapy. These techniques are as effective and safer than surgical ligation and vein stripping.[4]

Deep Venous Thrombosis

A **thrombus** is a blood clot that remains attached to a vessel wall (Figure 32-2). A detached thrombus is a **thromboembolus.** Venous thrombi are more common than arterial thrombi because flow and pressure are lower in the veins than in the arteries. **Deep venous thrombosis (DVT)** refers to clot formation in the large veins, primarily of the lower extremities and may result in venous thromboembolism (VTE) to the pulmonary circulation. The American Heart Association (AHA) estimates that

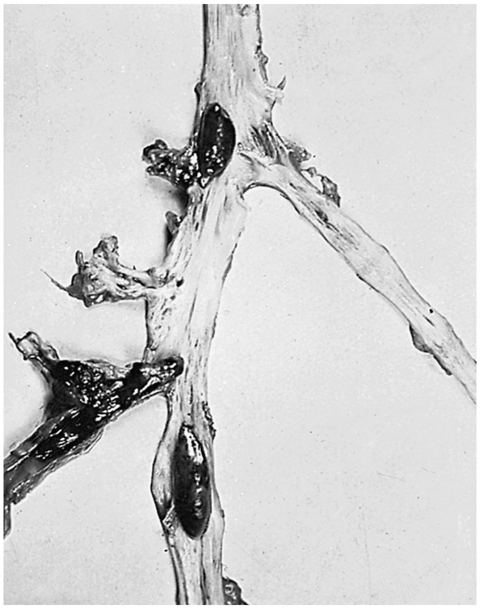

FIGURE 32-2 Multiple Venous Thrombi. (From Rosai J: *Ackerman's surgical pathology,* ed 8, vol 2, St Louis, 1996, Mosby.)

more than 900,000 incident or recurrent VTE events occur annually in the United States, of which approximately one third are fatal.[5] Three factors (triad of Virchow) promote venous thrombosis: (1) venous stasis (e.g., immobility, obesity, prolonged leg dependency [e.g., air travel], age, heart failure [HF]), (2) venous endothelial damage (e.g., trauma, medications), and (3) hypercoagulable states (e.g., inherited disorders, malignancy, pregnancy, oral contraceptives, hormone replacement, hyperhomocysteinemia, antiphospholipid syndrome).[6] Virtually everyone who is hospitalized is at significant risk for DVT, especially those with orthopedic trauma or surgery, spinal cord injury, and obstetric/gynecologic conditions. Numerous genetic abnormalities are associated with an increased risk for venous thrombosis primarily related to states of hypercoagulability. These inherited abnormalities include factor V Leiden mutation; prothrombin mutations; and deficiencies of protein C, protein S, and antithrombin. Inherited hypercoagulability states should be suspected in individuals who develop thrombi in the absence of the usual risk factors.[6,7]

Accumulation of clotting factors and platelets leads to thrombus formation in the vein, often near a venous valve. Inflammation around the thrombus promotes further platelet aggregation and the thrombus propagates or grows proximally. This inflammation may cause local symptoms, but because the vein is deep in the leg it is usually not accompanied by clinical symptoms or signs. If the thrombus creates significant obstruction to venous blood flow, increased pressure in the vein behind the clot may lead to edema of the extremity.

Most thrombi eventually dissolve without treatment, but untreated DVT is associated with a high risk of **thromboembolization** of a part of the clot from the leg to the lung (pulmonary embolism) (see Chapter 35).[6] In up to one third of individuals with DVT, persistent venous outflow obstruction may lead to **post-thrombotic syndrome (PTS),** a frequent complication of DVT characterized by chronic, persistent pain; edema; and ulceration of the affected limb.[8]

Because DVT is usually asymptomatic and difficult to detect clinically, prevention for at-risk individuals is crucial. If possible, individuals should be mobilized as soon as possible after illness, injury, or surgery. Prophylactic treatment can include low-molecular-weight heparin, antithrombin agents, warfarin, or pneumatic devices.[9,10] Unfortunately, even these measures may not prevent embolism in high-risk individuals such as those who have undergone hip replacement surgery.[11] In individuals at high risk for pulmonary embolism, but for whom anticoagulation is contraindicated, placement of an inferior vena caval filter may be necessary to prevent pulmonary embolism.

Diagnosis is most often made by combining measurement of serum D-dimer concentration with lower extremity ultrasonography. D-dimer is an indirect measure of the presence of thrombosis that is very sensitive but is not specific. If the D-dimer is negative, DVT is ruled out. If it is positive, the diagnosis must be confirmed with ultrasonography.[6,12] In selected individuals, computed tomography (CT) or magnetic resonance imaging (MRI) may be needed to make the diagnosis. If noninvasive testing is nondiagnostic, a venogram may be indicated.

DVT is treated with low-molecular-weight heparin, unfractionated intravenous heparin, antithrombin agents, or adjusted-dose subcutaneous heparin.[6] Thrombolytic therapy may be used to dissolve the clot more quickly and reduce the risk of postphlebotic syndrome, especially when a large clot is located in a proximal vein.[13] However, bleeding risk is increased, and many people have contraindications to the use of thrombolytics. Pharmacomechanical treatment involves catheter-mediated removal of clots that can be used in selected individuals and so far has a good safety record.[14] DVT has a recurrence rate of 26% 5 years after discontinuation of anticoagulant therapy, especially if it was unprovoked and no identifiable underlying condition can be reversed.[15] In these individuals aspirin therapy can reduce recurrence rates after discontinuation of anticoaglulants.[16]

Superior Vena Cava Syndrome

Superior vena cava syndrome (SVCS) is a progressive occlusion of the superior vena cava (SVC) that leads to venous distention in the upper extremities and head. The leading cause of SVCS is bronchogenic cancer (approximately 70% of cases), followed by lymphomas and metastasis of other cancers.[17] Benign causes of SVCS include thrombosis, histoplasmosis, tuberculosis, mediastinal fibrosis, cystic fibrosis, and benign tumors, such as retrosternal goiter.[18] Invasive therapies, including pacemaker wires, central venous catheters, and pulmonary artery catheters, can lead to acute and chronic SVCS.

The SVC is a relatively low-pressure vessel that lies in the closed thoracic compartment; therefore, tissue expansion can easily compress the SVC. The right mainstem bronchus abuts the SVC so that cancers occurring in this bronchus may press on the vessel and obstruct venous return to the right atrium. Additionally, the SVC is surrounded by lymph nodes and lymph chains that commonly become involved in thoracic cancers and compress the SVC during tumor growth. Because onset of SVCS is slow, collateral venous drainage to the azygos vein usually has time to develop.

Clinical manifestations of SVCS include edema and venous distention in the upper extremities and face, including the ocular beds. Individuals may complain of a feeling of fullness in the head, or tightness of shirt collars, necklaces, and rings. Cerebral and central nervous system (CNS) edema may cause headache, visual disturbance, and impaired consciousness. The skin of the face and arms may become purple and taut, and capillary refill time is prolonged. Respiratory distress may be present because of edema of bronchial structures or compression of the bronchus by a carcinoma.

Diagnosis is made by chest x-ray, Doppler studies, CT, MRI, and ultrasound. With slow onset and the development of collateral venous drainage, SVCS is generally not a vascular emergency but rather an oncologic emergency.[17] Treatment for malignant disorders can include radiation therapy, surgery, chemotherapy, and the administration of diuretics, steroids, and anticoagulants, as necessary. Treatment for nonmalignant causes may include bypass surgery using various grafts, thrombolysis (both locally and systemically), balloon angioplasty, and placement of intravascular stents.[18]

DISEASES OF THE ARTERIES

Hypertension

Hypertension is consistent elevation of systemic arterial blood pressure. Hypertension is the most common primary diagnosis in the United States—approximately 1 in 3 adults greater than 20 years of age has hypertension; this increases to nearly two thirds in those older than age 60. The prevalence of hypertension is nearly equal between men and women. Black adults have among the highest rates of hypertension in the world (44%). Approximately 80% of hypertensive adults are aware of their condition, 71% are using antihypertensive medication, but only 48% of those have their hypertension controlled.[5] Hypertension is defined in the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC7)[19] as a sustained systolic blood pressure of 140 mmHg or greater or a diastolic pressure of 90 mmHg or greater (Table 32-2). Normal blood pressure is associated with the lowest cardiovascular risk, whereas those who fall into the prehypertension category (which includes between 25% and 37% of the U.S. population) are at risk for developing hypertension and many associated cardiovascular complications unless lifestyle modification and treatment are instituted.[20]

Some individuals with hypertensive disease have isolated systolic hypertension. **Isolated systolic hypertension (ISH)** is elevated systolic blood pressure accompanied by normal diastolic blood pressure (less than 90 mmHg). ISH is becoming more prevalent in all age groups and is strongly associated with cardiovascular and cerebrovascular events.[21]

TABLE 32-2 CLASSIFICATION OF BLOOD PRESSURE FOR ADULTS AGE 18 YEARS OR OLDER

CATEGORY	SYSTOLIC (mmHg)		DIASTOLIC (mmHg)
Normal	<120	AND	<80
Prehypertension	120-139	OR	80-89
Stage 1 hypertension	140-159	OR	90-99
Stage 2 hypertension	≥160	OR	≥100

Data from the JNC 7 Report, *JAMA* 289(19):2560–2572, 2003.

Approximately 95% of cases of hypertension have no known cause and therefore are diagnosed as primary hypertension.[5] Secondary hypertension accounts for 5% of cases and is caused by altered hemodynamics associated with an underlying primary disease. Hypertension is a complex disorder that affects the entire cardiovascular system, and all types and stages of hypertension are associated with increased risk for target organ disease events, such as myocardial infarction (MI), kidney disease, and stroke.[5]

Factors Associated with Primary Hypertension

A combination of genetic and environmental factors is thought to be responsible for the development of primary hypertension. Genetic predisposition to hypertension is thought to be polygenic. The inherited defects are associated with renal sodium excretion, insulin and insulin sensitivity, activity of the sympathetic nervous system (SNS) and renin-angiotensin-aldosterone system (RAAS), and cell membrane sodium or calcium transport.[22] In blacks, variants of the apolipoprotein L1 *(APOL1)* gene are associated with hypertension and renal disease.[23]

Risk factors associated with primary hypertension include: (1) family history of hypertension; (2) advancing age; (3) gender (men younger than 55 and women older than 70 years); (4) black race; (5) high dietary sodium intake; (6) glucose intolerance (diabetes mellitus); (7) cigarette smoking; (8) obesity; (9) heavy alcohol consumption; and (10) low dietary intake of potassium, calcium, and magnesium.[19] Many of these factors are also risk factors for other cardiovascular disorders. In fact, hypertension, dyslipidemia, and glucose intolerance often are found together in a condition called metabolic syndrome (see Chapter 22).

Although populations with high dietary sodium intake have long been shown to have an increased incidence of hypertension, recent studies indicate that low dietary potassium, calcium, and magnesium intakes are also risk factors because without their intake, sodium is retained. The nicotine in cigarette smoke is a vasoconstrictor that can elevate systolic and diastolic blood pressure acutely. In habitual smokers an individual cigarette may not raise blood pressure, yet habitual smoking is associated with a high incidence of severe hypertension, myocardial hypertrophy, and death resulting from coronary artery disease (CAD). The incidence of hypertension is higher among heavy drinkers of alcohol (more than three drinks per day) than among abstainers, but moderate drinkers (two to four drinks per week) appear to have the lowest average blood pressures and cardiovascular mortality. Obesity is recognized as an important risk factor for hypertension, even in children and adolescents.

PATHOPHYSIOLOGY. Hypertension is caused by increases in cardiac output or total peripheral resistance, or both. (The many factors affecting cardiac output and peripheral resistance are described in Chapter 31.) Cardiac output is increased by any condition that increases heart rate or stroke volume, whereas peripheral resistance is increased by any factor that increases blood viscosity or reduces vessel diameter (vasoconstriction).

Primary Hypertension. **Primary hypertension** is the result of a complicated interaction between genetics and the environment that increase vascular tone (increased peripheral resistance) and blood volume, thus causing sustained increases in blood pressure. Multiple pathophysiologic mechanisms mediate these effects including the sympathetic nervous system (SNS), the RAAS, and natriuretic peptides. Inflammation, endothelial dysfunction, obesity-related hormones, and insulin resistance also contribute to both increased peripheral resistance and increased blood volume. Increased vascular volume is related to a decrease in renal excretion of salt, often referred to as a shift in the **pressure-natriuresis relationship.** This means that for a given blood pressure, individuals with hypertension tend to secrete less salt in their urine. The pathophysiology of primary hypertension is summarized in Figure 32-3.

The SNS contributes to the pathogenesis of hypertension in many people. In the healthy individual the SNS contributes to the maintenance of adequate blood pressure and tissue perfusion by promoting cardiac contractility and heart rate (maintenance of adequate cardiac output) and by inducing arteriolar vasoconstriction (maintenance of adequate peripheral resistance). In individuals with hypertension, overactivity of the SNS can result from increased production of catecholamines (epinephrine and norepinephrine) or from increased receptor reactivity involving these neurotransmitters.[24] Increased SNS activity causes increased heart rate and systemic vasoconstriction, thus raising the blood pressure. Efferent sympathetic outflow stimulates renin release, increases tubular sodium reabsorption, and reduces renal blood flow. Additional mechanisms of SNS-induced hypertension include structural changes in blood vessels (vascular remodeling), insulin resistance, increased renin and angiotensin levels, and procoagulant effects. The SNS is implicated in the cardiovascular and renal complications of hypertension, and new techniques such as renal denervation are being explored to treat hypertension.[25,26] The role of the SNS in the pathogenesis of cardiovascular disease is summarized in Figure 32-4.

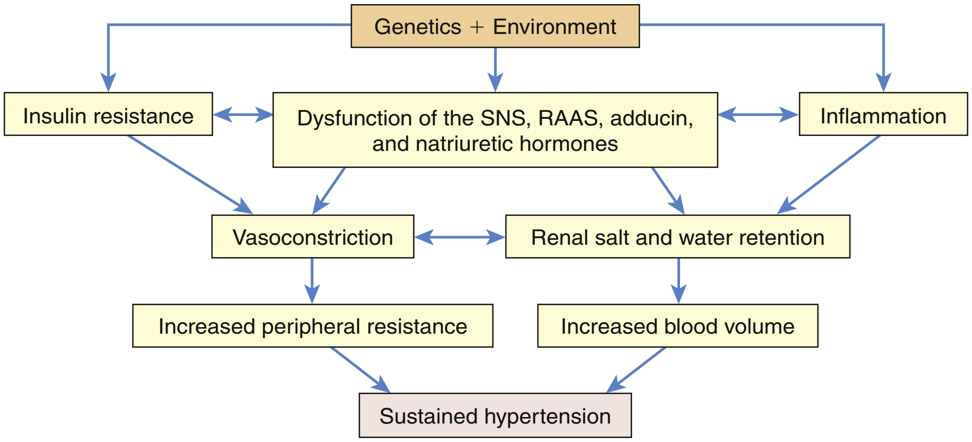

FIGURE 32-3 Pathophysiology of Hypertension. Numerous genetic vulnerabilities have been linked to hypertension and these, in combination with environmental risks, cause neurohumoral dysfunction (sympathetic nervous system [SNS], renin-angiotensin-aldosterone system [RAAS], adducin, and natriuretic hormones) and promote inflammation and insulin resistance. Insulin resistance and neurohumoral dysfunction contribute to sustained systemic vasoconstriction and increased peripheral resistance. Inflammation contributes to renal dysfunction, which, in combination with the neurohumoral alterations, results in renal salt and water retention and increased blood volume. Increased peripheral resistance and increased blood volume are two primary causes of sustained hypertension.

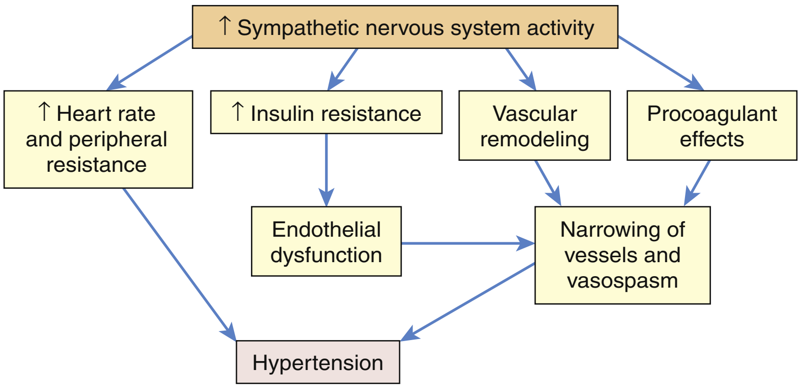

FIGURE 32-4 Role of the Sympathetic Nervous System in the Pathogenesis of Hypertension. Increased activity of the sympathetic nervous system (SNS) not only increases heart rate and peripheral resistance but also causes vascular remodeling with narrowing and vasospasm of arteries. The SNS contributes to insulin resistance, which is associated with endothelial dysfunction and decreased production of vasodilators, such as nitric oxide. The SNS also has procoagulant properties, making vascular spasm and thrombosis more likely. All of these factors contribute to sustained increases in blood pressure.

WHAT'S NEW?

The Renin-Angiotensin-Aldosterone System (RAAS) and Cardiovascular Disease

The RAAS has multiple effects on the cardiovascular system. There are two primary RAA systems. The best known includes the release of renin, the synthesis of angiotensin II (Ang II) through angiotensin-converting enzyme (ACE), stimulation of the AT1 receptor (AT1R), and secretion of aldosterone. Ang II causes systemic vasoconstriction and renal salt and water retention, and stimulates tissue growth and inflammation. When present in abnormal amounts, Ang II contributes to insulin resistance, remodeling of blood vessels, and decreased release of endothelial vasodilators and anticoagulants. In the heart, Ang II and aldosterone contribute to hypertensive hypertrophy and fibrosis of heart muscle, decreased contractility, and an increased susceptibility to arrhythmias and heart failure. In the kidney these hormones cause a shift in the pressure natriuresis curve, inflammation, and glomerular remodeling and are a major contributor to renal failure in individuals with hypertension and diabetes. Drugs that block this RAAS include ACE inhibitors, direct renin inhibitors, Ang II receptor blockers (ARBs), and aldosterone inhibitors. These medications are used widely in managing hypertension, myocardial infarction, and heart failure to lower blood pressure and to protect and improve cardiovascular and renal function. In contrast, the second RAAS serves a counterregulatory system. Activation of a second ACE pathway (ACE2) leads to the synthesis of angiotensin 1-7 from Ang II. Angiotensin 1-7 stimulates Mas receptors in the brain, blood vessels, heart, kidney, gut, pancreas, and inflammatory cells and has vasodilatory, antiproliferative, antifibrotic, and antithrombotic effects. These protective effects lead to lower blood pressure, less vascular inflammation and clotting, and decreased tissue remodeling and damage to target organ tissues. This pathway appears to be especially important in protecting renal tissue in those with diabetes and hypertension. Research is under way to develop genetic and pharmacologic interventions that will stimulate these protective RAAS pathways.

Data from Daien V et al: *Am J Hypertens* 25(1):126–132, 2012; Ferrario CM: ACE2: *Curr Opin Nephrol Hypertens* 20(1):1–6, 2011; Jia L et al: *Front Biosci* 17:221–231, 2012; Patel SK et al: *Am J Hypertens* 25(2):216–222, 2012; Putnam K et al: *Am J Physiol Heart Circ Physiol* 302(6):H1219–H1230, 2012; Souza LL, Costa-Neto CML: *J Cell Physiol* 227(5):2117–2122, 2012; Steckelings UM et al: *Exp Opin Emerging Drugs* 16(4):619–630, 2011; Volpe M: *QJM* 105(1):11–27, 2012

In the healthy individual the RAAS provides an important homeostatic mechanism for maintaining adequate blood pressure and therefore tissue perfusion (see Chapter 31). In hypertensive individuals, overactivity of the RAAS contributes to salt and water retention and increased vascular resistance. High levels of angiotensin II contribute to endothelial dysfunction, insulin resistance, dyslipidemia, and platelet aggregation and play an important role in the complications associated with the metabolic syndrome.[27,28] Further, angiotensin II mediates arteriolar remodeling, which is structural change in the vessel wall that results in permanent increases in peripheral resistance[29] (see Figures 31-28 and 32-5). Angiotensin II is associated with end-organ effects of hypertension, including atherosclerosis, renal disease, and cardiac hypertrophy.[30] Finally, aldosterone not only contributes to sodium retention by the kidney but also has other deleterious effects on the cardiovascular system.[31] Medications, such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (ARBs), oppose the activity of the RAAS and are effective in reducing blood pressure and protecting against target organ damage.[32] A second RAAS has also been described. This system uses ACE 2 to create Ang 1-7, which has cardiovascular protective effects. Its discovery may lead to new and more effective medications[33,34] (see What's New? The Renin-Angiotensin-Aldosterone System (RAAS) and Cardiovascular Disease).

The natriuretic hormones modulate renal sodium ($Na+$) excretion and require adequate potassium, calcium, and magnesium to function properly. The natriuretic hormones include atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin. These hormones induce diuresis; enhancement of renal blood flow and glomerular filtration rate, systemic vasodilatation, and suppression of aldosterone; and inhibition of the SNS.[35] Dysfunction of these hormones, along with alterations in the RAA system and the SNS, cause an increase in vascular tone and a shift in the pressure-natriuresis relationship. When there is inadequate natriuretic function, serum levels of the natriuretic peptides are increased. In hypertension, increased ANP and BNP levels are linked to an increased risk for ventricular hypertrophy, atherosclerosis, and heart failure.[36] Salt retention leads to water retention and increased blood volume, which contributes to an increase in blood pressure. Subtle renal injury results, with renal vasoconstriction and tissue ischemia. Tissue ischemia causes inflammation of the kidney and contributes to dysfunction of the glomeruli and tubules and promotes additional sodium retention.[37] In addition to increasing dietary intake of potassium, calcium, and magnesium in order to enhance natriuretic peptide function, a drug that mimics the effect of one of these hormones (nesiritide) is used to treat heart failure.[38] Newer and safer agonists are being studied.[35]

As mentioned, renal inflammation contributes to sodium retention. Inflammation also plays a role in the vascular dysfunction of hypertension. Endothelial injury and tissue ischemia result in the release of vasoactive inflammatory cytokines. Although many of these cytokines (e.g., histamine, prostaglandins) have vasodilatory actions in acute inflammatory injury, chronic inflammation contributes to vascular remodeling and smooth muscle contraction.[39] Endothelial injury and dysfunction in primary hypertension is further characterized by decreased production of vasodilators, such as nitric oxide, and increased production of vasoconstrictors, such as endothelin.[40] Endothelin blockade has been shown to reduce blood pressure and prevent proteinuria.[41]

Obesity is recognized as an important risk factor for hypertension in both adults and children and contributes to many of the neurohumoral, metabolic, renal, and cardiovascular processes that cause hypertension. Obesity causes changes in what are called the adipokines (leptin and adiponectin) and is associated with increased activity of the SNS and the RAAS.[42,43] Obesity is linked to inflammation, small artery remodeling, endothelial dysfunction, and insulin resistance and an increased

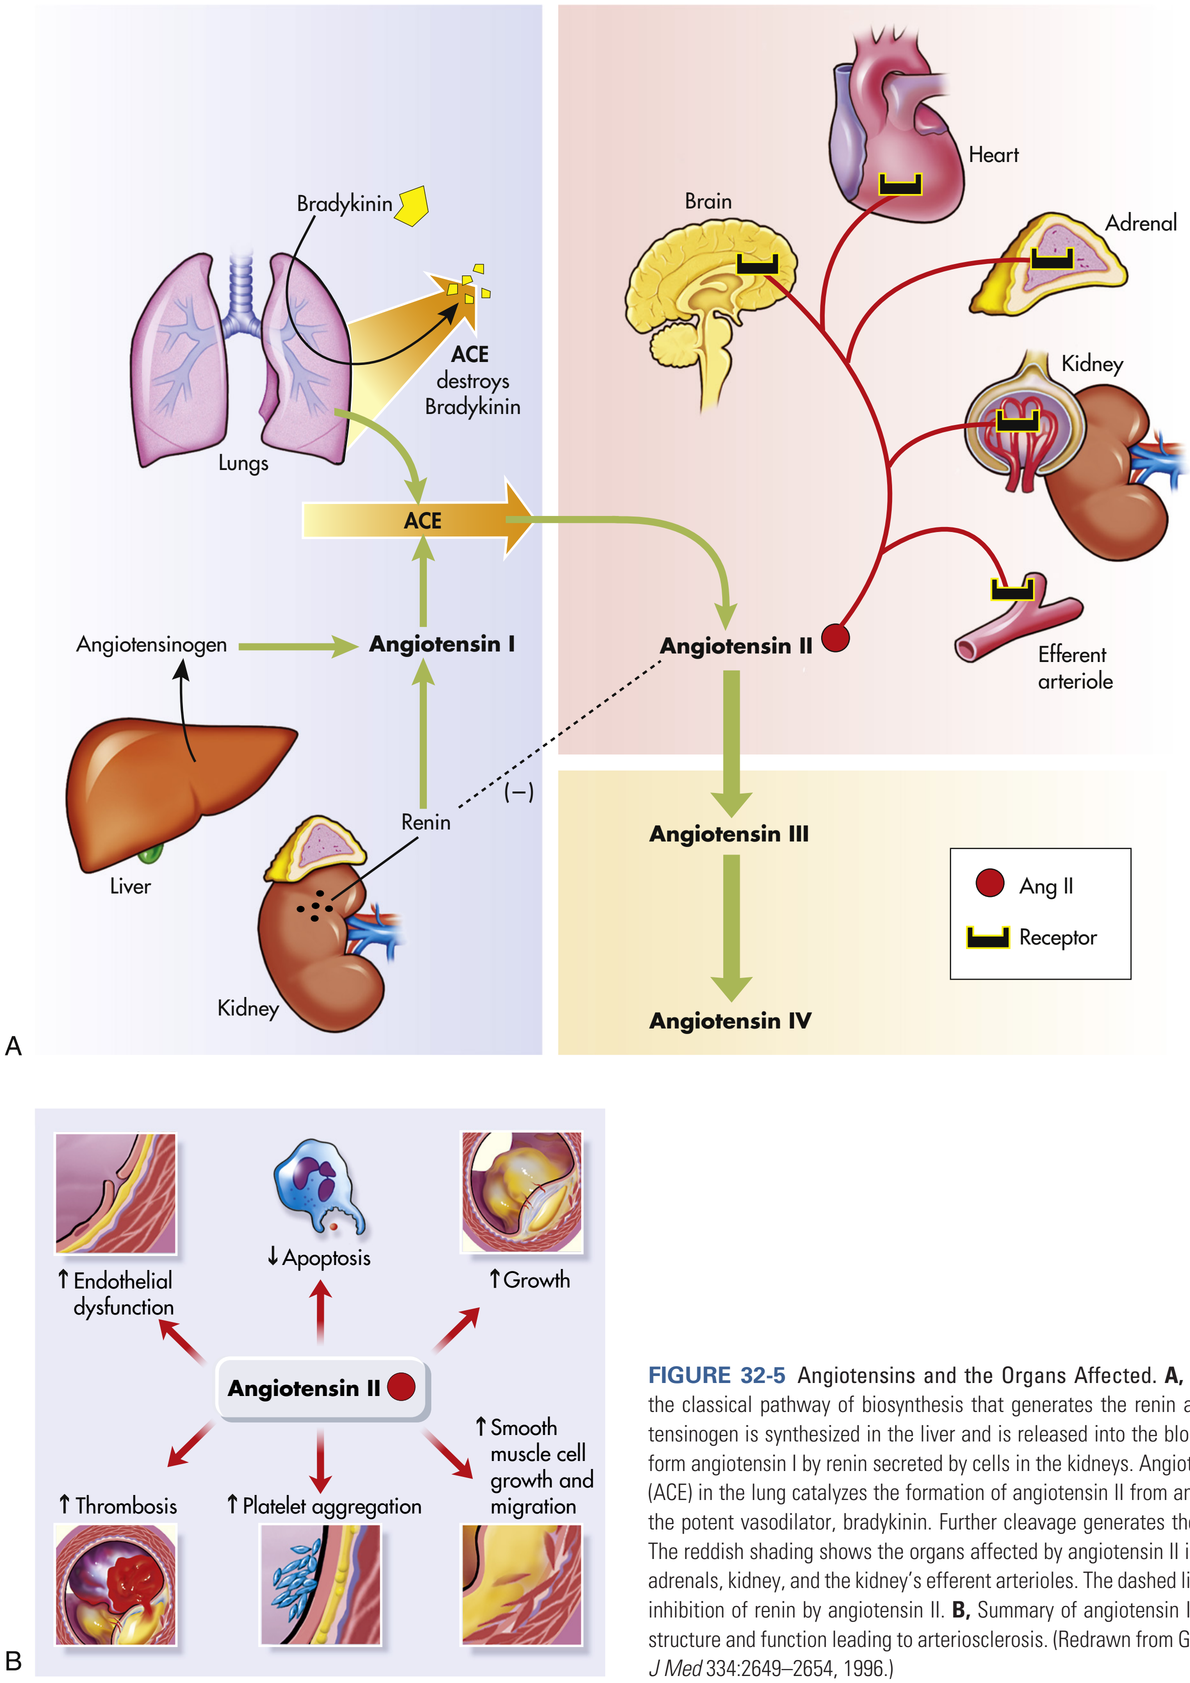

FIGURE 32-5 Angiotensins and the Organs Affected. **A,** The shaded blue area is the classical pathway of biosynthesis that generates the renin and angiotensin I. Angiotensinogen is synthesized in the liver and is released into the blood where it is cleaved to form angiotensin I by renin secreted by cells in the kidneys. Angiotensin-converting enzyme (ACE) in the lung catalyzes the formation of angiotensin II from angiotensin I, and destroys the potent vasodilator, bradykinin. Further cleavage generates the angiotensins III and IV. The reddish shading shows the organs affected by angiotensin II including the brain, heart, adrenals, kidney, and the kidney's efferent arterioles. The dashed line (on the left) shows the inhibition of renin by angiotensin II. **B,** Summary of angiotensin II effects on blood vessel structure and function leading to arteriosclerosis. (Redrawn from Goodfriend TL et al: *N Engl J Med* 334:2649–2654, 1996.)

WHAT'S NEW?

Obesity and Hypertension

Obesity is a well-known risk factor for hypertension. Adipocytes (fat cells) secrete leptin and adiponectin. Leptin's primary function is to interact with the hypothalamus to control body weight and fat deposition through appetite inhibition and increased metabolic rate. However, chronically high levels of leptin associated with obesity result in resistance to these weight-reducing functions and have been found to increase sympathetic nervous system activity, decrease renal sodium excretion, promote inflammation, and stimulate myocyte hypertrophy. Adiponectin is a protein that is produced by adipose tissue but is reduced in obesity. Decreased adiponectin is associated with insulin resistance, decreased endothelial-derived nitric oxide (vasodilator) production, and activation of the sympathetic nervous and renin-angiotensin-aldosterone systems. Taken together, these obesity-related changes result in vasoconstriction, salt and water retention, and renal dysfunction that may contribute to the development of hypertension. Obese individuals also have been found to have hypertrophic remodeling of subcutaneous small arteries, and endothelial dysfunction in response to acetylcholine. Microvascular dysfunction is linked to both the pathogenesis of hypertension and hypertension-related target organ damage. Obesity also is linked with insulin resistance, which also affects vascular function and contributes to the development of sustained hypertension. Further studies aimed at achieving a better understanding of these mechanisms may lead to new treatments for obesity-related hypertension.

Data from De Boer MP et al: *Microcirculation* 19(1):5–18, 2012; Dorresteijn JA, Visseren FL, Spiering W: *Obesity Rev* 13(1):17–26, 2012; Kalil GZ, Haynes WG: *Hypertens Res* 35(1):4–16, 2012; Rizzoni D et al: *Basic Clin Pharmacol Toxicol* 110(1):56–62, 2012.

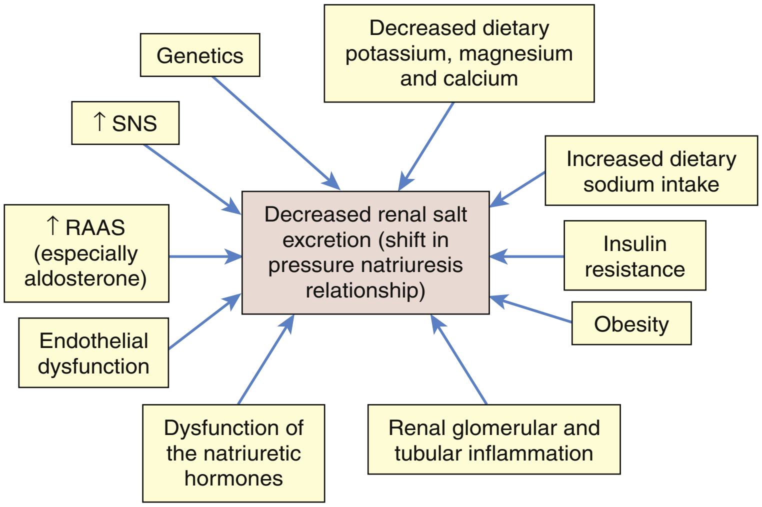

FIGURE 32-6 Shift in the Pressure-Natriuresis Relationship. Numerous factors have been implicated in the pathogenesis of sodium retention in individuals with hypertension. These factors cause less renal excretion of salt than would normally occur with increased blood pressure. This is called a *shift in the pressure-natriuresis relationship* and is believed to be a central process in the pathogenesis of primary hypertension. *RAAS,* Renin-angiotensin-aldosterone system; *SNS,* sympathetic nervous system.

risk for cardiovascular complications from hypertension (see What's New? Obesity and Hypertension).

Finally, insulin resistance is common in hypertension, even in individuals without clinical diabetes. Insulin resistance is associated with decreased endothelial release of nitric oxide and other vasodilators.[44] It also affects renal function and causes renal salt and water retention. Insulin resistance is associated with overactivity of the SNS and the RAAS. It is interesting to note that in many individuals with diabetes treated with drugs that increase insulin sensitivity, blood pressure often declines, even in the absence of antihypertensive drugs. The interactions between obesity, hypertension, insulin resistance, and lipid disorders in the metabolic syndrome result in a high risk of cardiovascular disease.[28]

It is likely that primary hypertension is an interaction between many of these factors leading to sustained increases in blood volume and peripheral resistance. The role of these mechanisms in increasing blood volume in the pathophysiology of primary hypertension is summarized in Figure 32-6.

Secondary Hypertension. **Secondary hypertension** is caused by an underlying disease process that raises peripheral vascular resistance or cardiac output. If the cause is identified and removed before permanent structural changes occur, blood pressure returns to normal. In addition, medications are an important and often unrecognized cause of secondary hypertension.[45] Table 32-3 summarizes the pathogenesis of major forms of secondary hypertension.

Complicated Hypertension. Chronic hypertension damages the walls of systemic blood vessels. Within the walls of arteries and arterioles, smooth muscle cells undergo hypertrophy and hyperplasia with associated fibrosis of the tunica intima and media in a process called vascular remodeling (Figure 32-7). Endothelial dysfunction, angiotensin II, catecholamines, insulin resistance, and inflammation contribute to this process. Once significant fibrosis has occurred, reduced blood flow and dysfunction of the organs perfused by these affected vessels is inevitable. Target organs for hypertension include the kidney, brain, heart, extremities, and eyes (these effects are summarized in Table 32-4).

TABLE 32-3 PATHOGENESIS OF MAJOR FORMS OF SECONDARY HYPERTENSION BY CAUSE

PRIMARY DISEASE	PATHOGENESIS OF HYPERTENSION
Renal Disorders	
Renal parenchymal disease	Disturbances in filtration and reabsorption of serum sodium, potassium, and calcium initiate the hemodynamics of early hypertension
Renovascular disease	Impaired blood flow and renal ischemia invoke the compensatory renin-angiotensin-aldosterone mechanism in an effort to raise the renal perfusion pressure
Renin-producing tumors	Elevated blood renin levels invoke elevations in angiotensin and aldosterone, which causes blood pressure to rise
Renal failure	Disturbances in filtration and reabsorption of serum sodium, potassium, and calcium initiate the hemodynamics of early hypertension
Primary sodium retention	Disturbance in filtration and/or reabsorption of serum sodium initiates the hemodynamics of early hypertension
Endocrine Disorders	
Acromegaly	Excess human growth hormone causes increased peripheral resistance
Hypothyroidism	Mucopolysaccharide deposits in vascular tissue increase resistance
Hypercalcemia	Calcium ion directly affects vascular tonicity; elevated serum calcium levels increase vascular tone and peripheral resistance
Hyperthyroidism	Increased inotropic effect on the heart elevates systolic pressure; diastolic pressure decreases as a result of decreased peripheral resistance
Adrenal disorders Cortical disturbances Cushing syndrome	Glucocorticoids facilitate sodium and water retention, initiating the hemodynamics of early hypertension
Primary aldosteronism	Excess aldosterone promotes sodium retention and initiation of the hemodynamics of early hypertension
Congenital adrenal hyperplasia	Excess production of adrenocortical hormones promotes sodium and water retention
Medullary disturbance: pheochromocytoma	Excess catecholamines raise vascular tone and increase peripheral resistance
Extra-adrenal chromaffin tumors	Excess catecholamines raise vascular tone and increase peripheral resistance
Vascular Disorders	
Coarctation of the aorta	Decreased blood flow in distal areas initiates maximum peripheral resistance as an autoregulatory effort to adjust perfusion pressure
Arteriosclerosis	Loss of elasticity in vessel walls results in increased peripheral resistance
Pregnancy-Induced Hypertension	Pathogenesis unclear
Neurologic Disorders	
Elevated intracranial pressure (brain tumor, encephalitis, respiratory acidosis of pulmonary or central nervous system [CNS] origin)	Higher systemic blood pressure required to maintain adequate cerebral perfusion
Quadriplegia, acute porphyria, familial dysautonomia, lead poisoning, Guillain-Barré syndrome	Interface with neural control of blood pressure initiates increased systemic blood pressure
Acute Stress	
Surgery, psychogenic hyperventilation, hypoglycemia, burns, pancreatitis, alcohol withdrawal, sickle cell crisis, resuscitation, increased intravascular volume	Acute stress precipitates release of catecholamines and glucocorticoids
Drugs and Other Substances	
Oral contraceptives and estrogen	Unknown; possibly caused by sodium retention, plasma retention, weight gain, changes in levels and actions of renin, angiotensin, and aldosterone
Corticosteroids	Same as for Cushing syndrome
Sympathetic stimulants, appetite suppressants, antihistamines	Raises vascular tone and increases vascular resistance
Licorice	Contains glycerrhizic acid, a mineralocorticoid that causes salt and water retention
Monoamine oxidase inhibitors	Hypertension may develop in an individual who routinely takes a monoamine oxidase (MAO) inhibitor with ingestion of a food containing tyramine, such as aged cheese

From Cheng J et al: *PLoS Pathog* May 5(5), 2009. (Epub ahead of print.); Kaplan NM: *Clinical hypertension,* ed 8, Baltimore, 2002, Lippincott Williams & Wilkins.

Cardiovascular complications include left ventricular hypertrophy, angina pectoris, congestive heart failure (left heart failure), CAD, MI, and sudden death. Myocardial hypertrophy in response to hypertension is mediated by several neurohormonal substances, including the SNS and angiotensin II. Hypertrophy is characterized by changes in the myocyte proteins, apoptosis of myocytes, and deposition of collagen in heart muscle, which causes it to become thickened, scarred, and less able to relax during diastole leading to diastolic heart failure.[46] In addition, the increased size of the heart muscle increases demand for oxygen delivery over time, contractility of the heart is impaired, and the individual is at increased risk for systolic heart failure. Vascular complications include the formation, dissection, and rupture of aneurysms (outpouchings in vessel walls); intermittent claudication; and gangrene resulting from vessel occlusion. Renal complications are parenchymal damage, nephrosclerosis, renal arteriosclerosis, and renal insufficiency or failure.[47]

Microalbuminuria (small amounts of protein in the urine) is an early sign of impending renal dysfunction and significantly increased risk for cardiovascular events.[48]

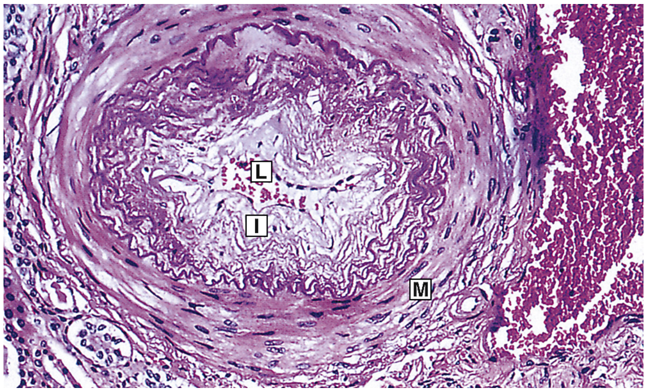

FIGURE 32-7 **Dramatic Hypertension Change in Small Arterioles.** Fibrous intimal proliferation *(I)* with reduction in lumen vessel caliber (radius) *(L)* and normal media *(M)*. (From Stevens A, Lowe JS, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

Changes in the vascular beds can be estimated by viewing the arterioles of the retina. Complications specific to the retina include retinal vascular sclerosis, exudation, and hemorrhage.[49] Cerebrovascular complications are similar to those of other arterial beds and include transient ischemia, stroke, cerebral thrombosis, aneurysm, and hemorrhage. Chronic hypertension also has been linked to cognitive decline with aging.[50-52]

Malignant hypertension (rapidly progressive hypertension in which diastolic pressure is usually greater than 140 mmHg) can cause encephalopathy. Encephalopathy occurs because high arterial pressure renders the cerebral arterioles incapable of regulating blood flow to the cerebral capillary beds. Capillary permeability is increased by high hydrostatic pressures in the capillaries, and vascular fluid exudes into the interstitial space. If blood pressure is not reduced, cerebral edema and cerebral dysfunction increase until death occurs. Organ damage resulting from malignant hypertension is life threatening. Besides encephalopathy, malignant hypertension can cause papilledema, cardiac failure, uremia, retinopathy, and cerebrovascular accident.

CLINICAL MANIFESTATIONS. The early stages of hypertension have no clinical manifestations other than elevated blood pressure. Most important, the lack of signs and symptoms means the individual is unlikely to seek health care; thus hypertension is called a *lanthanic (silent) disease*. The likelihood of developing primary hypertension increases with age, over and above the natural rise in blood pressure associated with aging. Although hypertension usually is thought to be an adult health problem, it is important to remember that hypertension does occur in children and is being diagnosed with increasing frequency. If elevated blood pressure is not detected and treated, it becomes established and may begin to accelerate its effect on tissues when the individual is 30 to 50 years of age. This sets the stage for the complications of hypertension that begin to appear during the fourth, fifth, and sixth decades of life. The clinical manifestations of chronic hypertension tend to be specific for the organs or tissues affected. Evidence of heart disease, renal insufficiency,

TABLE 32-4 PATHOLOGIC EFFECTS OF SUSTAINED, COMPLICATED PRIMARY HYPERTENSION

SITE OF INJURY	MECHANISM OF INJURY	POTENTIAL PATHOLOGIC EFFECT
Heart		
Myocardium	Increased workload combined with diminished blood flow through coronary arteries	Left ventricular hypertrophy, myocardial ischemia, left heart failure
Coronary arteries	Accelerated atherosclerosis (coronary artery disease)	Myocardial ischemia, myocardial infarction, sudden death
Aorta	Weakened vessel wall	Aneurysms, acute aortic syndromes
Kidneys	Renin and aldosterone secretion stimulated by reduced blood flow	Retention of sodium and water, leading to increased blood volume and perpetuation of hypertension
	Inflammation and ischemia	Tissue damage that compromises filtration
	High pressures in renal arterioles	Nephrosclerosis leading to renal failure
Brain	Reduced blood flow and oxygen supply; weakened vessel walls, accelerated atherosclerosis	Transient ischemic attacks, cerebral thrombosis, aneurysm, hemorrhage, acute brain infarction
Eyes (retinas)	Reduced blood flow	Retinal vascular sclerosis
	High arteriolar pressure	Exudation, hemorrhage
Arterial vessels of lower extremities	Reduced blood flow and high pressures in arterioles, accelerated atherosclerosis	Intermittent claudication, arterial thrombosis, gangrene

central nervous system dysfunction, impaired vision, impaired mobility, vascular occlusion, or edema can be caused by sustained hypertension. (See appropriate chapters for specific clinical manifestations of organ dysfunction.)

EVALUATION AND TREATMENT. A single elevated blood pressure reading does not mean that a person has hypertension. Diagnosis requires the measurement of blood pressure on at least two separate occasions averaging two readings at least 2 minutes apart, with the individual seated, the arm supported at heart level, after 5 minutes rest, with no smoking or caffeine intake in the past 30 minutes.[19] Some individuals benefit from 24-hour ambulatory blood pressure monitoring because of better correlation with end-organ damage and the ability to screen out "white coat hypertension" (elevated blood pressure that occurs only in a clinic setting) and "masked hypertension" (normal blood pressure in the clinic setting but elevated elsewhere).[53,54] Ambulatory measurement also detects those who fail to have a nocturnal decrease in blood pressure and who may be at higher cardiovascular risk. It is especially recommended for individuals with drug resistance, hypotensive symptoms with medications, episodic hypertension, and autonomic dysfunction.[54]

Evaluation of the hypertensive individual should include a complete medical history and assessment of lifestyle and other risk factors for hypertension and cardiovascular disease, as well as evidence of possible secondary causes of hypertension. Physical examination should include examination of the optic fundi; calculation of body mass index; auscultation for carotid, abdominal, and femoral bruits; examination of the heart and lungs; palpation of the abdomen; assessment of lower extremity pulses and edema; and neurologic examination. Further routine diagnostic tests for the evaluation of hypertension include hematocrit, urinalysis, biochemical blood profile (fasting glucose, sodium, potassium, calcium, creatinine, total cholesterol, high-density cholesterol, triglycerides), and an electrocardiogram (ECG). Optional tests include urinary albumin excretion or albumin/creatinine ratio. Individuals who have elevated blood pressure are assumed to have primary hypertension unless their history, physical examination, or initial diagnostic screening indicates secondary hypertension.

Treatment of primary hypertension depends on its severity. Figure 32-8 illustrates an overview of the JNC7 recommendations.[19] Treatment begins with reducing or eliminating risk factors. Lifestyle modification can prevent hypertension from developing in those individuals who fall into the prehypertension category, may control the blood pressure in stage I hypertension, and can enhance the effects of drug treatment for those with more significant blood pressure elevation. The usual dietary recommendations are to restrict sodium intake to 2.4 g/day, to increase potassium intake, to restrict saturated fat intake, and to adjust calorie intake as required to maintain optimum weight. The Dietary Approaches to Stop Hypertension (DASH) diet is recommended.[55,56] Although it has been

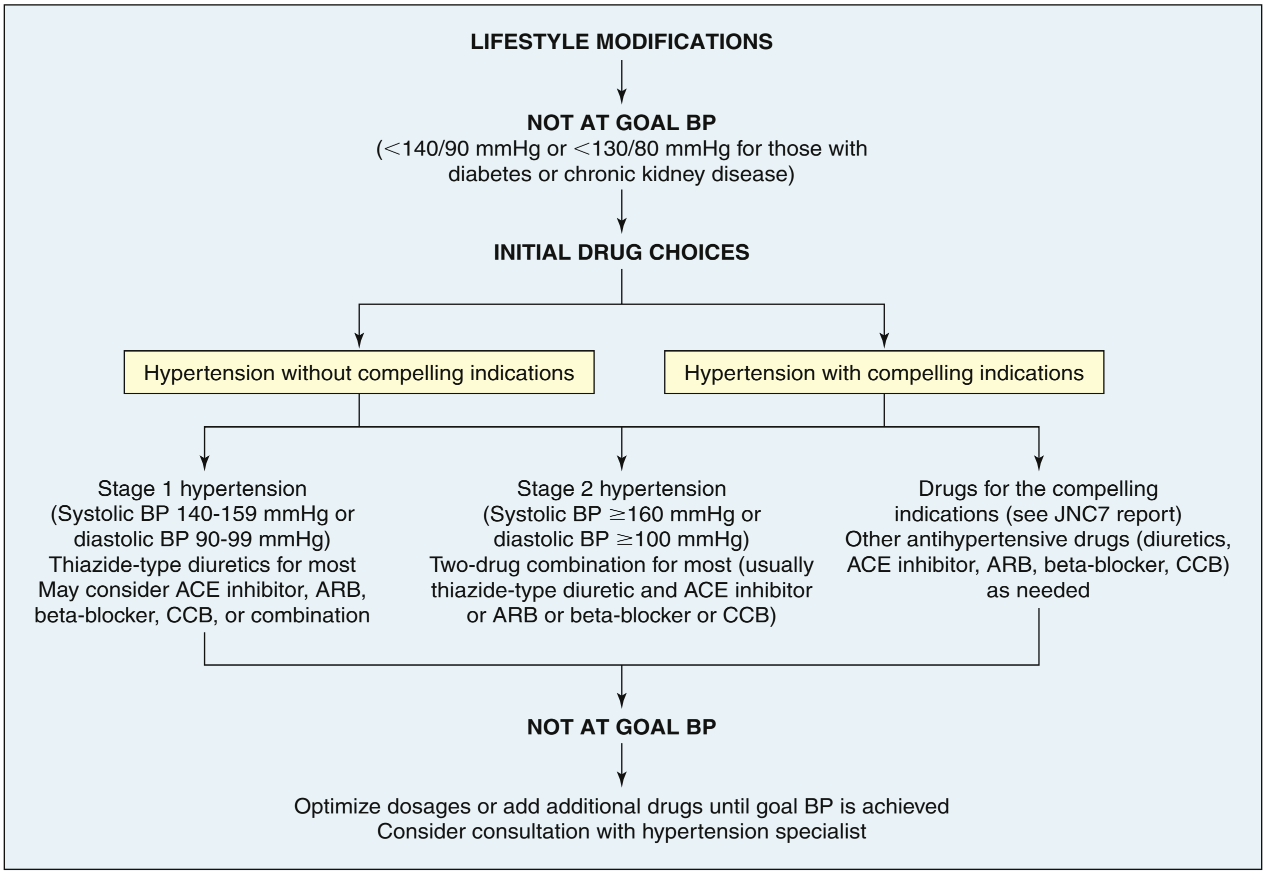

FIGURE 32-8 Summary of Treatment for Hypertension. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin-receptor blocker; *BP,* blood pressure; *CCB,* calcium channel blocker. (Data from Chobanian AV et al: *JAMA* 289:2560–2572, 2003.)

widely recommended since 1998, the DASH diet continues to be studied with beneficial effects extending to reduced coronary risks, increased insulin sensitivity, and improved lipid profiles, especially in those with diabetes.[57] An exercise program that promotes endurance and relaxation usually is recommended. Physical training increases stroke volume, which has the effect of lowering heart rate and hence systolic blood pressure, and should consist of regular aerobic physical activity. Relaxation is expected to reduce levels of circulating catecholamines, which has the effect of reducing vascular tone and blood pressure. Individuals are counseled to stop smoking to eliminate vasoconstrictor effects of nicotine.

Pharmacologic treatment of hypertension reduces the risk of end-organ damage and prevents major diseases, such as myocardial ischemia and stroke. Thiazide diuretics and beta-blockers have been shown to be safe and effective medications for lowering blood pressure and preventing the cardiovascular complications of hypertension for many individuals. However, these medications are associated with lipid disorders and glucose intolerance.[58] Many individuals will have "compelling indications" for choosing a particular antihypertensive as a first-line medication. For example, individuals with heart failure or those who have chronic kidney disease, are postmyocardial infarction, or have had recurrent stroke should begin antihypertensive treatment with an ACE inhibitor, ARB, or aldosterone antagonist.[19] It is widely anticipated that the new report from the National Committee on the Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC8) will have a greater emphasis on managing the RAAS in hypertension as a first-line intervention; however, diuretics and beta-blockers will continue to be effective choices for many individuals.[59] If a person requires two drugs for blood pressure control, the recommendation is combinations of thiazide diuretics and other antihypertensives, such as beta-blockers and ACE inhibitors. As described on page 1133, a new development is the use of renal denervation, which is being investigated for the treatment of selected individuals with severe or refractory hypertension.[25,60]

Orthostatic (Postural) Hypotension

Orthostatic (postural) hypotension means a decrease in systolic and diastolic arterial blood pressure on standing. The American Autonomic Society (AAS) and the American Academy of Neurology (AAN) define orthostatic hypertension as a systolic blood pressure decrease of at least 20 mmHg or a diastolic blood pressure decrease of at least 10 mmHg within 3 minutes of standing up. It can be categorized as arteriolar, venular, or mixed.[61] Compensatory changes during standing normally increase sympathetic activity mediated through stretch receptors (baroreceptors) in the carotid sinus and the aortic arch (see Chapter 31). This reflex response to shifts in volume caused by postural changes leads to a prompt increase in heart rate and constriction of the systemic arterioles, which maintains a stable blood pressure. These compensatory mechanisms are not effective in maintaining a stable blood pressure in individuals with orthostatic hypotension.

Orthostatic hypotension may be acute or chronic. **Acute orthostatic hypotension** (temporary type) may result from: (1) altered body chemistry, (2) drug action (e.g., antihypertensives or antidepressants), (3) prolonged immobility caused by illness, (4) starvation, (5) physical exhaustion, (6) any condition that produces volume depletion (e.g., massive diuresis, potassium or sodium depletion), and (7) venous pooling (e.g., pregnancy, extensive varicosities of the lower extremities). Older adults are susceptible to this type of orthostatic hypotension, in which postural reflexes are slowed as part of the aging process.

Chronic orthostatic hypotension can be categorized as (1) secondary to a specific disease, and (2) idiopathic or primary. The diseases that cause secondary orthostatic hypotension are endocrine disorders (e.g., adrenal insufficiency, diabetes mellitus), metabolic disorders (e.g., porphyria), or diseases of the central or peripheral nervous system (e.g., intracranial tumors, cerebral infarcts, Wernicke encephalopathy, peripheral neuropathies). Cardiovascular autonomic neuropathy is a common cause of orthostatic hypotension in diabetes and is a serious and often overlooked complication. Severe chronic autonomic failure may result from multiple system atrophy (MSA), in which there are multiple central nervous system degenerative changes, and Parkinson disease. Individuals with these disorders also may exhibit supine hypertension, altered drug sensitivity, hyperresponsiveness of blood pressure to hypo/hyperventilation, sleep apnea, and other neurologic disturbances.[62,63]

Idiopathic, or primary, orthostatic hypotension is the term for hypotension in which there is no known initial cause. It affects men more often than women and usually occurs between the ages of 40 and 70 years. Up to 18% of the older adult population may be affected by chronic orthostatic hypotension.[61] It is a significant risk factor for falls and associated injuries and has been associated with an increased risk for cardiovascular events. In addition to cardiovascular symptoms, impotence and bowel and bladder dysfunction often are found in this type.

Orthostatic hypotension often is accompanied by dizziness, blurring or loss of vision, and syncope or fainting. To assess hypotensive episode frequency, severity, and correlation with symptoms, 24-hour blood pressure monitoring is recommended. No curative treatment is available for idiopathic orthostatic hypertension. In the secondary form, postural hypotension improves when the underlying disorder is corrected. Several treatments can help acute and chronic orthostatic hypotension, including liberalization of salt intake, raising the head of the bed, thigh-high stockings, volume expansion with mineralocorticoids, and vasoconstrictors such as midodrine.[61]

Aneurysm

An **aneurysm** is a localized dilation or outpouching of a vessel wall or cardiac chamber. Laplace's law can provide an understanding of the hemodynamics of an aneurysm (Figure 32-9). (Laplace's law is discussed in detail in Chapter 31.) **True aneurysms** involve all three layers of the arterial wall and are best described as a weakening of the vessel wall. Most are fusiform and circumferential (Figure 32-10). **False aneurysm** is an extravascular hematoma that communicates with the intravascular space. A common cause of this type of lesion is a leak between a vascular graft and a natural artery. Saccular aneurysms are basically spherical.

Arteriosclerosis and hypertension are found in more than half of all individuals with aneurysms. Chronic hypertension results in mechanical and shear forces that contribute to remodeling and weakening of the vessel wall. Atherosclerosis is a common cause of aneurysms because plaque formation erodes the vessel wall. Infections, such as syphilis, collagen disorders (such as Marfan syndrome), and traumatic injury to the chest or abdomen, also can cause aortic aneurysms. Genetic susceptibilities have been identified including gene polymorphisms for the production of growth factors, myosin, and

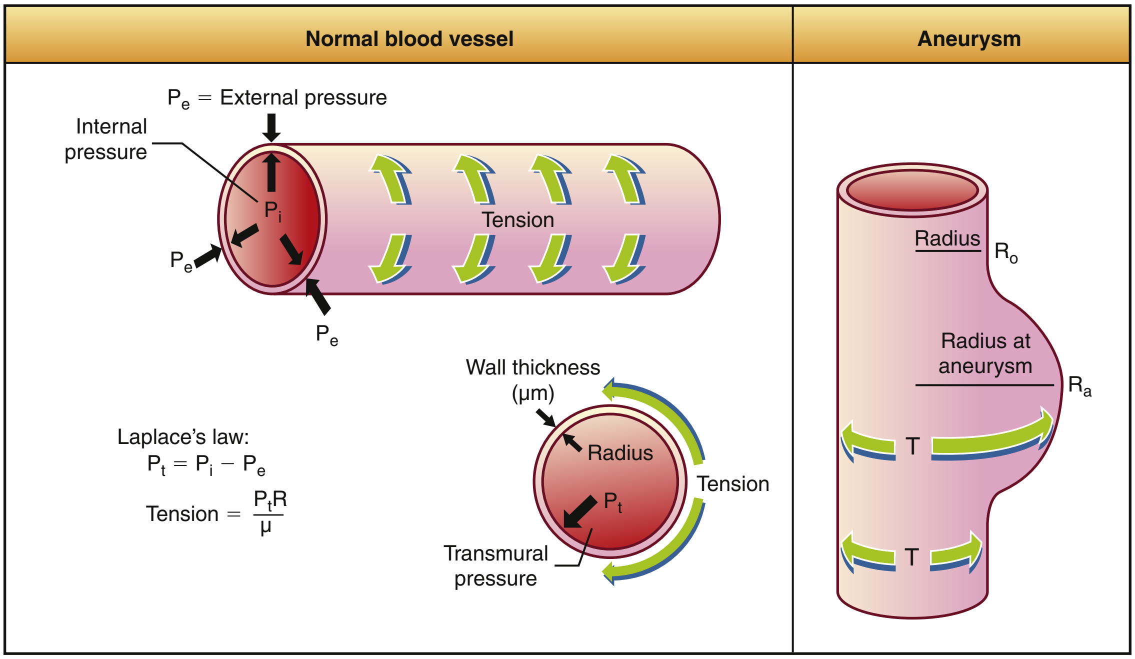

FIGURE 32-9 Pressure-Tension and Wall Thickness Relations in Blood Vessels or Cardiac Chambers (Laplace's Law).

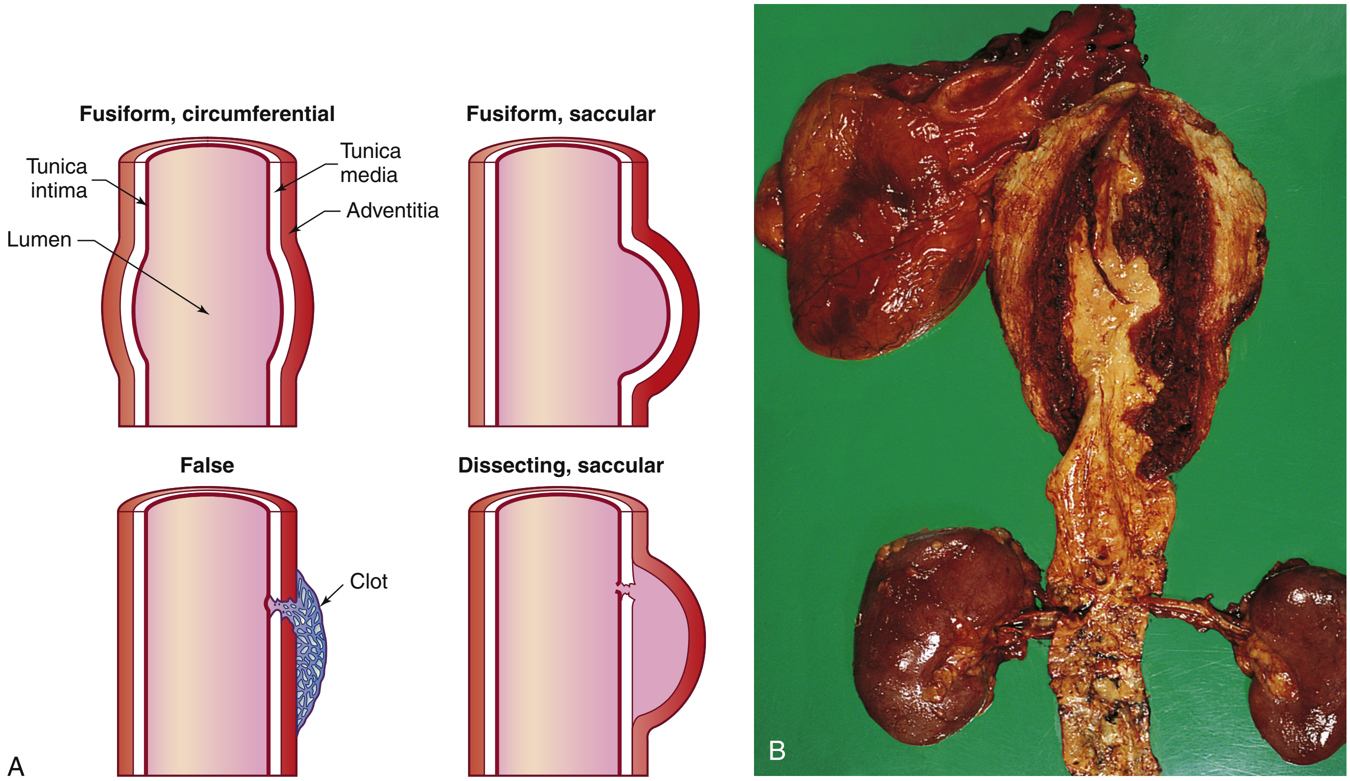

FIGURE 32-10 Longitudinal Sections Showing Types of Aneurysms. **A,** The fusiform circumferential and fusiform saccular aneurysms are true aneurysms, caused by weakening of the vessel wall. False and saccular aneurysms involve a break in the vessel wall, usually caused by trauma. **B,** Dissecting aneurysm of thoracic aorta. (**B** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

proteases. Inflammation (with the production of toxic oxygen radicals) and changes in cytokines, such as TGF-β, activate matrix degrading proteins and smooth muscle cell apoptosis resulting in loss of medial elastic lamellae and thinning of the tunica media.[64]

Aneurysms most commonly occur in the thoracic or abdominal aorta. The aorta is particularly susceptible to aneurysm formation because of constant stress on the vessel wall and the absence of penetrating vasa vasorum in the media layer (Figure 32-11, *A*). The prevalence of abdominal aortic aneurysms 2.9 to 4.9 cm in diameter ranges from 1.3% in men 45 to 54 years of age to 12.5% in men 75 to 84 years of age. For women, the prevalence ranges from zero in the youngest to 5.2% in the oldest age group.[5] The prevalence of aneurysms has decreased in men ages 65 years and older likely because of improvements in risk factor management.[65]

Formation of a ventricular wall aneurysm occurs when intraventricular tension stretches the noncontracting infarcted muscle (see Figure 32-11, *B*). The stretching produces infarct expansion, a weak and thin layer of necrotic muscle, and fibrous tissue that bulges with each systole. With time the aneurysm becomes more fibrotic but continues to bulge with each systole, thus acting as a "reservoir" for some of the stroke volume.

Clinical manifestations depend on where the aneurysm is located. Aneurysms in the heart present with dysrhythmias, heart failure, and embolism of clots to the brain or other vital organs. Aortic aneurysms often are asymptomatic until they rupture, when they become painful. Symptoms of dysphagia (difficulty in swallowing) and dyspnea (breathlessness) are caused by the pressure of a thoracic aneurysm on surrounding organs. An abdominal aneurysm can impair flow to an extremity and cause symptoms of ischemia. Aneurysms that occur elsewhere in the body have variable symptoms and signs related to the size of the aneurysm and the potential for rupture and hemorrhage.

The diagnosis of an aneurysm is usually confirmed by ultrasonography, CT, MRI, or angiography. The goals of medical treatment of aneurysms are to maintain a low blood volume and low blood pressure to decrease mechanical forces thought to contribute to vessel wall dilation. Medical treatment is indicated for slow-growing aortic aneurysms, particularly in early stages, and includes smoking cessation, reducing blood pressure and blood volume, and β-adrenergic blockage.[64] For those aneurysms that are dilating rapidly, surgical treatment often is indicated. Surgery or endovascular repair should be done when aortic aneurysms reach 5 cm in diameter. The risk for eventual rupture approaches 20% for abdominal aortic aneurysms greater than 5 cm, and greater than 50% for aneurysms more than 7 cm in diameter.[5] New endovascular surgical techniques with placement of a stent make aneurysm repair possible even in those individuals with acute symptoms or complications.[66]

Aortic aneurysms can be complicated by the acute aortic syndromes that include aortic dissection, hemorrhage into the vessel wall, or vessel rupture. **Aortic dissection** is a devastating complication that can involve any part of the aorta (ascending, arch, or descending) and can disrupt flow through arterial branches, thus creating a surgical emergency. Dissection of the layers of the arterial wall occurs when there is a tear in the intima and blood enters the wall of the artery (see Figure 32-10). This occurs most commonly when there is trauma to the aorta or when there is tissue ischemia and necrosis at the edge of an atherosclerotic plaque that weakens the intima. Persistent chronic hypertension and inflammation contribute to further degradation of the vessel wall with fibrotic obstruction of vessels that feed the arterial wall. Emergent evaluation and surgical intervention are indicated.[67]

Arterial Thrombus Formation

As in venous thrombosis, arterial thrombi tend to develop wherever intravascular conditions promote activation of the

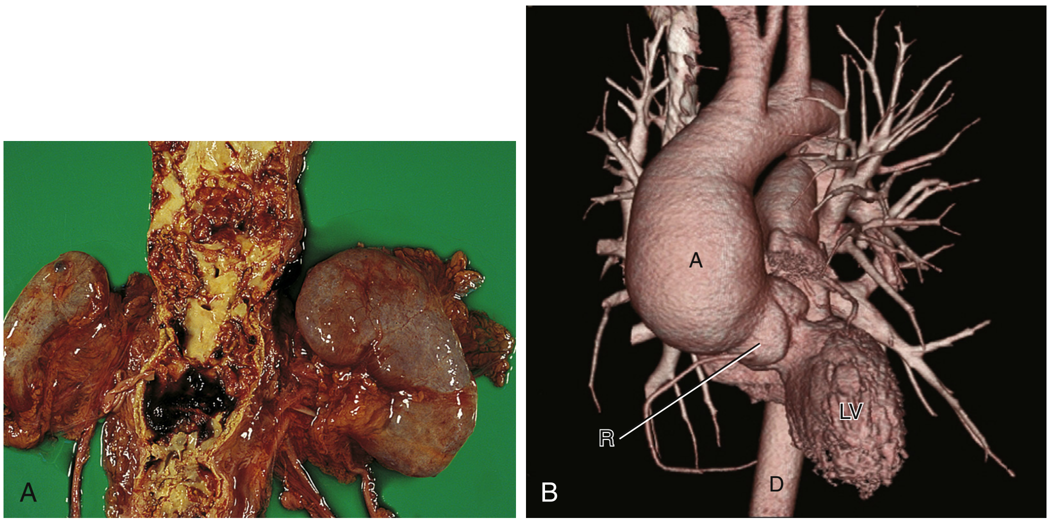

FIGURE 32-11 Aneurysms. **A,** Abdominal aortic atherosclerotic aneurysm. **B,** A three dimensional CT scan shows the aneurysm. *(A)* involves the ascending thoracic aorta. *D,* descending aorta; *LV,* left ventricle. coagulation, or clotting, cascade. These conditions include intimal irritation and roughening, inflammation, traumatic injury, infection, and low blood pressures or obstructions that cause blood stasis and pooling within the vessels. (Mechanisms of coagulation are described in Chapter 27.) In the arteries, activation of the coagulation cascade usually is caused by roughening of the tunica intima by atherosclerosis. Invasion of the tunica intima by an infectious agent also roughens the normally smooth lining of the artery, causing platelets to adhere readily. Anatomic changes of an artery (such as an aneurysm) can stimulate thrombus formation, particularly if the change results in pooling of arterial blood. Thrombi form also on heart valves altered by calcification or bacterial vegetation. Valvular thrombi are associated most commonly with inflammation of the endocardium (endocarditis) and rheumatic heart disease.

Widespread arterial thrombus formation can occur in shock, particularly shock resulting from septicemia. In septic shock, systemic inflammation activates the intrinsic and extrinsic pathways of coagulation resulting in microvascular thrombosis throughout the systemic arterial circulation (see Chapters 29 and 48).

Arterial thrombi pose two potential threats to the circulation. First, the thrombus may grow large enough to occlude the artery, causing ischemia in tissue supplied by the artery. Second, the thrombus may dislodge, becoming a thromboembolus that travels through the vascular system until it occludes flow into a distal systemic vascular bed.

Diagnosis of arterial thrombi is usually accomplished through the use of Doppler ultrasonography and angiography. Pharmacologic treatment involves the administration of heparin, warfarin derivatives, thrombin inhibitors, or thrombolytics. A balloon-tipped catheter also can be used to remove or compress an arterial thrombus. Various combinations of drug and catheter therapies are sometimes used concurrently.

Embolism

Embolism is the obstruction of a vessel by an **embolus**—a bolus of matter that is circulating in the bloodstream. The embolus may consist of a dislodged thrombus; an air bubble; an aggregate of amniotic fluid; an aggregate of fat, bacteria, or cancer cells; or a foreign substance. An embolus travels in the bloodstream until it reaches a vessel through which it cannot fit. No matter how tiny it is, an embolus eventually will lodge in a systemic or pulmonary vessel. The source of the embolus determines whether the embolus will lodge in a vessel of the pulmonary or systemic circulation. Pulmonary emboli originate in the venous circulation (mostly from the deep veins of the legs) or in the right heart (see p. 1275). Arterial emboli most commonly originate in the left heart and are associated with thrombi after MI, valvular disease, left heart failure, endocarditis, and dysrhythmias.

Embolism causes ischemia or infarction in tissues distal to the obstruction. A limb that is ischemic because of arterial occlusion is characterized (1) by an almost waxy whiteness of the skin because the vasculature is devoid of erythrocytes, and (2) by numbness and pain resulting from neural ischemia.

Embolism to a central organ causes organ dysfunction and pain. For example, pulmonary artery embolism causes chest pain and dyspnea; renal artery embolism causes abdominal pain and oliguria; and mesenteric artery embolism causes abdominal pain and a paralytic, ischemic bowel. In the coronary, cerebral, and peripheral arterial systems, embolism may occur as a result of rupture or mechanical disruption of an atherosclerotic plaque. This phenomenon is sometimes referred to as cholesterol embolization syndrome or atheroembolism.[68,69] Embolism to a coronary or cerebral artery is an immediate threat to life if the embolus severely obstructs a major vessel. Occlusion of a coronary artery causes an MI (see p. 1157), whereas occlusion of a cerebral artery causes a stroke (see Chapter 18).

Infarction and subsequent necrosis of a central organ are life threatening, not only because of organ dysfunction but also because of sepsis. Necrotic tissue is a rich medium for the growth of bacteria from the lungs, bowel, and occasionally, bladder, and can quickly lead to septicemia.

Thromboembolism

Thromboembolism is a vascular obstruction resulting from a dislodged thrombus. The most common source of arterial thromboemboli to the systemic circulation is the heart. Mitral or aortic valvular disease, especially that associated with abnormal heart rhythms (atrial fibrillation and flutter), causes thrombus formation on roughened vascular surfaces and in atrial blood as a result of stasis. More than half of these thromboemboli lodge in the lower extremities (in the femoral and popliteal arteries). Others lodge in the coronary arteries and the cerebral vasculature. Heart failure also is associated with an increased risk of thrombotic complications, although the mechanism for this increased risk is unclear.

Air Embolism

Room air that enters the circulation through intravenous lines is probably the most common cause of air embolism. Room air is about 70% nitrogen. Although nitrogen dissolves quickly in blood, large amounts of air cannot be dissolved rapidly enough to prevent the displacement of blood in the arterioles and capillary beds. Ischemia and necrosis occur when air totally blocks a vessel.

Air also can be introduced into the bloodstream if trauma to the chest causes air from the lungs to enter the vascular space. For example, gunshot wounds and puncture wounds of the thorax sometimes introduce air emboli. Treatment for air embolism is supportive, including bed rest and supplemental oxygen, once the connection between the source of air and the vascular system is eliminated.

Amniotic Fluid Embolism

The great intra-abdominal pressures generated during labor and delivery may force amniotic fluid into the mother's bloodstream through the highly vascular uterine wall. Amniotic fluid not only displaces blood, reducing oxygen, nutrient, and waste exchange, but also introduces antigens, cells, and protein aggregates that trigger inflammation, coagulation, and the immune response within the bloodstream. Capillary beds usually are affected by amniotic fluid emboli, especially the capillary beds of the lungs and kidneys. Treatment is

supportive and may include dialysis, particularly after a cesarean delivery or hysterectomy.

Bacterial Embolism

Isolated bacteria in the bloodstream do not cause embolism, but aggregates of bacteria may be large enough to do so. The most common cause of bacterial embolism is subacute bacterial endocarditis, during which clumps of vegetation are dislodged from infected cardiac valves and ejected into the pulmonary or systemic circulation. A less common cause is erosion of an artery or vein by bacteria at a source of infection, such as an abscess. Treatment for bacterial embolism includes bed rest, supplemental oxygen, and antibiotics to eradicate the source of infection.

Fat Embolism

Trauma to the long bones is associated with fat embolism, particularly in the lungs. Two mechanisms have been proposed to account for the generation of fat emboli after skeletal trauma. The first is that trauma to the bones initiates defective fat metabolism, causing globules of fat to form in the blood. Platelets adhere to these globules until the conglomerate is large enough to lodge in a capillary bed. The second possible explanation is that globules of fat are released from fatty bone marrow exposed by fracture. Again, platelets adhere to the fat globules, and embolism occurs.

Treatment for fat embolism consists of prompt immobilization of fractures and supportive measures that include administration of supplemental oxygen, steroids, and glucose. Steroid administration may decrease the inflammation that occurs with vascular occlusion. Inflammation in the pulmonary bed is especially dangerous because it can cause acute respiratory distress syndrome (ARDS) (see Chapter 35).

Foreign Matter

Foreign matter can enter the bloodstream during trauma or through an intravenous or intra-arterial line. Small particles, such as drug precipitates, small glass shards, or fibers from linen, are sometimes introduced unintentionally into a vessel through intravenous injections or manipulation of monitoring lines. Once in the blood, these small particles initiate the coagulation cascade. The thromboemboli that form around the particles are large enough to occlude a vessel and result in ischemia. Treatment is aimed at preventing thrombus formation around the particle, dissolution of the particle, and supportive measures to alleviate ischemia. If the bolus of foreign matter is relatively large, it usually is removed surgically.

Peripheral Vascular Diseases

Thromboangiitis Obliterans (Buerger Disease)

Thromboangiitis obliterans (**Buerger disease**) is an inflammatory disease of the peripheral arteries. It is associated with smoking in approximately 95% of cases—the other 5% are related to frostbite, trauma, or the use of sympathomimetic drugs.[70] The incidence of Buerger disease has been steadily declining, presumably because of a decrease in cigarette smoking in men. Inflammatory lesions are accompanied by thrombi and sometimes by vasospasm of arterial segments. The pathogenesis of thromboangiitis obliterans is still being explored. There is evidence of significant T-cell activation and autoimmunity, as well as a lack of appropriate production of endothelial precursor cells in the bone marrow.[71] Inflammation, thrombus formation, and vasospasm eventually can occlude and obliterate portions of small and medium-size arteries. Typically affected are the digital, tibial, and plantar arteries of the feet and the digital, palmar, and ulnar arteries of the hands.

The chief symptoms of thromboangiitis obliterans are pain and tenderness of the affected part. Clinical manifestations are caused by sluggish blood flow and include rubor (redness of the skin), which is caused by dilated capillaries under the skin, and cyanosis, which is caused by blood that remains in the capillaries after its oxygen has diffused into the interstitium. Chronic ischemia causes the skin to thin and become shiny and the nails to become thickened and malformed. In advanced disease, ischemia resulting from vessel obliteration can cause gangrene, which may require amputation.

There are five primary criteria for the diagnosis of Buerger disease: (1) onset before age 50; (2) history of tobacco use; (3) ischemia of the digits; (4) typical arteriographic findings; and (5) exclusion of autoimmune disease, thrombophilia, diabetes, and proximal embolic source.[70] The most important part of treatment is cessation of cigarette smoking. All other measures are aimed at improving circulation to the foot or hand and include exercise and dependent positioning to improve circulation, vasodilators to alleviate vasospasm, and antithrombotics to prevent thrombus formation. If vasospasm persists, sympathectomy may be performed. Newer therapies include immunomodulation, spinal cord stimulation, and bone marrow transplantation.[70,72]

Raynaud Phenomenon and Disease

Raynaud phenomenon and Raynaud disease are characterized by attacks of vasospasm in the small arteries and arterioles of the fingers and, less commonly, the toes. Although the clinical manifestations of the phenomenon and the disease are the same, their causes differ.

Raynaud phenomenon is secondary to systemic diseases, such as collagen vascular disease (e.g., scleroderma), chemotherapy, cocaine use, hypothyroidism, pulmonary hypertension, thoracic outlet syndrome, serum sickness, vasculitis, malignancy, or long-term exposure to environmental conditions, such as cold or vibrating machinery in the workplace. Raynaud phenomenon associated with malignancy can be especially severe and is an important clue to finding a previously undiagnosed cancer.[73]

Raynaud disease is a primary vasospastic disorder of unknown origin. Blood vessels in affected individuals demonstrate endothelial dysfunction with an imbalance in endothelium-derived vasodilators (e.g., nitric oxide) and vasoconstrictors (e.g., endothelin-1). Platelet activation also may play a role. It tends to affect young women and to consist of vasospastic attacks triggered by brief exposure to cold or by emotional stress. Genetic predisposition may play a role in its development.

The clinical manifestations of the vasospastic attacks of either disorder are changes in skin color and sensation caused by ischemia. Vasospasm occurs with varying frequency and severity and causes pallor, numbness, and the sensation of cold in the digits. Attacks tend to be bilateral, and manifestations usually begin at the tips of the digits and progress to the proximal phalanges. Sluggish blood flow resulting in ischemia may cause the skin to appear cyanotic. Rubor follows as vasospasm ends and the capillaries become engorged with oxygenated blood. Rubor often is accompanied by throbbing and paresthesias. Skin color returns to normal after the attack, but frequent, prolonged attacks interfere with cellular metabolism, causing the skin of the fingertips to thicken and the nails to become brittle. In severe, chronic Raynaud phenomenon or disease, ischemia eventually can cause ulceration and gangrene. This outcome is rare, however.

The diagnostic criteria for Raynaud disease include not only the characteristic clinical manifestations described previously but also the absence of necrosis, no detectable underlying cause, normal capillaroscopy findings, normal laboratory tests for inflammation, and negative tests for antinuclear factors.[74]

Treatment for Raynaud phenomenon consists of removing the stimulus or treating the primary disease process. When Raynaud phenomenon is associated with malignancy, surgical removal of the tumor may resolve the ischemia. For Raynaud phenomenon not associated with malignancy, treatment is limited to amelioration of symptoms with arm exercises and medications, such as calcium channel blockers, alpha-blockers, prostaglandin analogs, or endothelin antagonists.[74]

Treatment of Raynaud disease is limited to prevention or alleviation of vasospasm itself, because no underlying disorder has been identified. Stimuli that trigger attacks (e.g., emotional stress, cold) are avoided, and cigarette smoking is stopped to eliminate the vasoconstricting effects of nicotine. Exercises that build centrifugal force in the extremities also are helpful in the early stages of vasospasm. If attacks of vasospasm become frequent or prolonged, pharmacologic management can include calcium channel blockers, nitric oxide agonists, alpha-blockers, prostaglandin analogs, and selective serotonin reuptake inhibitors. Biofeedback may be helpful.[75] Sympathectomy may be recommended in severe cases but is not always effective and has a high rate of recurrence.[76] If ischemia leads to ulceration and gangrene, amputation is necessary.

Atherosclerosis

Atherosclerosis is a form of arteriosclerosis in which thickening and hardening of the vessel are caused by the accumulation of lipid-laden macrophages within the arterial wall, which leads to the formation of a lesion called a **plaque.** Atherosclerosis is not a single disease but rather a pathologic process that can affect vascular systems throughout the body, resulting in ischemic syndromes that can vary widely in their severity and clinical manifestations. It is the leading cause of coronary artery and cerebrovascular disease. (Atherosclerosis of the coronary arteries is described on p. 1148; atherosclerosis of the cerebral arteries is discussed in Chapter 18.)

PATHOPHYSIOLOGY. Atherosclerosis is an inflammatory disease that develops and proceeds in the presence of elevated plasma cholesterol levels.[77] Both innate and adaptive immunity play a role in the development and progression of atherosclerotic lesions.[78] Pathologically, the lesions progress from endothelial injury and dysfunction to fatty streak to fibrotic plaque to complicated lesion (Figures 32-12 and 32-13). Atherosclerosis begins with injury to the endothelial cells that line artery walls. Possible causes of endothelial injury include the common risk factors for atherosclerosis, such as smoking, hypertension, diabetes, increased levels of low-density lipoprotein (LDL), decreased levels of high-density lipoprotein (HDL), and autoimmunity.[79,80] Other causes of endothelial injury include inflammatory factors that are being explored as nontraditional cardiovascular risk factors, such as elevated C-reactive protein (CRP), increased serum fibrinogen, infection, and periodontal disease. These risk factors are discussed in more detail in the following section on coronary artery disease (see p. 1148). Recent evidence indicates that individuals with a defect in the production of precursor endothelial cells in the bone marrow are at greater risk for atherosclerotic disease because these precursor cells are not available to repair injured endothelium.[81]

Once injury has occurred, endothelial dysfunction and inflammation lead to the following pathophysiologic events:

1. Injured endothelial cells become inflamed and cannot make normal amounts of antithrombotic and vasodilating cytokines (see Figure 31-23).
2. Numerous inflammatory cytokines are released, including tumor necrosis factor-alpha (TNF-α), interferon-gamma (IFN-γ), interleukin-1 (IL-1), toxic oxygen radicals, CRP, and heat shock proteins.
3. Macrophages adhere to injured endothelium by way of adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1).
4. These macrophages then release enzymes and toxic oxygen radicals that create oxidative stress, oxidize LDL, and further injure the vessel wall.
5. Growth factors also are released, including angiotensin II, fibroblast growth factor, TGF-β, and platelet-derived growth factor, which stimulate smooth muscle cell proliferation in the affected vessel.

LDL penetrates into the subintima of arterial walls, where it is trapped by proteoglycans. Inflammation, oxidative stress, and activation of macrophages cause the aggregated LDL to become oxidized (see Figure 32-13). Diabetes, smoking, and hypertension (especially with increased levels of angiotensin II) contribute to increased LDL oxidation. Oxidized LDL is toxic to endothelial cells and causes smooth muscle proliferation. Oxidized LDL also increases endothelial adhesion molecule expression, which recruits more monocyte/macrophages that penetrate the vessel wall. Several types of receptors on these macrophages (Toll-like receptors [TLRs], LDL receptor-related protein [LRP]) enable detection and engulfment of the LDL, which contributes to activation of additional innate and adaptive immune responses.[82,83] Macrophages filled with oxidized LDL are called **foam cells** (see Figure 32-13).

Once these lipid-laden foam cells accumulate in significant amounts, they form a lesion called a **fatty streak** (see Figure 32-12). These lesions can be found in the walls of arteries of most

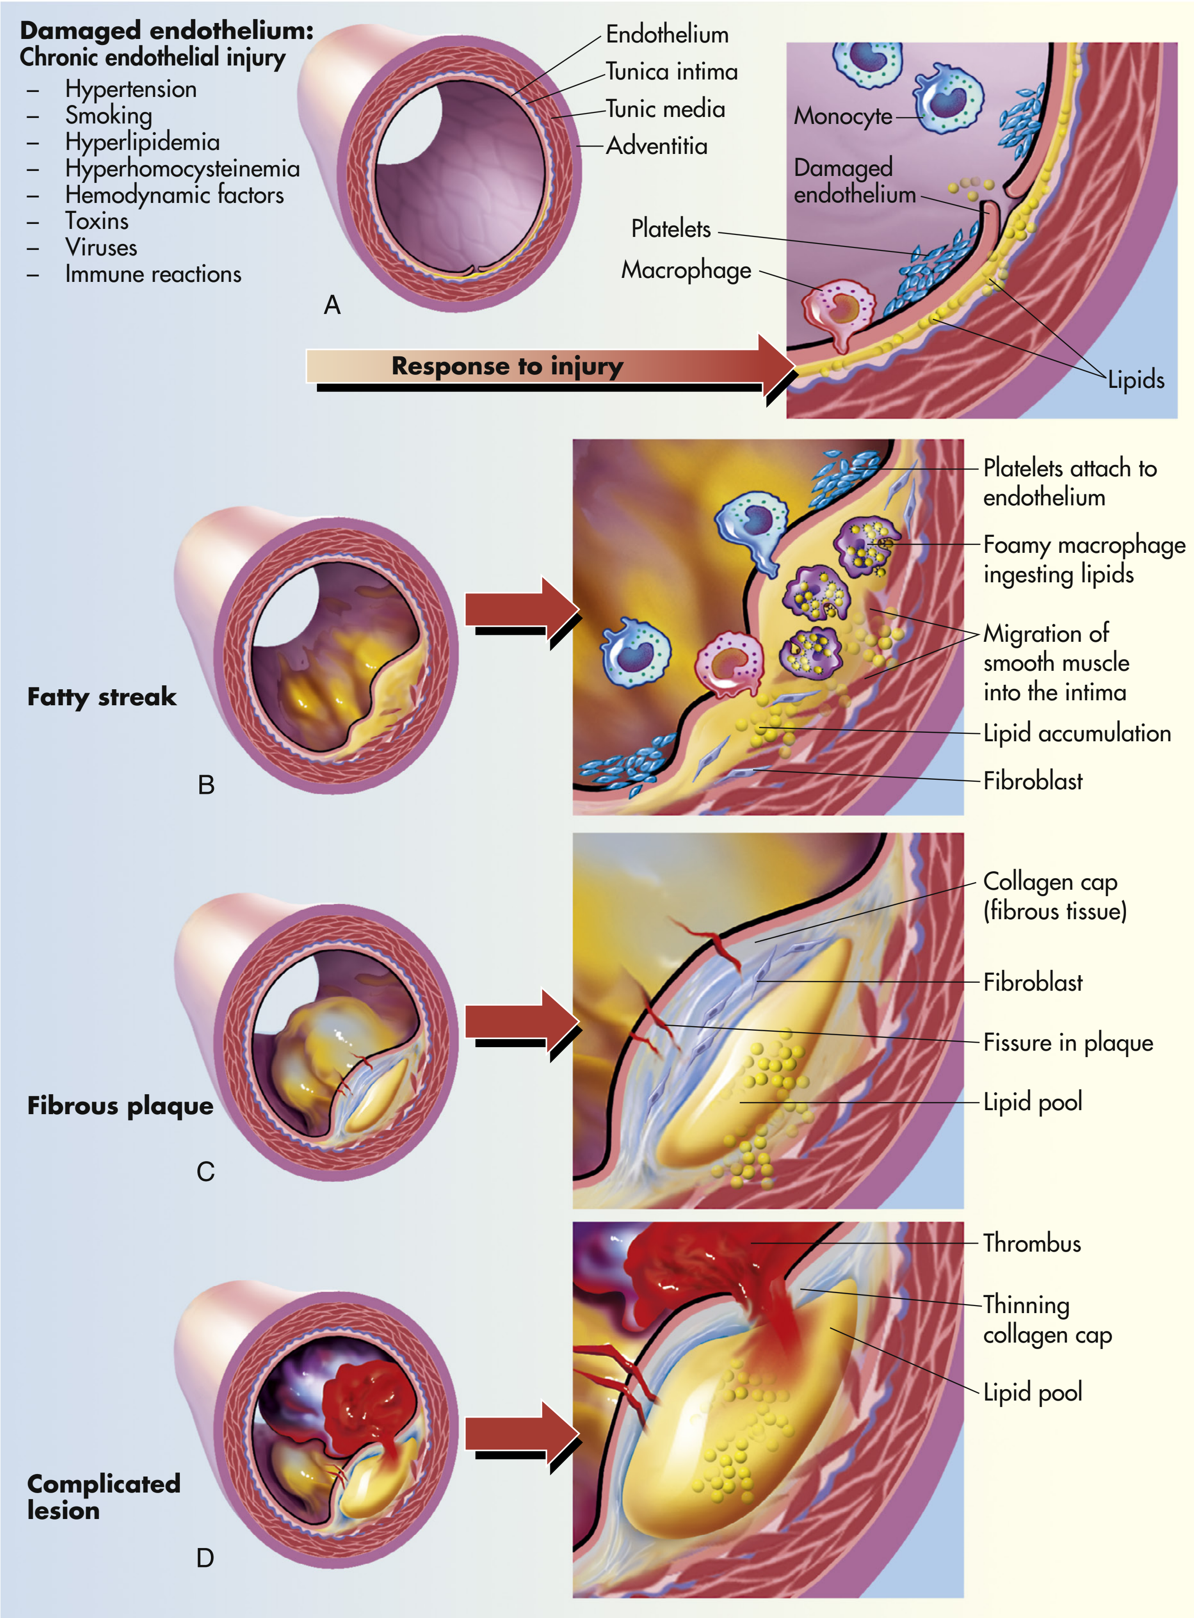

FIGURE 32-12 Progression of Atherosclerosis. **A,** Damaged endothelium. **B,** Diagram of fatty streak and lipid core formation (see Figure 32-13 for a diagram of oxidized low-density lipoprotein [LDL]). **C,** Diagram of fibrous plaque. Raised plaques are visible: some are yellow; others are white. **D,** Diagram of complicated lesion; thrombus is red; collagen is blue. Plaque is complicated by red thrombus deposition.

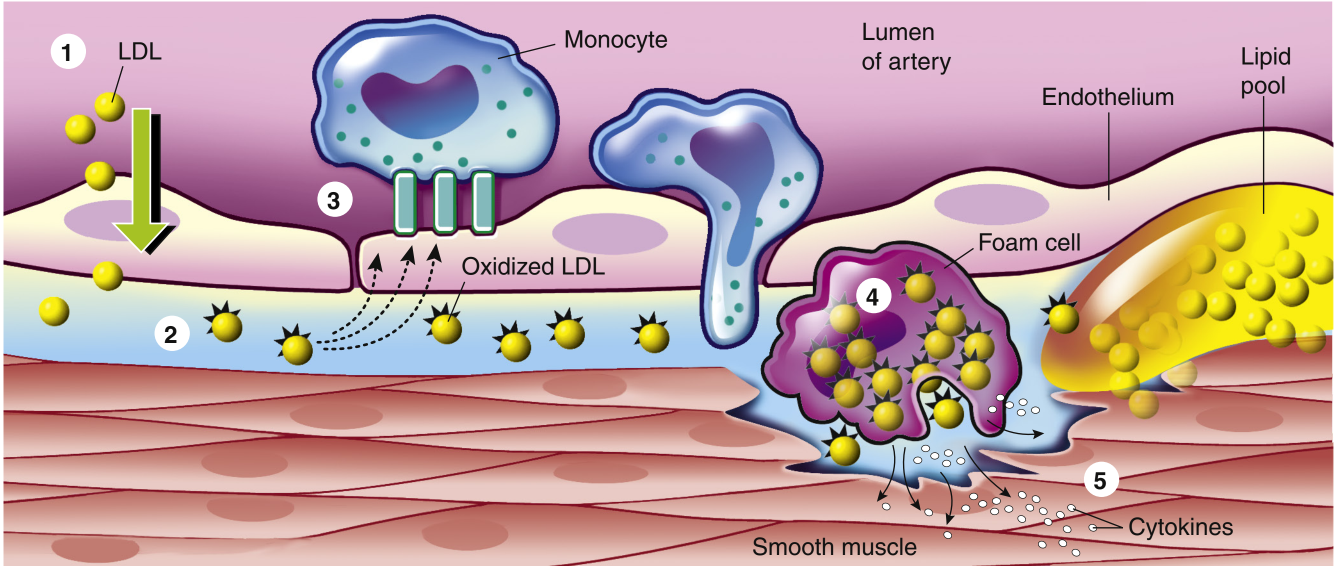

FIGURE 32-13 **Low-Density Lipoprotein Oxidation.** **(1)** Low-density lipoprotein (LDL) enters the arterial intima through an intact endothelium. In hypercholesterolemia, the influx of LDL exceeds the eliminating capacity and an extracellular pool of LDL is formed. This is enhanced by association of LDL with the extracellular matrix. **(2)** Intimal LDL is oxidized through the action of free oxygen radicals formed by enzymatic or nonenzymatic reactions. **(3)** This generates proinflammatory lipids that induce endothelial expression of the adhesion molecule; vascular cell adhesion molecule-1 activates complement and stimulates chemokine secretion. All of these factors cause adhesion and entry of mononuclear leukocytes, particularly monocytes and T lymphocytes. **(4)** Monocytes differentiate into macrophages. Macrophages up-regulate and internalize oxidized LDL and transform into foam cells. Macrophage update of oxidized LDL also leads to presentation of fragments of it to antigen-specific T cells. **(5)** This induces an autoimmune reaction that leads to production of proinflammatory cytokines. Such cytokines include interferon-gamma, tumor necrosis factor-alpha, and interleukin-1, which act on endothelial cells to stimulate expression of adhesion molecules and procoagulant activity; on macrophages to activate proteases, endocytosis, nitric oxide (NO), and cytokines; and on smooth muscle cells (SMCs) to include NO production and inhibit growth, collagen, and actin expression. (Modified from Crawford MH, DiMarco JP, Paulus WJ: *Cardiology, ed 3,* London, 2010, Mosby.)

people, even young children. Once formed, fatty streaks produce more toxic oxygen radicals and cause immunologic and inflammatory changes, resulting in progressive damage to the vessel wall. At this point, smooth muscle cells proliferate, produce collagen, and migrate over the fatty streak forming a **fibrous plaque** (see Figure 32-12). This process is mediated by many inflammatory cytokines, including growth factors (e.g., TGF-β).[84] The fibrous plaque may calcify, protrude into the vessel lumen, and obstruct blood flow to distal tissues, especially during exercise, which may cause symptoms (e.g., angina or intermittent claudication).

Many plaques, however, are "unstable," meaning they are prone to rupture even before they affect blood flow and are clinically silent until they rupture. Plaque rupture occurs because of the inflammatory activation of proteinases (matrix metalloproteinases and cathepsins), apoptosis of cells within the plaque, and bleeding within the lesion (plaque hemorrhage).[85] Plaques that have ruptured are called **complicated plaques** (see Figure 32-12). Once rupture occurs, exposure of underlying tissue results in platelet adhesion, initiation of the clotting cascade, and rapid thrombus formation that may suddenly occlude the affected vessel, resulting in ischemia and infarction. Aspirin or other antithrombotic agents are used to prevent this complication of atherosclerotic disease.

CLINICAL MANIFESTATIONS. Atherosclerosis presents with symptoms and signs that result from inadequate tissue perfusion because of obstruction of the vessels that supply them. Partial vessel obstruction may lead to transient ischemic events, often associated with exercise or stress. Once the lesion becomes complicated, increasing obstruction with superimposed thrombosis may result in tissue infarction. CAD caused by atherosclerosis is the major cause of myocardial ischemia and is one of the most important health issues in the United States. Atherosclerotic obstruction of the vessels supplying the brain is the major cause of stroke. Similarly, any part of the body may become ischemic when its blood supply is compromised by atherosclerotic lesions. Often more than one vessel is involved with this disease process; consequently, an individual may present with symptoms from several ischemic tissues at the same time, and disease in one area may indicate that the individual is at risk for other ischemic complications elsewhere.

EVALUATION AND TREATMENT. In evaluating individuals for the presence of atherosclerosis, a complete health history (including risk factors and symptoms of ischemia) is essential. Physical examination may reveal arterial bruits and evidence of decreased blood flow to tissues. Laboratory tests include measurement of lipids, blood glucose, and high sensitivity CRP (hs-CRP). Judicious use of x-ray films, electrocardiography, ultrasonography, nuclear scanning, CT, MRI, and angiography may be necessary to identify affected vessels, particularly coronary vessels. New

modalities aimed at identifying vulnerable plaques before the rupture are being evaluated.[86]

Current management of atherosclerosis is focused on detecting and treating preclinical lesions with drugs aimed at stabilizing and reversing plaques before they rupture.[87] Once a lesion obstructs blood flow, the primary goal in managing atherosclerosis is to restore adequate blood flow to the affected tissues. If an individual has presented with acute ischemia (e.g., MI, stroke), interventions are specific to the diseased area and are discussed further under those topics. In situations in which the disease process does not require immediate intervention, management focuses on reducing risk factors, removing the initial causes of vessel damage, and preventing lesion progression. This includes exercise, smoking cessation, and control of hypertension and diabetes when appropriate while reducing LDL cholesterol by diet or medications or both. (Management of atherosclerotic risk factors is discussed further starting on p. 1154.)

Peripheral Artery Disease

Peripheral artery disease (PAD) refers to atherosclerotic disease of arteries that perfuse the limbs, especially the lower extremities. PAD affects approximately 8 to 12 million Americans, 12% to 20% of whom are 65 years of age or older, and is associated with significant morbidity and mortality. Prevalence increases with age, and PAD disproportionately affects blacks.[5] The risk factors for PAD are the same as those for atherosclerotic disease, and it is especially prevalent in individuals who smoke and those with diabetes. PAD is a significant predictor of systemic atherosclerotic disease such that those with documented PAD have nearly double the risk of coronary artery disease than those without.

Lower-extremity ischemia, resulting from arterial obstruction in PAD, can be gradual or acute. In most individuals gradually increasing obstruction to arterial blood flow to the legs caused by atherosclerosis in the iliofemoral vessels results in pain with ambulation called **intermittent claudication.** However, only 10% of people with PAD have the classic symptom of intermittent claudication, and 40% do not complain of leg pain.[5] If a thrombus forms over the atherosclerotic lesion, perfusion can cease acutely with severe pain, loss of pulses, and skin color changes in the affected extremity.

Evaluation for PAD requires a careful history and physical examination that focuses on looking for evidence of atherosclerotic disease (e.g., bruits), ankle-brachial index, and noninvasive Doppler measurement of blood flow. Treatment includes risk factor reduction (smoking cessation and treatment of diabetes, hypertension, and dyslipidemia) and antiplatelet therapy. Symptomatic PAD should be managed with vasodilators in combination with antiplatelet or antithrombotic medications (aspirin, cilostazol, ticlopidine, or clopidogrel), cholesterol-lowering medications, and exercise rehabilitation.[88] If acute or refractory symptoms occur, emergent percutaneous or surgical revascularization may be indicated. Newer treatment modalities that are being explored include autologous stem cell therapies, gene therapy, and angiogenesis.[89,90]

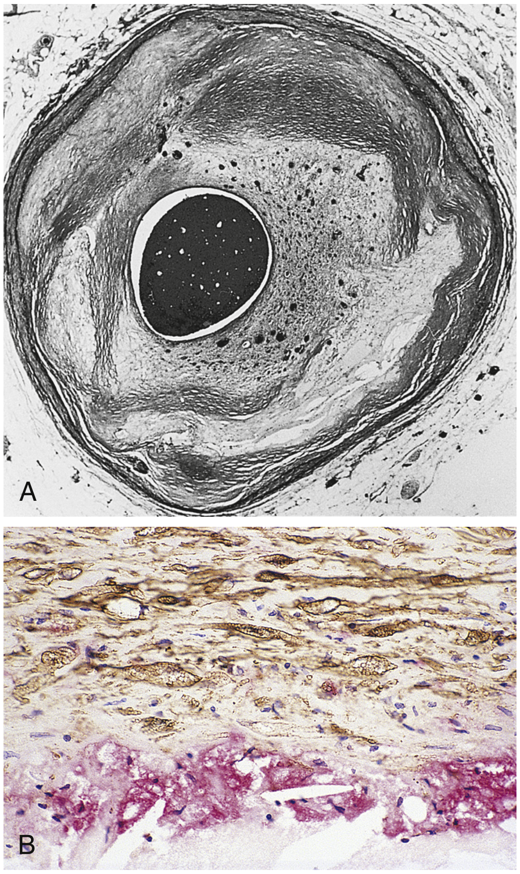

FIGURE 32-14 Atherosclerosis. **A,** Concentric coronary plaque. The lumen is central. Multiple new small blood vessels are shown within the plaque, the late result of disruption. **B,** Cell types in a fibrolipid plaque. The plaque cap (brownish) contains numerous elongated smooth muscle cells; some contain lipid. Macrophages are clustered on the edge of the core. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes

CAD, myocardial ischemia, and MI form a pathophysiologic continuum that impairs the pumping ability of the heart by depriving the heart muscle of blood-borne oxygen and nutrients. The earliest lesions of the continuum are those of **coronary artery disease (CAD)** which occludes the coronary arteries. By far the most common cause of coronary artery obstruction is atherosclerosis (Figure 32-14). CAD can diminish the myocardial blood supply until deprivation impairs myocardial metabolism enough to cause **ischemia,** a local state in which the cells are temporarily deprived of blood supply. They remain alive but cannot function normally. Persistent ischemia or the complete occlusion of a coronary artery causes **acute coronary syndrome. Infarction** (irreversible myocardial injury) constitutes the often-fatal event known as a *heart attack.*

Development of Coronary Artery Disease

The American Heart Association estimates that approximately 7% of the U.S. population older than age 20 years has CAD, resulting in approximately 610,000 new and 325,000 recurrent heart attacks each year (one every 25 seconds) causing 1 of every 6 deaths.[5]

TABLE 32-5 CRITERIA FOR DYSLIPIDEMIA

	OPTIMAL	NEAR OPTIMAL	DESIRABLE	LOW	BORDERLINE	HIGH	VERY HIGH
Total cholesterol			<200		200-239	≥240	
LDL	<100	100-129			130-159	160-189	≥190
Triglycerides			<150		150-199	200-499	≥500
HDL				<40		≥60

HDL, High-density lipoprotein; *LDL,* low-density lipoprotein.

Risk factors for CAD are the same as those for atherosclerosis and can be categorized as conventional (major) versus nontraditional (novel) and modifiable versus nonmodifiable. Much new information has been obtained about the conventional risk factors that has markedly improved the prevention and management of CAD.[91] In addition, the more recently identified nontraditional risk factors have provided insight in to the pathogenesis of CAD and may lead to more effective interventions.

Conventional or major risk factors for CAD that are nonmodifiable include: (1) advanced age, (2) male gender or women after menopause, and (3) family history. Aging and menopause are associated with increased exposure to risk factors and poor endothelial healing. Family history may contribute to CAD through genetics and shared environmental exposures. Many gene polymorphisms have been associated with CAD and its risk factors.[92] Blood type also has been linked to cardiovascular risk, with type O associated with the lowest risk and type AB the highest.[93]

Major modifiable conventional risks include: (1) dyslipidemia, (2) hypertension, (3) cigarette smoking, (4) diabetes and insulin resistance, (5) obesity, (6) sedentary lifestyle, and (7) an atherogenic diet. In individuals with known CAD, the majority have the growing epidemic of obesity in the United States. If individuals receive appropriate preventive care, modification of these factors can significantly reduce the risk for CAD. Of great concern is the finding that exposure to particulate matter air pollution is associated with an increase in myocardial infarction risk and air pollution is a worsening global problem.[94]

Dyslipidemia. The link between CAD and elevated plasma lipoprotein concentrations is well documented.[5] The term **lipoprotein** refers to lipids, phospholipids, cholesterol, and triglycerides bound to carrier proteins. Lipids (cholesterol in particular) are required by most cells for the manufacture and repair of plasma membranes. Cholesterol is also a necessary component for the manufacture of such essential substances as bile acids and steroid hormones. Although cholesterol can easily be obtained from dietary fat intake, most body cells also can manufacture cholesterol.

The cycle of lipid metabolism is complex. Dietary fat is packaged into particles known as **chylomicrons** in the small intestine. Chylomicrons are required for absorption of fat; they function by transporting exogenous lipid from the intestine to the liver and peripheral cells. Chylomicrons are the least dense of the lipoproteins and primarily contain triglyceride. Some of the triglyceride may be removed and either stored by adipose tissue or used by muscle as an energy source. The chylomicron remnants, composed mainly of cholesterol, are taken up by the liver. A series of chemical reactions in the liver results in the production of several lipoproteins that vary in density and function. These include **very-low-density lipoproteins (VLDLs),** primarily triglyceride and protein; **low-density lipoproteins (LDLs),** mostly cholesterol and protein; and **high-density lipoproteins (HDLs),** mainly phospholipids and protein.

Dyslipidemia (or **dyslipoproteinemia**) refers to abnormal concentrations of serum lipoproteins as defined by the Third Report of the National Cholesterol Education Program (Table 32-5).[95] It is estimated that nearly half of the U.S. population has some form of dyslipidemia, especially among white and Asian populations.[5] These abnormalities are the result of a combination of genetic and dietary factors. Primary or familial dyslipoproteinemias result from genetic defects that cause abnormalities in lipid-metabolizing enzymes and abnormal cellular lipid receptors (Table 32-6). Secondary causes of dyslipidemia include several common systemic disorders, such as diabetes, hypothyroidism, pancreatitis, and renal nephrosis, as well as the use of certain medications such as certain diuretics, beta-blockers, glucocorticoids, interferons, and antiretrovirals.

An increased serum concentration of LDL is a strong indicator of coronary risk. LDL is responsible for the delivery of cholesterol to the tissues. Serum levels of LDL are normally controlled by hepatic receptors for LDL that bind LDL and limit liver synthesis of this lipoprotein. High dietary intake of cholesterol and fats, often in combination with a genetic predisposition to accumulations of LDL in the serum (e.g., dysfunction of the hepatic LDL receptor), results in high levels of LDL in the bloodstream. LDL oxidation, migration into the vessel wall, and phagocytosis by macrophages are key steps in the pathogenesis of atherosclerosis (see p. 1145 and Figure 32-13). LDL also plays a role in endothelial injury, inflammation, and immune responses that have been identified as being important in atherogenesis.[79] The term LDL actually describes several types of LDL molecules. Measurement of LDL subfractions allows for better prediction of coronary risk. For example, LDL-C measurements allow for detection of the small dense LDL particles that are the most atherogenic, and apolipoprotein B (structural protein found in both LDL and VLDL) levels are a very strong predictor of future coronary events.[96]

Low levels of HDL cholesterol also are a strong indicator of coronary risk. HDL is responsible for "reverse cholesterol transport," which returns excess cholesterol from the tissues to the liver, where it binds to hepatic receptors (including the LDL receptor) and is processed and eliminated as bile or converted to cholesterol-containing steroids.[97] Recent evidence shows that

HDL can remove excess cholesterol from the arterial wall through several pathways, including mediating the efflux of cholesterol from lipid-laden macrophages (foam cells) through the activation of adenosine triphosphate (ATP)–binding cassette transporter proteins (ABC proteins).[98] This discovery has resulted in the initiation of a whole new area of pharmacologic investigation into optimizing HDL function. HDL also participates in endothelial repair and decreases thrombosis. As HDL cholesterol is transported, it progresses through three subtypes of HDL: pre-β HDL, HDL3, and HDL2. Apolipoprotein (ApoA-I) on the pre-β HDL

TABLE 32-6 FAMILIAL DYSLIPOPROTEINEMIAS

NAME	LABORATORY FINDINGS	CLINICAL FEATURES	THERAPY
Type I: exogenous hyperlipidemia; fat-induced hypertriglyceridemia	Cholesterol normal Triglycerides increased three times Chylomicrons increased	Abdominal pain Hepatosplenomegaly Skin and retinal lipid deposits Usual onset: childhood	Low-fat diet
Type IIa: hypercholesterolemia	Triglycerides normal LDL increased Cholesterol increased	Premature vascular disease Xanthomas of tendons and bony prominences Common Onset: all ages	Low-saturated-fat and low-cholesterol diet Cholestyramine[a] Colestipol[b] Lovastatin[c] Nicotinic acid[d] Neomycin[e] Intestinal bypass
Type IIb: combined hyperlipidemia; carbohydrate-induced hypertriglyceridemia	LDL, VLDL increased Cholesterol increased Triglycerides increased	Same as IIa	Same as IIa; *plus* carbohydrate restriction Clofibrate[f] Gemfibrozil[g] Lovastatin
Type III: dysbetalipoproteinemia	IDL or chylomicron remnants increased Cholesterol increased Triglycerides increased	Premature vascular disease Xanthomas of tendons and bony prominences Uncommon Onset: adulthood	Weight control Low-carbohydrate, low-saturated-fat, and low-cholesterol diet Alcohol restriction Clofibrate Gemfibrozil Lovastatin Nicotinic acid Estrogens[h] Intestinal bypass
Type IV: endogenous hyperlipidemia; carbohydrate-induced hypertriglyceridemia	Glucose intolerance Hyperuricemia Cholesterol normal or increased VLDL increased Triglycerides increased	Premature vascular disease Skin lipid deposits Obesity Hepatomegaly Common onset: adulthood	Weight control Low-carbohydrate diet Alcohol restriction Clofibrate Nicotinic acid Intestinal bypass
Type V: mixed hyperlipidemia; carbohydrate and fat-induced hypertriglyceridemia	Glucose intolerance Hyperuricemia Chylomicrons increased VLDL increased LDL increased Cholesterol increased Triglycerides increased three times	Abdominal pain Hepatosplenomegaly Skin lipid deposits Retinal lipid deposits Onset: childhood	Weight control Low-carbohydrate and low-fat diet Clofibrate Lovastatin Nicotinic acid Progesterone[i] Intestinal bypass

IDL, Intermediate-density lipoprotein; *LDL,* low-density lipoprotein; *VLDL,* very-low-density lipoprotein.

[a]*Cholestyramine* (Questran), anion exchange resin; binds bile acids; enhances cholesterol excretion.

[b]*Colestipol* (Colestid), same as cholestyramine.

[c]*Lovastatin,* 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor; decreases cholesterol synthesis in the liver.

[d]*Nicotinic acid* (niacin), decreases release of free fatty acids from adipose tissue; increases lipogenesis in liver; decreases glucagon release; most effective for type V disorder.

[e]*Neomycin,* experimental medication; questionable mode of action; decreases LDLs.

[f]*Clofibrate* (Atromid-S), decreases release of free fatty acids from adipose tissue; decreases hepatic secretion of VLDL and increases catabolism of VLDL.

[g]*Gemfibrozil* (Lopid), similar to clofibrate but increases HDLs more.

[h]*Estrogens,* decrease IDL levels in type III disorders; experimental.

[i]*Progesterone,* decreases plasma triglycerides in type V disorders; experimental.

binds cholesterol where it is converted to cholesteryl ester creating HDL3. HDL3 then increases in size to form HDL2, which is fully loaded with cholesterol. The smaller HDL3 molecule is the most protective in preventing atherosclerosis, and research continues to explore the best approach to increasing this type of HDL.[79]

Despite the wealth of evidence that HDL plays an important role in preventing atherosclerotic coronary disease, studies have suggested that raising overall levels of HDL is not adequate to prevent cardiovascular disease. A study of individuals who have a rare genetic trait that increases their HDL levels dramatically failed to show any reduced cardiovascular risk in that population.[99] Furthermore, niacin and fibrates are drugs that can cause modest increases in HDL, but are not correlated with an improvement in cardiovascular risk in individuals without documented coronary disease (primary prevention) (see What's New? Controversies in the Use of Medications for the Primary Prevention of Cardiovascular Disease). Drugs that are being developed are aimed specifically at increasing HDL and include recombinant apolipoprotein A-I (ApoA-I) mimetics, thiazolidinediones (used to treat diabetes), and cholesteryl ester transfer protein inhibitors, although their effectiveness in preventing heart disease and their safety are still being evaluated.[100] At present, experts recommend exercise, weight loss, fish oil consumption, and moderate alcohol to increase HDL levels.

Other lipoproteins associated with increased cardiovascular risk include elevated serum VLDL (triglycerides) and increased lipoprotein (a). Triglycerides are associated with an increased risk for CAD, especially in combination with other risk factors such as diabetes.[101] Because of this, the measurement of "non-HDL cholesterol" (LDL plus VLDL) is frequently used to assess cardiovascular risk rather than just LDL or HDL levels alone. **Lipoprotein (a) (Lp[a])** is a genetically determined molecular complex between LDL and a serum glycoprotein called apoprotein (a) that has been shown to be an important risk factor for coronary atherosclerosis, especially in women.[102]

Hypertension. Hypertension is responsible for a two- to threefold increased risk of atherosclerotic cardiovascular disease including MI.[103] It contributes to endothelial injury, a key step in atherogenesis (see p. 1145), and causes myocardial hypertrophy, which increases myocardial demand for coronary flow. The overactivity of the SNS and RAAS commonly found in hypertension also contributes to the genesis of coronary artery disease. Drugs that block the effects of the SNS and RAAS to treat hypertension have many positive effects on the vasculature.

Cigarette Smoking. Direct and passive (environmental) smoking increase the risk of CAD. The mechanism by which smoking increases atherosclerosis is uncertain. Nicotine stimulates the release of catecholamines (epinephrine and norepinephrine), which increases heart rate and causes peripheral vascular constriction. As a result blood pressure increases, as do cardiac workload and oxygen demand. Cigarette smoking is associated with an increase in LDL and a decrease in HDL, and contributes to vessel inflammation and thrombosis. The risk of CAD increases with heavy smoking and decreases when smoking is stopped.

Diabetes Mellitus. Diabetes mellitus and insulin resistance are extremely important risk factors for CAD. Insulin resistance, hyperinsulinemia, and hyperglycemia have multiple effects on the cardiovascular system. These effects can include endothelial damage, thickening of the vessel wall, increased inflammation and leukocyte adhesion, increased thrombosis, glycation of vascular proteins, and decreased production of endothelial-derived vasodilators such as nitric oxide[104,105] (diabetes and atherogenesis are described in more detail in Chapter 22). Diabetes is also associated with dyslipidemia because of the resulting alteration of hepatic lipoprotein synthesis and increases triglycerides and in LDL oxidation.[106] Aggressive management of this additional risk factor can significantly improve CAD risk in individuals with diabetes.

Obesity and Sedentary Lifestyle. It is estimated that nearly two thirds of the U.S. adult population is overweight or obese

WHAT'S NEW?

Controversies in the Use of Medications for the Primary Prevention of Cardiovascular Disease

Despite clear evidence for the benefit of the use of medications to improve lipid levels in individuals who already have documented atherosclerotic disease (secondary prevention), primary prevention of cardiovascular disease through pharmacologic modulation of lipid levels remains controversial. Although some clinical trials and meta-analyses have shown a reduction in primary cardiovascular events with the use of the 3-hydroxy-3-methyl-glutaryl-CoA (HMG-CoA) reductase drugs (statins), niacin, and other cholesterol-lowering medications, other studies have provided mixed results, especially in women. In addition, statin use is linked to several significant complications including muscle soreness, elevation in liver enzymes, cognitive impairment, and diabetes. For example, in a recent large study exploring the role of statins in primary prevention, statin therapy lowered low-density lipoprotein (LDL) and C-reactive protein and reduced overall cardiovascular risk by 39% and overall mortality by 17%. But it also increased the risk for diabetes by 28% among individuals with risk factors for diabetes at baseline. Overall, women demonstrate less cardiovascular benefit than men, and have no improvement in mortality with the use of statins for primary prevention. The ability to weigh the risks and benefits of medication use for primary prevention is complicated by these mixed results.

Low levels of high-density lipoprotein (HDL) also have been strongly correlated with increased cardiovascular risk, yet several primary prevention trials in which drugs such as niacin and fibrates raised HDL levels failed to demonstrate benefit. In fact, use of the cholesteryl ester transfer protein (CETP) inhibitor torcetrapib, which is highly effective at increasing HDL levels, actually resulted in an increase in cardiovascular risk. Subsequent clinical studies found that this adverse risk response to torcetrapib was "molecule specific" and independent of its CETP inhibition effect. The other two CETP inhibitors, dalcetrapib and anacetrapib, have so far been well tolerated in phase I and II clinical trials and do not adversely affect blood pressure and aldosterone as torcetrapib did. It is clear from these studies that despite decades of research, there is still much work needed to fully understand the proper role of medications in the prevention of cardiovascular disease.

Data from Badimon L, Vilahur G: *Ann N Y Acad Sci* (1):18–32, 2012; Boden WE et al: *N Engl J Med* 365(24):2255–2267, 2011; Cholesterol Treatment Trialists' (CTT) Collaborators: *Lancet* 380:581–590, 2012; Gutierrez J et al: *Arch Intern Med* 172(12):909–919, 2012; Johns DG et al: *Drugs* 72(4):491–507, 2012; Michos ED et al: *J Am Coll Cardiol* 59(23):2058–2064, 2012; Prasad V, Vandross A: *Arch Intern Med* 172(8):656–659, 2012; Ridker PM et al: *Lancet* 380:565–571, 2012; Sampson UK, Fazio S, Linton MF: *Curr Atheroscler Rep* 14(1):1–10, 2012.

resulting in a much increased risk for CAD and stroke. An estimated 47 million residents have a combination of obesity, dyslipidemia, and hypertension (called **metabolic syndrome**) (see Chapter 22), which is associated with an even higher risk for CAD events.[107] Obesity is caused by genetics, diet, and inadequate physical exercise. Abdominal obesity has the strongest link with increased CAD risk and is related to insulin resistance, decreased HDL, increased blood pressure, and inflammation.[108] Obesity also is associated with changes in the adipokines (see following) that affect cardiovascular risk. A sedentary lifestyle not only increases the risk of obesity but also has an independent effect on increasing CAD risk. Physical activity and weight loss offer substantial reductions in risk factors for CAD. There is emerging evidence that bariatric surgery procedures, such as gastric bypass, can provide sustained improvement in risk factors for cardiovascular disease such as hypertension, dyslipidemia, and diabetes[109,110] (see What's New? Cardiovascular Risk Reduction with Bariatric Surgery).

Nontraditional Risk Factors. Nontraditional, or novel, risk factors for CAD include: (1) increased serum markers for inflammation and thrombosis, (2) troponin I, (3) hyperhomocysteinemia, (4) adipokines, (5) infection, (6) air pollution, and (7) coronary artery calcification and carotid wall thickness. The amount of risk conferred by these relatively newly identified factors is still being explored, although the preponderance of evidence suggests that the traditional risk factors continue to be more predictive of cardiovascular disease and should remain the focus of risk factor reduction efforts.[111]

Markers of Inflammation and Thrombosis. Of the numerous markers of inflammation that have been linked to an increase in CAD risk (hs-CRP, fibrinogen, protein C, plasminogen activator inhibitor), the relationship between serum levels of CRP and CAD has been explored in the greatest depth. **Highly sensitive C-reactive protein (hs-CRP)** is an acute phase reactant or protein mostly synthesized in the liver and is an indirect measure of atherosclerotic plaque-related inflammation. Elevated levels of hs-CRP are associated with numerous other CAD risk factors including smoking, obesity, and diabetes, and have been found to be an independent risk factor for coronary disease. However, as a nonspecific serum marker for inflammation, its utility as a screening tool for cardiovascular risk continues to be debated. A recent study demonstrated that hs-CRP levels can be used to better assign individuals into cardiovascular risk categories that aid in decision-making about pharmacologic interventions for individuals with other risk factors for coronary disease.[112] Other markers of inflammation associated with CAD include erythrocyte sedimentation rate, von Willebrand factor concentration, uric acid, IL-6, IL-18, TNF-α, fibrinogen, and YKL-40 is a 40 kDa (mass) glycoprotein produced by inflammatory cells, cancer cells, and stem cells.

Troponin I. Troponin I (TnI) is a serum protein whose measurement is used as a sensitive and specific diagnostic test to help identify myocardial injury during acute coronary syndromes. Highly sensitive TnI assays are used in individuals without a history of CAD to assess risk for future CHD events, mortality, and heart failure.[96]

Hyperhomocysteinemia. **Hyperhomocysteinemia** occurs because of a genetic lack of the enzyme that breaks down homocysteine (an amino acid) or because of a nutritional deficiency of folate, cobalamin (vitamin B_{12}), or pyridoxine (vitamin B_6). Although it has not been identified by the AHA as a major risk factor for CAD, hyperhomocysteinemia is associated with increased LDL oxidation, decreased endogenous vasodilators, increased smooth muscle proliferation, and an increased tendency for thrombosis. Elevated levels of homocysteine may interact with other risk factors (such as dyslipidemia and hypertension) in certain populations to further increase coronary risk.[113] Routine serum measurement of homocysteine is not currently recommended, and prevention and management have been focused on increasing the dietary intake of folate and B vitamins. Unfortunately, no controlled treatment study has shown that folic acid supplements reduce the risk of atherosclerosis or that taking these vitamins affects the development or recurrence of cardiovascular disease.

Adipokines. Adipokines are a group of hormones released from adipose cells. The two that are most studied are adiponectin and leptin. Leptin is primarily implicated in obesity, hypertension, and diabetes (see p. 1134) but is also being explored as a factor in autoimmune responses affecting blood vessels.[114] Decreased adiponectin in obese individuals has been linked to a significant increase in cardiovascular risk. Its antiatherogenic effects include

WHAT'S NEW?

Cardiovascular Risk Reduction with Bariatric Surgery

With the devastating increase in obesity-related diabetes and cardiovascular disease, bariatric surgical procedures for weight loss are being used in more and more individuals. Although there are surgery-related risks, including bleeding, leakage at the surgical site, and hernias, the number of bariatric procedures is increasing rapidly, and safer surgical techniques are being developed. Bariatric surgery has been shown to be effective in reversing diabetes, metabolic syndrome, hypertension, and dyslipidemia with associated risk reduction for cardiovascular disease. For example, one large study documented a 72% reversal of diabetes with gastric bypass surgery as compared to 21% of those who underwent medically managed weight loss. Similarly, more than 80% of individuals with dyslipidemia treated with surgery were found to have significant improvements in low-density lipoprotein, high-density lipoprotein, and triglycerides such that they were able to discontinue their drug regimens. These changes have been found to be sustained (over 6 years) in a large proportion of surgically treated individuals. Although approximately 7% of weight is regained, and some individuals have recurrence of their diabetes, overall mortality is reduced after bariatric surgery as compared with medically managed weight loss. The American Heart Association recommends bariatric surgery for individuals who have severe obesity in whom efforts at medical therapy have failed and an acceptable operative risk is present.

Data from Adams TD et al: *JAMA* 308(11):1122–1131, 2012; Apovian CM, Gokce N: *Circulation* 125(9):1178–1182, 2012; Benraouane F, Litwin SE: *Curr Opin Cardiol* 26(6):555–561, 2011; Mingrone G et al: *N Engl J Med* 366(17):1577–1585, 2012; Olbers T, Svensson PA, Carlsson LM: *JAMA* 307(1):56–65, 2012; Poirier P et al: *Circulation* 123(15):1683–1701, 2011; Sjostrom L et al: *N Engl J Med* 366(17):1567–1576, 2012.

anti-inflammatory, insulin-sensitizing enhancement of nitric oxide generation, attenuation of reactive oxygen species production in endothelial cells, and reduced vascular smooth muscle cell proliferation.[115] A more recently described adipokine is resistin, which has been linked to inflammation, endothelial dysfunction, thrombosis, and smooth muscle cell dysfunction.[116] Emerging evidence suggests that adipokine changes occurring in perivascular adipose cells may play a significant role in metabolic and vascular disorders.[117] Weight loss and exercise improve adipokine levels and are correlated with improved cardiovascular risk.

Infection. Infections with various microorganisms, including *Chlamydia pneumoniae, Helicobacter pylori*, and cytomegalovirus, have been linked to an increased risk for CAD, although cause and effect have not been proven. Periodontal disease also has been linked to an increased risk for CAD.[118] One hypothesis is that systemic infection results in increased inflammation of vessels and therefore contributes to vascular disease. Unfortunately, the use of antibiotics for the prevention and treatment of CAD has not yielded consistently positive results.

Air Pollution. Exposure to air pollution, especially roadway exposures, is strongly correlated with coronary risk. It is postulated that toxins in pollution contribute to macrophage activation, oxidation of LDL, thrombosis, and inflammation of vessel walls.[119]

Coronary Artery Calcification (CAC) and Carotid Artery Wall Thickness (*CAWT*). Coronary risk related to changes in vessel walls can be assessed using various types of vascular imaging techniques. CAC, as detected by CT scanning, and CIMT, as detected by ultrasonography, are two important imaging modalities in widespread use for determining coronary heart disease risk.[120,121]

Myocardial Ischemia

PATHOPHYSIOLOGY. The coronary arteries normally supply blood flow sufficient to meet the demands of the myocardium as it labors under varying workloads. Oxygen extraction from these vessels occurs with maximal efficiency. If efficient exchange does not meet myocardial oxygen needs, healthy coronary arteries are able to dilate to increase the flow of oxygenated blood to the myocardium. Narrowing of a major coronary artery by more than 50% impairs blood flow sufficiently to hamper cellular metabolism under conditions of increased myocardial demand (see Figure 32-14).

Myocardial ischemia develops if the supply of coronary blood cannot meet the demand of the myocardium for oxygen and nutrients. Imbalances between myocardial demand and coronary blood supply can result from a number of conditions. Common causes of increased myocardial demand for blood include tachycardia, exercise, hypertension (hypertrophy), and valvular disease. The most common cause of decreased coronary blood flow and resultant myocardial ischemia is the formation of atherosclerotic plaques in the coronary circulation. As the plaque increases in size, it may partially occlude the vessel lumina, thus limiting coronary flow and causing ischemia especially during exercise. Some plaques are "unstable," meaning they are prone to ulceration or rupture (see p. 1156 and Figure 32-20). When this ulceration or rupture occurs, underlying tissues of the vessel wall are exposed, resulting in platelet adhesion and thrombus formation. Thrombus formation can suddenly cut off blood supply to the heart muscle, resulting in acute myocardial ischemia, and if the vessel obstruction cannot be reversed rapidly, ischemia will progress to infarction. Myocardial ischemia also can result from other causes of decreased blood and oxygen delivery to the myocardium, such as coronary spasm, hypotension, dysrhythmias, and decreased oxygen-carrying capacity of the blood (anemia, hypoxemia).

Myocardial cells become ischemic within 10 seconds of coronary occlusion. After several minutes the heart cells lose the ability to contract, and cardiac output decreases. Ischemia also causes conduction abnormalities that lead to changes in the electrocardiogram and may initiate dysrhythmias. Anaerobic processes take over, and lactic acid accumulates. Cardiac cells remain viable for approximately 20 minutes under ischemic conditions. If blood flow is restored, aerobic metabolism resumes, contractility is restored, and cellular repair begins. If the coronary artery occlusion persists beyond 20 minutes, MI occurs (Figure 32-15).

CLINICAL MANIFESTATIONS. Individuals with reversible myocardial ischemia present clinically in several ways. Chronic coronary

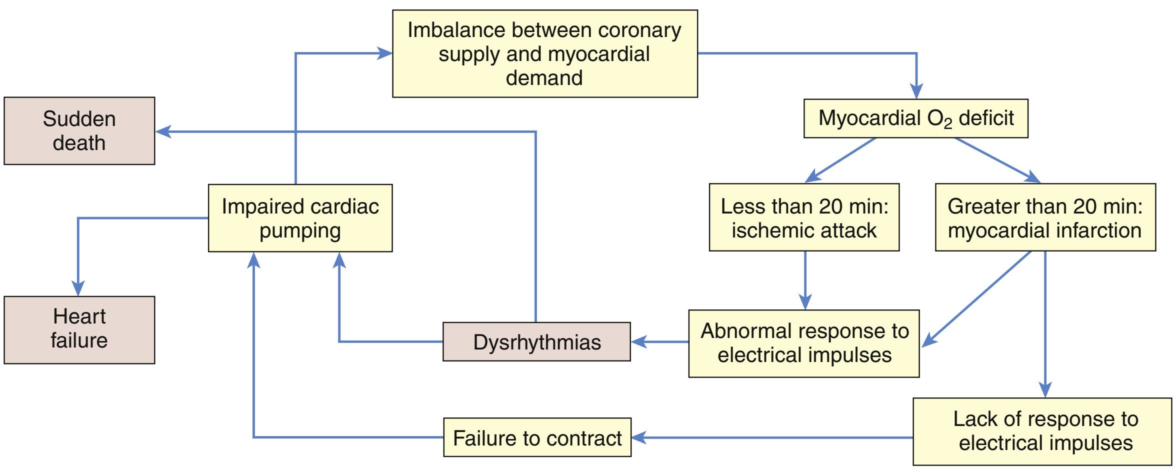

FIGURE 32-15 Cycle of Ischemic Events.

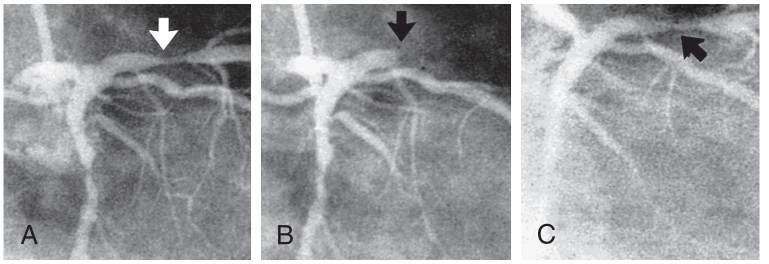

FIGURE 32-16 Angiogram. **A,** Baseline (*arrow* points to narrowing). **B,** Transient total occlusion of left anterior descending branch of the left coronary artery after mental stress *(arrow)*. **C,** After administration of nitrates and nifedipine, artery reopened to same diameter as baseline *(arrow)*. (From Stern S, editor: *Silent myocardial ischemia,* St Louis, 1998, Mosby.)

obstruction usually results in recurrent predictable chest pain called **stable angina.** Abnormal vasospasm of coronary vessels results in unpredictable chest pain called **Prinzmetal angina.** Myocardial ischemia that does not cause detectable symptoms is called **silent ischemia.**

Stable Angina. Angina pectoris is chest pain caused by myocardial ischemia. Stable angina is caused by gradual luminal narrowing and hardening of the arterial walls, so that affected vessels cannot dilate in response to increased myocardial demand associated with physical exertion or emotional stress. If demand is decreased, no necrosis of myocardial cells results. **Angina pectoris** is typically experienced as transient substernal chest discomfort, ranging from a sensation of heaviness or pressure to moderately severe pain. Individuals often describe the sensation by clenching a fist over the left sternal border. The discomfort may be mistaken for indigestion. The pain is caused by the buildup of lactic acid or abnormal stretching of the ischemic myocardium that irritates myocardial nerve fibers. These afferent sympathetic fibers enter the spinal cord from levels C3 to T4, accounting for the variety of locations and radiation patterns of anginal pain. Pain may radiate to the neck, lower jaw, left arm, and left shoulder or occasionally to the back or down the right arm. Pallor, diaphoresis, and dyspnea may be associated with the pain. The pain is usually relieved by rest and nitrates; lack of relief indicates an individual may be developing infarction.

Myocardial ischemia in women may not present with typical anginal pain. Common symptoms in women include atypical chest pain, palpitations, sense of unease, and severe fatigue. Similarly, in individuals who have autonomic nervous system dysfunction, such as older adults or those with diabetes, angina may be mild, atypical, or even silent (see following).

Prinzmetal Angina. Prinzmetal angina (also called variant angina) is chest pain attributable to transient ischemia of the myocardium that occurs unpredictably and almost exclusively at rest. Pain is caused by vasospasm of one or more major coronary arteries with or without associated atherosclerosis. The angina may result from decreased vagal activity, hyperactivity of the sympathetic nervous system, and decreased nitric oxide activity. Other causes include altered calcium channel function in arterial smooth muscle and endothelial dysfunction with release of inflammatory mediators, such as serotonin, histamine, endothelin, or thromboxane. Serum markers of inflammation, such as CRP and IL-6, may be elevated in individuals with this form of angina. The pain often occurs at night during rapid eye movement sleep and may have a cyclic pattern of occurrence. If the spasm persists long enough, infarction or serious dysrhythmias may occur. However, most individuals are successfully treated with vasodilators and overall prognosis is good.[122]

Silent Ischemia and Mental Stress (Induced Ischemia). Myocardial ischemia does not always cause angina and may be associated only with nonspecific symptoms such as fatigue, dyspnea, or feeling of unease. Some individuals only have silent ischemia, whereas episodes of silent myocardial ischemia may occur in individuals who also experience angina. Silent ischemia and atypical symptoms are more common in women, although the pathophysiologic mechanisms are poorly understood.[123] Global or regional abnormalities in left ventricular sympathetic afferent innervation have been implicated in autonomic dysfunction in diabetes mellitus, following surgical denervation during coronary artery bypass grafting (CABG) or cardiac transplantation, or following ischemic local nerve injury by MI.[124] Silent ischemia also may occur in some individuals during mental stress (Figures 32-16 and 32-17). Mental stress has been linked to increased markers of inflammation, such as CRP, decreased activity of vasodilators, such as nitric oxide, and a hypercoagulable state that may contribute to acute ischemic events.[125] Although stress management has been associated with a reduction in CAD events in men, further research into the brain-heart pathways is under way to better elucidate appropriate interventions.

Screening for silent ischemia is based on the presence of risk factors and is most often detected using stress radionucleotide imaging. Detection of silent ischemia is important because it is an indicator of increased risk for serious cardiovascular disease (CVD) events, and aggressive treatment may be indicated.[124]

EVALUATION AND TREATMENT. Many individuals with reversible myocardial ischemia exhibit a normal physical examination between episodes. Physical examination of an individual experiencing myocardial ischemia may disclose tachycardia, extra heart sounds (gallops or murmurs), and pulmonary congestion indicating impaired left ventricular function. The presence of **xanthelasmas** (small fat deposits) around the eyelids or **arcus senilis** of the eyes (a yellow lipid ring around the cornea) suggests dyslipidemia and possible atherosclerosis. The presence of peripheral or carotid arterial bruits suggests probable atherosclerotic disease and increases the likelihood that CAD is present.

Electrocardiography is a critical tool for diagnosing myocardial ischemia. Because many individuals have normal ECGs

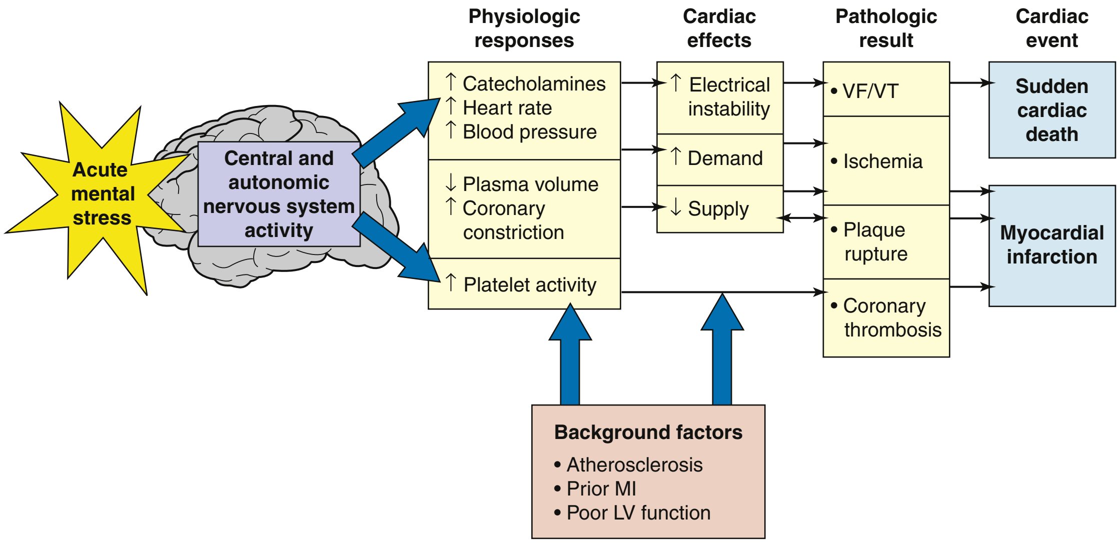

FIGURE 32-17 **Pathophysiologic Model of Acute Stress Effects Triggering Cardiac Clinical Events.** Acting via the central and autonomic nervous systems, stress can produce a cascade of physiologic responses that may lead to myocardial ischemia, potentially fatal dysrhythmia, plaque rupture, or coronary thrombosis. *LV,* Left ventricular; *MI,* myocardial infarction; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia. (From Kranz DS et al: Mental stress as a trigger of myocardial ischemia and infarction. In Deedwania PC, Tofler GH, editors: *Triggers and timing of cardiac events,* ed 2, London, 1996, Saunders.)

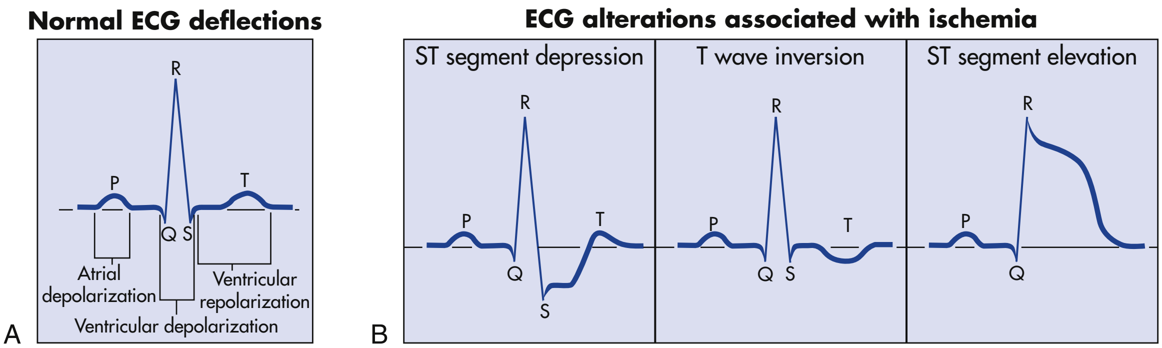

FIGURE 32-18 **Electrocardiogram (ECG) and Ischemia. A,** Normal ECG. **B,** Electrocardiographic alterations associated with ischemia.

in the absence of pain, diagnosis may require that electrocardiography be performed during an attack of angina. Transient ST-segment depression and T-wave inversion are characteristic signs of subendocardial ischemia frequently seen in angina. ST elevation, indicative of transmural ischemia, can be seen in individuals with Prinzmetal angina but is more common in infarction (Figure 32-18). The ECG also can give some indication of which coronary artery is involved. Approximately 30% of individuals with angina have nondiagnostic ECG tracings and require other diagnostic studies.

Stress radionucleotide imaging is indicated to detect ischemic changes in asymptomatic individuals with multiple risk factors for coronary disease, such as diabetes and dyslipidemia, and for older individuals who plan to start vigorous exercise. Stress testing is made more sensitive when radioisotope imaging is added to the ECG as an indicator of myocardial ischemia. Currently, the modality of choice for the diagnosis of myocardial ischemia is single-photon emission computed tomography (SPECT), which is effective at identifying ischemia and estimating risk for coronary events. Radioisotope imaging with thallium-201 and stress echocardiography also are used. Unfortunately, although all of these tests are helpful in documenting coronary obstruction, they cannot detect the presence of unstable plaques, which are the cause of the majority of acute coronary syndromes.

Imaging the coronary arteries for the evaluation of atherosclerotic plaques involves the use of CT with and without angiography, MRI, or intravascular ultrasound. Coronary angiography is useful in determining the anatomic extent of CAD. The procedure is expensive and carries some risk; thus it is used primarily to evaluate for possible percutaneous coronary intervention (PCI) or CABG surgery for individuals whose noninvasive studies suggest severe disease.

The primary aim of therapy for myocardial ischemia and angina is to increase delivery of oxygen by improving coronary artery blood flow and to reduce myocardial oxygen consumption. Recommendations for appropriate diet, exercise, and risk reduction strategies have been widely distributed. Coronary blood flow is improved by reversing vasoconstriction, preventing clotting, and reducing plaque growth and rupture. Myocardial oxygen consumption is reduced by manipulation

of blood pressure, heart rate, contractility, and left ventricular volume. Many different classes of drugs are available to manage stable angina, including nitrates, β-adrenergic receptor blockers, and calcium channel blockers. Therapy should be individualized.[126,127]

Nitrates improve coronary blood flow and reduce myocardial demand by decreasing peripheral vascular resistance and venous return to the heart (preload) and thereby reduce cardiac workload. Nitrates can be used for short-term symptom relief, and long acting nitrates are available in several forms.[126]

β-Adrenergic receptor blockers are first-line therapy to reduce the myocardial oxygen requirements that occur with physical exertion. Beta-blockers diminish catecholamine-induced elevations of heart rate, myocardial contractility, and blood pressure. Reduction in heart rate provides additional diastolic filling time for coronary perfusion, leading to enhanced oxygen delivery to the heart.

Calcium channel blockers decrease the influx of calcium into myocardial cells and vascular smooth muscle cells. They also modify the pacemaker activity of the sinoatrial (SA) node and conduction properties of the atrioventricular (AV) node so that myocardial oxygen demand is reduced. However, short-acting formulations should be used with caution because of potentially harmful effects on cardiac contractility and heart rate.[126]

Combinations of nitrates, beta-blockers, and calcium antagonists may provide dramatic relief from clinical manifestations of ischemic heart disease, which improves quality of life and may make more invasive interventions unnecessary. However, they do not reverse the atherosclerotic process; thus the individual remains at risk for persistent or worsening CAD. Antianginal medications have not been shown to prolong life or prevent MI in individuals with stable angina. Medications aimed at plaque stabilization, regression, and prevention of clotting also are indicated in the majority of individuals. These include statins, ACE inhibitors or receptor blockers, and antithrombotics.[126]

Coronary revascularization is indicated for those individuals who do not respond adequately to antianginal drugs or who have high-risk atherosclerotic lesions. **Percutaneous coronary intervention (PCI)** is a procedure whereby stenotic (narrowed) coronary vessels are dilated with a catheter. Several different types of catheters can be used to open the blocked vessel. PCI is most often used to treat single-vessel disease, but it can be effective with multiple-vessel disease or restenosis of a coronary artery bypass graft in selected individuals. Restenosis of the artery is the major complication of the procedure; however, placement of a coronary stent can reduce this risk (see What's New? Medical Devices—Are They Safe and Effective?) Antithrombotic treatment such as aspirin, clopidogrel, or glycoprotein IIb/IIIa receptor antagonists after stenting also can improve outcomes.[128]

Severe CAD can be surgically treated by CABG, usually using the saphenous vein from the lower leg. In selected individuals, a modified CABG procedure called minimally invasive direct coronary artery bypass (MIDCAB) can be used with much less surgical morbidity and more rapid recovery. Investigational therapies for refractory angina that stimulate angiogenesis include transmyocardial laser revascularization (TMR), gene therapy for myocardial angiogenesis, spinal cord stimulation, laser revascularization, and percutaneous in situ coronary venous arterialization. New drugs being evaluated in the medical management of myocardial ischemic syndromes include ranolazine, trimetazidine, nicorandil, and ivabradine.[126]

WHAT'S NEW?

Medical Devices—Are They Safe and Effective?

There have been many medical technology advances for individuals with cardiovascular problems, such as stents, defibrillators, and mechanical heart valves. Although many of these treatments are lifesaving, many of these cardiovascular medical devices are approved for use before they are adequately tested. Although the same is true for numerous new drugs, because these devices require invasive procedures or because once they are implanted they are necessary to sustain life, they are considered high risk. Between January 1, 2000, and December 31, 2011, only 48% of devices were tested using an active control group prior to approval by the U.S. Food and Drug Administration (FDA) and 35% were approved without any control group at all. Thus about half of high-risk cardiac devices were approved without determining if they provide better outcomes than other treatments. As more devices are approved, concern is increasing about the relative risks and benefits of these interventions.

Data from Chen CE, Dhruva SS, Redberg RF: *JAMA* 308(17):1740–1742, 2012; Goldberg NH et al: *JAMA* 305(17):1786–1789, 2011.

Acute Coronary Syndromes

The process of atherosclerotic plaque progression can be gradual. However, when there is sudden coronary obstruction caused by thrombus formation over a ruptured or ulcerated atherosclerotic plaque, acute coronary syndromes result (Figure 32-19). **Unstable angina** is the result of reversible myocardial ischemia and is a harbinger of impending infarction. **Myocardial infarction (MI)** results when prolonged ischemia causes irreversible damage to the heart muscle. MI can be further subdivided into **non–ST-elevation MI (non-STEMI)** and **ST-elevation MI (STEMI).** Sudden cardiac death can occur as a result of any of the acute coronary syndromes.

An atherosclerotic plaque that is prone to rupture is called "unstable" and has a core that is especially rich in deposited oxidized LDL and a thin fibrous cap (Figure 32-20). These unstable plaques may not extend into the lumen of the vessel and may be clinically silent until they rupture. Plaque disruption (ulceration or rupture) occurs because of shear forces, inflammation with release of multiple inflammatory mediators, secretion of macrophage-derived degradative enzymes, and apoptosis of cells at the edges of the lesions. Exposure of the plaque substrate activates the clotting cascade. In addition, platelet activation results in the release of coagulants and exposure of platelet glycoprotein IIb/IIIa surface receptors, resulting in further platelet aggregation and adherence. The resulting thrombus can form very quickly (Figure 32-21, *A*). Vessel obstruction is further exacerbated by the release of vasoconstrictors, such as thromboxane A2 and endothelin. The thrombus may break up before permanent myocyte damage has occurred (unstable angina) or it may cause prolonged ischemia with infarction of the heart

muscle (myocardial infarction) (see Figure 32-21, *B*). Diagnostic tests aimed at identifying unstable plaques before they rupture include intravascular ultrasound or MRI, angioscopy, and spectroscopy. Medications such as statins, ACE inhibitors, and beta-blockers can help stabilize plaques and prevent rupture.

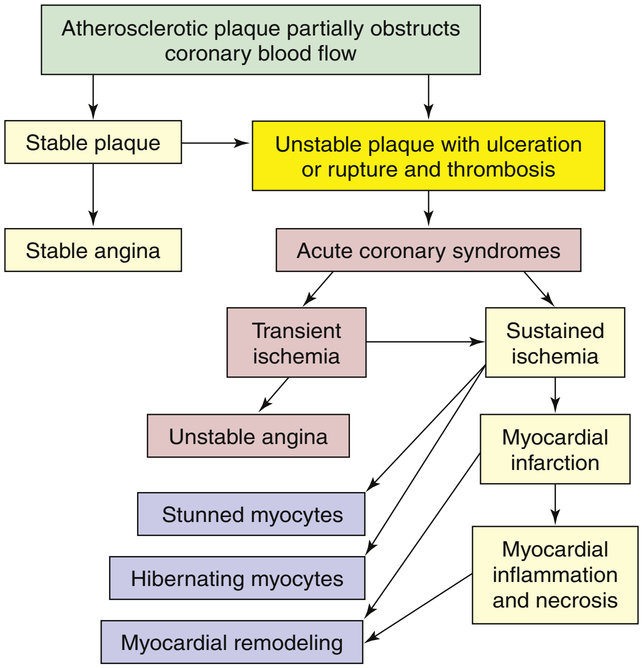

FIGURE 32-19 Pathophysiology of Acute Coronary Syndromes. The atherosclerotic process can lead to stable plaque formation and stable angina or can result in unstable plaques that are prone to rupture and thrombosis. Thrombus formation on a ruptured plaque that disperses in less than 20 minutes leads to transient ischemia and unstable angina. If the vessel obstruction is sustained, myocardial infarction with inflammation and necrosis of the myocardium result. In addition, myocardial infarction is associated with other structural and functional changes, including myocyte stunning and hibernation and myocardial remodeling.

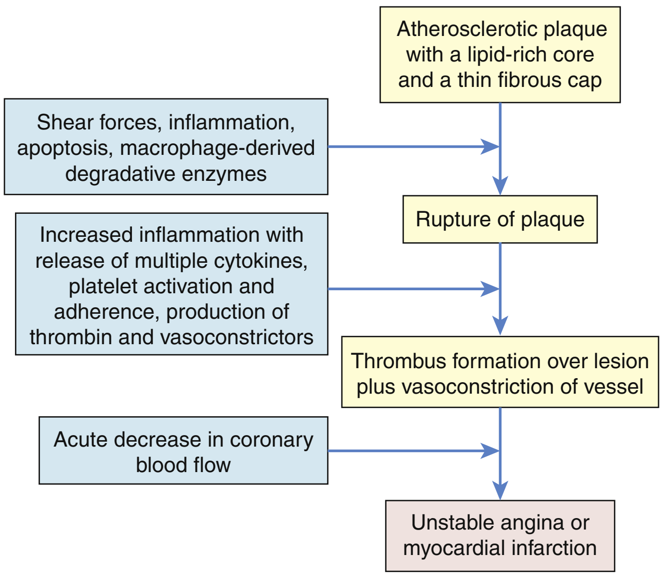

FIGURE 32-20 Pathogenesis of Unstable Plaques and Thrombus Formation.

Unstable Angina. Unstable angina is a form of acute coronary syndrome that results in reversible myocardial ischemia. It is important to recognize this syndrome because it signals that the atherosclerotic plaque has ruptured, and infarction may soon follow.

PATHOPHYSIOLOGY. Unstable angina occurs when fissuring or superficial erosion of the plaque leads to transient episodes of thrombotic vessel occlusion and vasoconstriction at the site of plaque damage. This thrombus is labile and occludes the vessel for no more than 10 to 20 minutes, with return of perfusion before significant myocardial necrosis occurs.

CLINICAL MANIFESTATIONS. Unstable angina presents as new-onset angina, angina that is occurring at rest, or angina that is increasing in severity or frequency (Box 32-1). Individuals may experience increased dyspnea, diaphoresis, and anxiety as the angina worsens.

EVALUATION AND MANAGEMENT. Physical examination may reveal evidence of ischemic myocardial dysfunction such as tachycardia or pulmonary congestion. The ECG most commonly reveals ST-segment depression and T-wave inversion during pain that resolves as the pain is relieved. The serum cardiac biomarkers (troponins, creatine phosphokinase-myocardial bound [CPK-MB] and lactate dehydrogenase [LDH1]) remain normal. Approximately 20% of people with unstable angina progress within hours to days to MI or death. Management of unstable angina requires immediate hospitalization with administration of oxygen, aspirin (if not contraindicated), nitrates, and morphine if pain is still present. Additional antithrombotic therapy with clopidogrel or IIb/IIIa platelet receptor antagonists may be indicated. Beta-blockers and ACE inhibitors also may be used. Anticoagulants, such as low-molecular-weight heparin, or direct thrombin inhibitors (e.g., fondaparinux) also can be given. Individuals with refractory angina and those with electrical or hemodynamic instability require immediate intervention with PCI or CABG.[129,130]

Myocardial Infarction. When coronary blood flow is interrupted for an extended period, myocyte necrosis occurs. This results in MI. In the majority of cases of MI, the decrease in coronary flow is the result of atherosclerotic CAD; other causes include coronary spasm and coronary artery embolism. Pathologically there are two major types of MI: subendocardial infarction and transmural infarction. Clinically, however, MI is categorized as non-STEMI or STEMI.

PATHOPHYSIOLOGY. Plaque progression, disruption, and subsequent clot formation is the same for myocardial infarction as it is for unstable angina (see Figures 32-19, 32-20, and 32-21). In this case, however, the thrombus is less labile and occludes the vessel for a prolonged period, such that myocardial ischemia progresses to myocyte necrosis and death. The duration of ischemia determines the size and character of the infarction.[131] If the thrombus breaks up before complete distal tissue necrosis has occurred, the infarction will involve only the myocardium directly beneath the endocardium (subendocardial MI). This infarction usually presents with ST depression and T-wave inversion and is termed non-STEMI. It is especially important to recognize this form of acute coronary syndrome because recurrent clot formation on the disrupted atherosclerotic

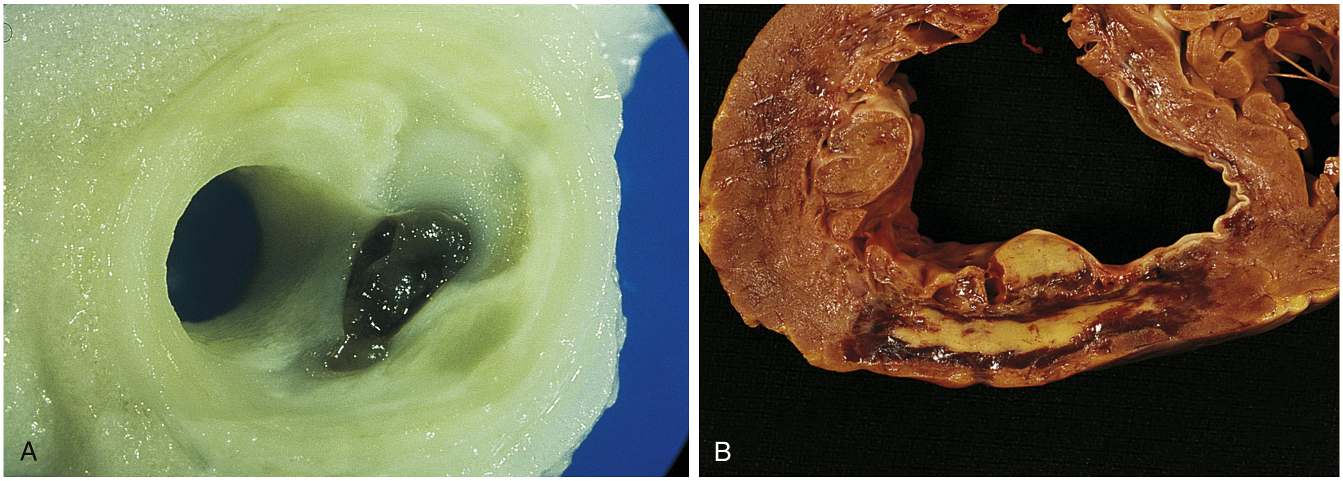

FIGURE 32-21 Plaque Disruption and Myocardial Infarction. **A,** Plaque disruption. The cap of the lipid-rich plaque has become torn with the formation of a thrombus, mostly inside the plaque. **B,** Myocardial infarction. This infarct is 6 days old. The center is yellow and necrotic with a hemorrhagic red rim. The responsible coronary artery occlusion is probably in the right coronary artery. The infarct is on the posterior wall. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

BOX 32-1 THREE PRINCIPAL PRESENTATIONS OF UNSTABLE ANGINA

Rest angina*—angina occurring at rest and prolonged, usually >20 minutes

New-onset angina—new-onset angina of at least Canadian Cardiovascular Society (CCS) class III severity

Increasing angina—previously diagnosed angina that has become distinctly more frequent, longer in duration, or lower in threshold (i.e., increased by ≥1 CCS class to at least CCS class III severity)

From Anderson J et al: *J Am Coll Cardiol* 50:e1–e157, 2007. Originally adapted from Braunwald E: *Circulation* 80:410–414, 1989.

*Individuals with non–ST-elevation myocardial infarction (non-STEMI) usually present with angina at rest.

plaque is likely to occur unless some intervention is undertaken as soon as possible. If the thrombus lodges permanently in the vessel, the infarction will extend through the myocardium all the way from endocardium to epicardium (transmural MI), resulting in severe cardiac dysfunction. Transmural infarction usually causes marked elevations in the ST segments on ECG. Individuals with elevations are categorized as having STEMI. Clinically it is important to identify those with STEMI because they are at highest risk for serious complications and require immediate intervention.

Cellular Injury. Cardiac cells can withstand ischemic conditions for about 20 minutes before cellular death takes place. After only 30 to 60 seconds of hypoxia, ECG changes are visible. Yet even if cells are metabolically altered and nonfunctional, they can remain viable if blood flow returns within 20 minutes. Reports suggest previous recurrent episodes of myocardial ischemia can result in myocyte adaptation to oxygen deprivation and preservation of myocardium. This process, termed **ischemic preconditioning,** is being studied to determine whether it has potential prophylactic or therapeutic uses.[132]

After 8 to 10 seconds of decreased blood flow, the affected myocardium becomes cyanotic and cooler. Myocardial oxygen reserves are used very quickly (within about 8 seconds) after complete cessation of coronary flow. Glycogen stores decrease as anaerobic metabolism begins. Unfortunately, glycolysis can supply only 65% to 70% of the total myocardial energy requirement and produces much less ATP than aerobic processes. Hydrogen ions and lactic acid accumulate. Because myocardial tissues have poor buffering capabilities and myocardial cells are very sensitive to low cellular pH, accumulation of these products further compromises the myocardium. Acidosis may make the myocardium more vulnerable to the damaging effects of lysosomal enzymes and may suppress impulse conduction and contractile function, thereby leading to heart failure.

Oxygen deprivation also is accompanied by electrolyte disturbances, specifically, loss of potassium, calcium, and magnesium from cells. Myocardial cells deprived of necessary oxygen and nutrients lose contractility, thereby diminishing the heart's pumping ability. Ischemic myocardial cells release catecholamines (epinephrine and norepinephrine), predisposing the individual to serious imbalances of sympathetic and parasympathetic function, irregular heartbeats (dysrhythmia), and heart failure. Catecholamines mediate the release of glycogen, glucose, and stored fat from body cells. Therefore, plasma concentrations of free fatty acids and glycerol rise within 1 hour after onset of acute MI. Excessive levels of free fatty acids can have a harmful detergent effect on cell membranes. Norepinephrine elevates blood sugar levels through stimulation of liver and skeletal muscle cells. It also suppresses pancreatic B-cell activity, which reduces insulin secretion and elevates blood glucose further. Hyperglycemia is noted approximately 72 hours after an acute MI and is associated with an increased risk of death; therefore, careful glucose monitoring and control after MI is essential.

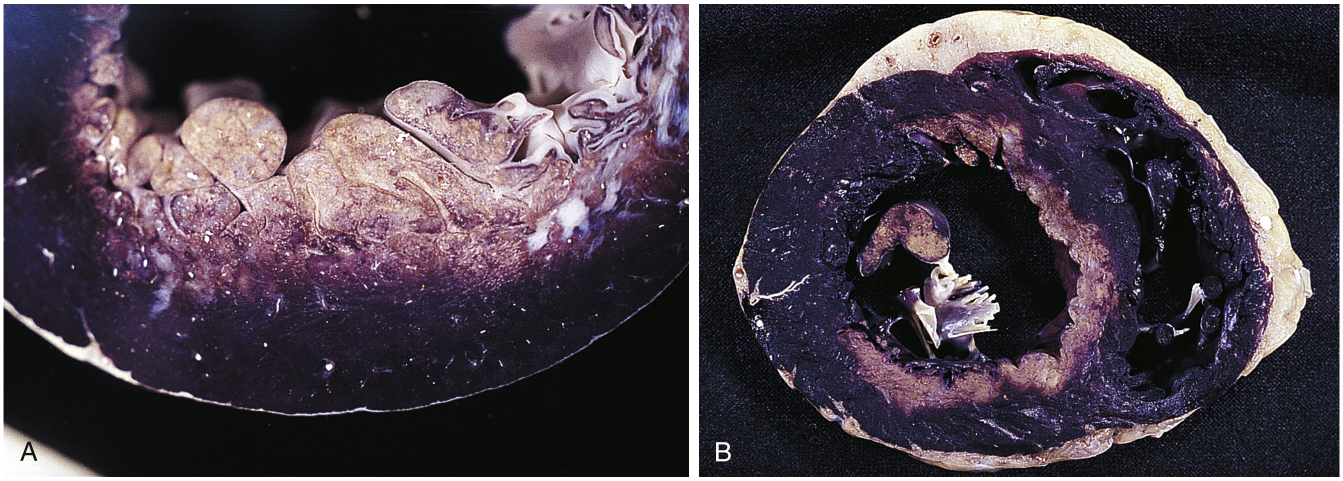

FIGURE 32-22 Myocardial Infarction. **A,** Local infarct confined to one region. **B,** Massive large infarct caused by occlusion of three coronary arteries. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

TABLE 32-7 **TISSUE CHANGES AFTER MYOCARDIAL INFARCTION**

TIME AFTER MYOCARDIAL INFARCTION	TISSUE CHANGES	STAGE OF HEALING PROCESS
6-12 hours	No gross changes; subcellular cyanosis with decreased temperature	Not begun
18-24 hours	Pale to gray-brown; slight pallor	Inflammatory response; intercellular enzyme release
2-4 days	Visible necrosis: yellow-brown in center and hyperemic around edges	Proteolytic enzymes remove debris; catecholamines, lipolysis, and glycogenolysis elevate plasma glucose and increase free fatty acids to assist depleted myocardium recovery from anaerobic state
4-10 days	Area soft, with fatty changes in center, regions of hemorrhage in infarcted area	Debris cleared; collagen matrix laid down
10-14 days	Weak, fibrotic scar tissue with beginning revascularization	Healing continues but area very mushy, vulnerable to stress
6 weeks	Scarring usually complete	Tough inelastic scar replaces necrotic myocardium

Note: Processes of tissue healing are described and illustrated in Chapter 7.

Ischemic injury can be exacerbated by what is termed **reperfusion injury** once blood flow is restored. This process involves the release of toxic oxygen radicals, calcium flux, and pH changes that cause a sustained opening of mitochondrial permeability transition pores (mPTP) and contribute to resultant cellular death. Therapies aimed at reducing reperfusion injury are being explored, including endovascular cooling, adenosine, atrial natriuretic peptide, cyclosporine, nicorandil, and incretins.[131,132]

Angiotensin II is released during myocardial ischemia and contributes to the pathogenesis of MI in several ways. First, it results in the systemic effects of peripheral vasoconstriction and fluid retention. These homeostatic responses are counterproductive in that they increase myocardial work and thus exacerbate the effects of the loss of myocyte contractility. Angiotensin II is also released locally, where it is a growth factor for vascular smooth muscle cells, myocytes, and cardiac fibroblasts; promotes catecholamine release; and causes coronary artery spasm.

Cellular Death. After about 20 minutes of myocardial ischemia, irreversible hypoxic injury causes cellular death and tissue necrosis. (Types of necrosis are described in Chapter 2.) Necrosis of myocardial tissue results in the release of certain intracellular enzymes through the damaged cell membranes into the interstitial spaces. The lymphatics pick up the enzymes and transport them into the bloodstream, where they can be detected by serologic tests. Recent evidence has found that along with necrosis myocardial tissue also is destroyed by the tightly controlled process of apoptosis. An increased understanding of the steps of the apoptotic pathway of MI may lead to new therapies aimed at limiting infarct size.[133]

Structural and Functional Changes. MI results in structural and functional changes of cardiac tissues (Figure 32-22). Table 32-7 outlines the tissue changes that may follow MI. Gross tissue changes in the area of infarction may not become apparent for several hours, despite almost immediate onset (within 30 to 60 seconds) of ECG changes. The infarcted myocardium is surrounded by a zone of hypoxic injury, which may progress to necrosis, undergo remodeling, or return to normal.

Cardiac tissue surrounding the area of infarction also undergoes pathophysiologic changes. **Myocardial stunning,**

a temporary loss of contractile function that persists for hours to days after perfusion, has been restored. This pathophysiologic state can occur both with MI and in individuals who suffer ischemia during cardiovascular procedures such as cardiac surgery. Stunning is caused by the alterations in electrolyte pumps, calcium homeostasis, and the release of toxic oxygen radicals. It is characterized by decreased contraction and conduction and can contribute to heart failure, shock, and dysrhythmias. Stunning is less severe in individuals who have experienced ischemic preconditioning. New therapies are being explored that can simulate ischemic preconditioning prior to cardiovascular procedures, or that can be used after ischemic events to reduce the effects of stunning (post-conditioning).[131,134]

Hibernating myocardium refers to tissue that is persistently ischemic and undergoes metabolic adaptation to prolong myocyte survival until perfusion can be restored. Restoring adequate perfusion to the myocardium with revascularization therapies can improve myocardial function.[135]

Myocardial remodeling is a process mediated by angiotensin II, aldosterone, catecholamines, adenosine, oxidative stress, and inflammatory cytokines, which causes myocyte hypertrophy, scarring, and loss of contractile function in the areas of the heart distant from the site of infarction.[136] These changes can be limited and even reversed (reverse remodeling) through rapid restoration of coronary flow and the use of ACE inhibitors, beta-blockers, statins, sequential pacemakers, and ventricular assist devices after MI.[137]

Repair. MI causes a severe inflammatory response that ends with wound repair (see Chapter 7). Repair consists of degradation of damaged cells, proliferation of fibroblasts, and synthesis of scar tissue. Many cell types, hormones, and nutrient substrates must be available for optimal healing to proceed. Within 24 hours, leukocytes infiltrate the necrotic area and proteolytic enzymes from scavenger neutrophils degrade necrotic tissue. A collagen matrix is deposited and is initially weak, mushy, and vulnerable to reinjury. Unfortunately it is at this time in the recovery period (10 to 14 days after infarction) that individuals feel more capable of increasing activities and thus may stress the newly formed scar tissue. After 6 weeks the necrotic area is completely replaced by scar tissue, which is strong but unable to contract and relax like healthy myocardial tissue.

CLINICAL MANIFESTATIONS. The first symptom of acute MI is usually sudden, severe chest pain. It is not possible to distinguish between angina and MI by symptoms alone, although the pain associated with MI tends to be more severe and prolonged. It may be described as heavy and crushing, such as an "elephant sitting on my chest." Radiation to the neck, jaw, back, shoulder, or left arm is common. Some individuals (especially older adults or those with diabetes) experience no pain, thereby having a "silent" infarction. Infarction often simulates a sensation of unrelenting indigestion. Nausea and vomiting may occur because of reflex stimulation of vomiting centers by pain fibers. Vasovagal reflexes from the area of the infarcted myocardium also may affect the gastrointestinal tract. Various cardiovascular changes are found on physical examination:

1. The SNS is reflexively activated to compensate, resulting in a temporary increase in heart rate and blood pressure, although severe myocardial damage may cause hypotension despite elevated catecholamine activity.
2. Abnormal extra heart sounds reflect left ventricular dysfunction.
3. Cardiac murmurs may indicate acute valvular insufficiency.
4. Pulmonary findings of congestion including dullness to percussion and inspiratory crackles at the lung bases can occur if the individual develops heart failure.
5. Peripheral vasoconstriction may cause the skin to become cool and clammy.

EVALUATION AND TREATMENT. The diagnosis of acute MI is made on the basis of history, physical examination, ECG, and serial cardiac biomarker alterations (Box 32-2). It is important to note that nearly half of MIs are not preceded by any previous angina symptoms and up to one-third present with STEMI as the first symptomatic manifestation of coronary disease.[5] MI can occur

BOX 32-2 UNIVERSAL DEFINITION OF MYOCARDIAL INFARCTION

The term *myocardial infarction* should be used when there is evidence of myocardial necrosis in a clinical setting with myocardial ischemia. Under these conditions any one of the following criteria meets the diagnosis for myocardial infarction:

- Detection of rise and/or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the upper reference limit (URL) together with evidence of myocardial ischemia with at least one of the following:
- Symptoms of ischemia
- Electrocardiographic changes indicative of new ischemia (new ST-T changes or new left bundle branch block ([LBBB])
- Development of pathologic Q waves in the electrocardiogram
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
- Sudden, unexpected cardiac death, involving cardiac arrest, often with symptoms suggestive of myocardial ischemia, and accompanied by presumably new ST elevation, or new LBBB, and/or evidence of fresh thrombus by coronary angiography and/or at autopsy; but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood.
- For percutaneous coronary interventions (PCIs) in patients with normal baseline troponin values, elevations of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than 3 × 99th percentile URL have been designated as defining PCI-related myocardial infarction. A subtype related to a documented stent thrombosis is recognized.
- For coronary artery bypass grafting (CABG) in patients with normal baseline troponin values, elevations of cardiac biomarkers above the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than 5 × 99th percentile URL plus either new pathologic Q waves or new LBBB, or angiographically documented new graft or native coronary artery occlusion, or imaging evidence of new loss of viable myocardium have been designated as defining CABG-related myocardial infarction.
- Pathologic findings of an acute myocardial infarction

Data from Thygesen K, Alpert J, White H: *J Am Coll Cardiol* 50:2173–2195, 2007.

in various regions of the heart wall and may be described as anterior, inferior, posterior, lateral, subendocardial, or transmural depending on its location and extent of tissue damage from infarction. Twelve-lead ECGs help localize the affected area through identification of changes in ST segments and T waves (Figure 32-23). The infarcted myocardium is surrounded by a zone of hypoxic injury, which may progress to necrosis or return to normal, and adjacent to this zone of hypoxic injury is a zone of reversible ischemia (Figure 32-24). In STEMI, a characteristic Q wave often develops on ECG some hours later.

Cardiac troponin I (cTnI) is the most specific indicator of MI and should be obtained on admission to the emergency department. cTnI elevation is detectable 2 to 4 hours after onset of symptoms. Additional measurements within 6 to 9 hours and again at 12 to 24 hours are recommended if clinical suspicion is high and previous samples were negative. cTnI has a sensitivity of more than 95% and a negative predictive value of 99% for the diagnosis of acute MI.[138] Troponin levels also can be used to estimate infarct size and therefore the likelihood of complications.[139] Other biomarkers released by myocardial cells include CPK-MB and LDH. These isoenzymes exist in several different active molecular forms called isoenzymes and are present in different amounts within particular tissues. Blood is drawn for troponin and isoenzyme determinations as soon as possible after the onset of symptoms; serial serum levels of these biomarkers are assessed for several days.

Additional laboratory data may reveal leukocytosis and elevated CRP, both of which indicate inflammation. The individual's blood sugar is usually elevated and the glucose tolerance level may remain abnormal for several weeks. Hypoxemia may accompany heart failure.

Acute MI requires admission to the hospital. The individual should be placed on supplemental oxygen and given an aspirin immediately (clopidogrel or prasugrel if intolerant to aspirin). Pain is treated with morphine sulfate. Continuous monitoring of cardiac rhythms and biomarker changes is essential because the first 24 hours after onset of symptoms is the time of highest risk for sudden death. Non-STEMI is treated in the same way as unstable angina including antithrombotics, anticoagulation

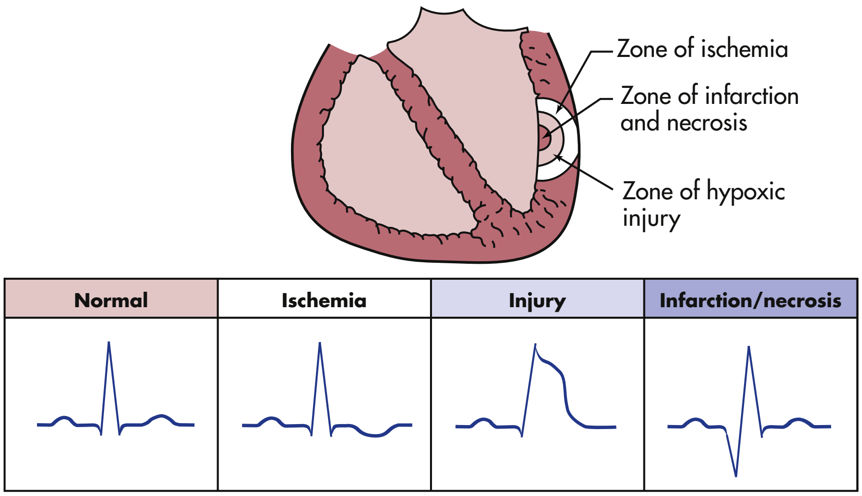

FIGURE 32-24 Electrocardiographic Alterations Associated with the Three Zones of Myocardial Infarction.

or PCI, or both.[130] STEMI is best managed with emergent PCI and antithrombotics.[139a] Thrombolytics may be used if PCI is not readily available. Hyperglycemia is treated with insulin.[140] Once the person is stabilized, further management includes ACE inhibitors, beta-blockers, and statins.[138,141,142] Individuals who are in shock require aggressive fluid resuscitation, inotropic drugs, and possible emergent invasive procedures.[143]

Bed rest, followed by gradual return to activities of daily living, reduces the myocardial oxygen demands of the compromised heart. Individuals not receiving thrombolytic or heparin infusion must receive DVT prophylaxis as long as their activity is significantly limited. Stool softeners are given to eliminate the need for straining, which can precipitate bradycardia and can be followed by increased venous return to the heart, causing possible cardiac overload. Education on diet, caffeine, smoking cessation, exercise, and other aspects of risk factor reduction is crucial for secondary prevention of recurrent myocardial ischemia.

Approximately 1% to 2% of people initially diagnosed with STEMI do not have myocardial infarction, but rather have a stress-induced syndrome known as the *broken heart syndrome* or *Takotsubo cardiomyopathy*. These individuals present with the acute onset of chest pain, ST elevation, elevated troponins, and BNP after emotional stress, but generally do not have coronary artery disease and must be managed differently[144] (see What's New? The Broken Heart Syndrome).

COMPLICATIONS. The number and severity of postinfarction complications depend on the location and extent of necrosis, the individual's physiologic condition before the infarction, and the availability of swift therapeutic intervention.

Dysrhythmias (arrhythmias), which are disturbances of cardiac rhythm, are the most common complication of acute MI. Dysrhythmias can be caused by ischemia, hypoxia, autonomic nervous system (ANS) imbalances, lactic acidosis, electrolyte abnormalities, alterations of impulse conduction pathways or conduction defects, drug toxicity, or hemodynamic abnormalities. Dysrhythmias may originate from the atria, ventricles, nodal regions, or conduction tissues. The seriousness of dysrhythmias depends on the hemodynamic consequences. (Dysrhythmias are described in Table 32-12.) Prophylactic use of antiarrhythmics, such as lidocaine and amiodarone, do not improve mortality; however, individuals at high risk should be considered for implantable cardioverter-defibrillators (ICDs).

Acute MI is accompanied by functional impairment of the myocardium. The severity of functional impairment depends on the size and the site of infarction. Functional changes can include: (1) decreased cardiac contractility with abnormal wall motion, (2) altered left ventricular compliance, (3) decreased stroke volume, (4) decreased ejection fraction, (5) increased left ventricular end-diastolic pressure (LVEDP), and (6) SA or AV node malfunction. Many infarctions result in some degree of left ventricular failure (congestive heart failure), which is characterized by pulmonary congestion, reduced myocardial contractility, and abnormal heart wall motion. Anterior infarction is associated with more severe left heart failure than is inferior infarction. If cardiac output is insufficient to maintain normal arterial pressure and to perfuse the kidneys and other organs adequately, **cardiogenic shock** develops.[143] (Cardiogenic shock is discussed in Chapter 48.)

Inflammation of the pericardium (**pericarditis**) is a common complication of acute MI. Pericardial friction rubs often are noted 2 to 3 days after MI and are associated with anterior chest pain that worsens with respiratory effort. Specific treatment is not required; however, corticosteroids dramatically relieve symptoms. **Dressler postinfarction syndrome,** which is a delayed form of acute pericarditis, can occur from 1 week to several months after acute MI. Although poorly understood, the syndrome is thought to be an immunologic (antigen-antibody) response to the necrotic myocardium. Pain, fever, friction rub, pleural effusion, and arthralgias may accompany this syndrome. Steroids may alleviate symptoms.

WHAT'S NEW?

The Broken Heart Syndrome

Episodes of extreme mental stress, like the loss of a loved one, have been linked to sudden onset of myocardial ischemia, arrhythmias, heart failure, shock, and even death. This has been called the "broken heart syndrome." This phenomenon, now called Takotsubo cardiomyopathy, was first described in Japan in 1991, where it was found to occur most often in postmenopausal women at times of acute stress. Since then it has been found to occur in women and men of all ages, and many other stressful triggers have been identified such as earthquakes, lightning strikes, noncardiac surgery, seizures, trauma, anesthesia, and alcohol withdrawal to name just a few. Although the manifestations are variable, it has been found that many individuals have weakening and ballooning of the left ventricular apex during systole that begins within minutes to hours after the stressful episode. Although the pathophysiology is still being explored, catecholamines play an important role in the pathogenesis causing coronary artery spasm, coronary microvascular abnormalities, direct myocardial damage, and neurogenic myocardial stunning. Postmenopausal women may be especially vulnerable because of estrogen deficiency–mediated effects on the microvasculature. On myocardial biopsy, most people have inflammation without necrosis. People with Takotsubo cardiomyopathy present clinically with the same symptoms as acute ST-elevation myocardial infarction (STEMI), including chest pain, dyspnea, ST-segment elevation, and moderately elevated cardiac biomarkers, such as troponins and brain natriuretic peptide. The American Heart Association/May Criteria for the diagnosis describe transient dyskinesia of the left ventricle in the absence of acute coronary artery disease, acute head trauma, myocarditis, or other forms of cardiomyopathy. Management usually includes aspirin, beta-blockers, angiotensin-converting enzyme inhibitors, and statins, although targeted emotional support and standard psychologic counseling have the greatest effect on recovery and reducing the risk for recurrence. An interprofessional team that includes a social worker, pastor, and mental health care providers has been found beneficial for those suffering from this cardiomyopathy.

Data from Ahmed KA, Madhavan M, Prasad A: *Coron Artery Dis* 23(4):259–264, 2012; Golabchi A, Sarrafzadegan N: *J Res Med Sci* 16(3):340–345, 2011; Neil CJ et al: *Exp Rev Cardiovasc Ther* 10(2):215–221, 2012; Shah RM et al: *Am J Ther* 19(3):e105–e113, 2012.

Organic brain syndrome may occur in acute or chronic form if blood flow to the brain is impaired secondary to MI. Transient ischemic attacks or an outright cerebrovascular accident may result from thromboemboli that have broken loose from the wall of the left ventricle or from cardiac valves.

Cardiac complications of MI can include rupture of heart structures. Tissue necrosis in or around the papillary muscles can cause rupture of these muscles or of the chordae tendineae. Factors that lead to rupture of the free wall of the infarcted ventricle include thinning of the wall, poor collateral flow, shearing effect of muscular contraction against the stiffened necrotic area, marked necrosis at the terminal end of the blood supply, and aging of the myocardium with laceration of the myocardial microstructure. Infarctions around septal structures that separate the heart chambers can lead to septal rupture. Ruptures are associated with audible, harsh cardiac murmurs; increased LVEDP; and decreased systemic blood pressure.

Weakening of the wall of the infarcted ventricle can cause **ventricular aneurysm** formation. According to Laplace's law, with decreased muscle mass at the infarcted site, the wall is weakened and tension stretches the noncontracting infarcted heart muscle, thus producing infarct expansion or aneurysm formation (see p. 1140 for a discussion of aneurysm). Decreased muscle mass causes an increase in the radius of the ventricle, and because the radius is directly proportional to pressure and tension, both increase with time. The wall of the aneurysm becomes more fibrotic but continues to bulge with systole. The bulge results in impaired pump function. Although rare, rupture may occur when the tension becomes too great. Death in individuals with a left ventricular aneurysm is usually related to ventricular tachydysrhythmias and not to ventricular rupture. Left ventricular aneurysm is a late complication of MI, occurring months or years after the acute event.

Thromboembolism is commonly found during postmortem examinations of individuals who have died of MI. Thromboemboli may disseminate from debris and clots that collect inside dilated aneurysmal sacs or from the infarcted endocardium and travel to the pulmonary or systemic vascular systems. Pulmonary emboli also may result from the breaking loose of deep venous thrombi of the legs in individuals who are confined to bed (see p. 1275). Early mobilization and prophylactic anticoagulation therapy are essential to reduce the incidence of this complication.

Sudden death resulting from cardiac arrest is often caused by dysrhythmias, particularly ventricular fibrillation. Other dysrhythmias may be equally lethal. Widespread knowledge of cardiopulmonary resuscitation has increased the probability of survival during the first few hours after cardiac insult. Immediate intervention and careful monitoring also have reduced mortality and have improved chances for long-term survival. Several factors, however, contribute to the risk of death during acute infarction or reduce the chances of long-term survival, despite the best possible treatment. They are: (1) degree of left ventricular dysfunction, (2) degree of left ventricular ischemia, (3) potential for ventricular dysrhythmias, and (4) the individual's age.

DISORDERS OF THE HEART WALL

Disorders of the Pericardium

Pericardial disease is often a manifestation of another disorder, such as infection (bacterial, viral, fungal, rickettsial, parasitic); trauma or surgery; neoplasm; or a metabolic, immunologic, or vascular disorder (uremia, rheumatoid arthritis, systemic lupus erythematosus, periarteritis nodosa). The pericardial response to injury from these diverse causes may consist of acute pericarditis, pericardial effusion, or constrictive pericarditis.

Acute Pericarditis

Acute pericarditis is acute inflammation of the pericardium. The etiology of acute pericarditis is most often idiopathic or caused by viral infection by coxsackievirus, influenza, hepatitis, measles, mumps, or varicella viruses. It also is the most common cardiovascular complication of human immunodeficiency virus (HIV) infection. Other causes include MI, trauma, neoplasm, surgery, uremia, bacterial infection (especially tuberculosis), connective tissue disease (especially systemic lupus erythematosus and rheumatoid arthritis), or radiation therapy.[145] The pericardial membranes become inflamed and roughened, and a pericardial effusion may develop that can be serous, purulent, or fibrinous (Figure 32-25). Possible sequelae of pericarditis include recurrent pericarditis, pericardial constriction, and cardiac tamponade.

Most individuals with acute pericarditis describe several days of fever, myalgias, and malaise followed by the sudden onset of severe chest pain that worsens with respiratory movements and with lying down. Although the pain may radiate to the back, it is generally felt in the anterior chest and may be confused initially with the pain of acute MI. Individuals with acute pericarditis also may report dysphagia, restlessness, irritability, anxiety, and weakness.

Physical examination often discloses low-grade fever and sinus tachycardia. A pericardial friction rub—a short, scratchy, grating sound—may be heard at the cardiac apex and left sternal

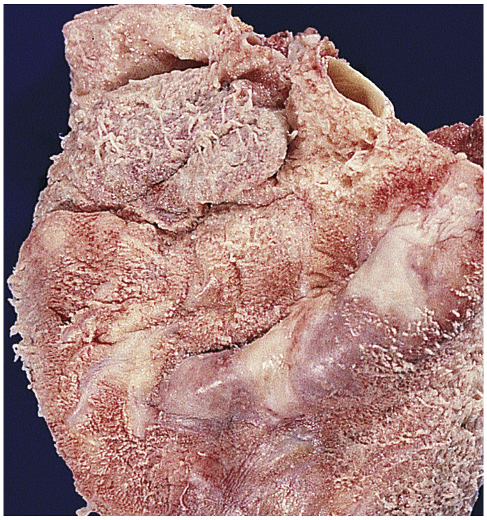

FIGURE 32-25 Acute Pericarditis. Note shaggy coat of fibers covering surface of heart. (From Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

border and is highly specific for pericarditis. The rub is caused by the roughened pericardial membranes rubbing against each other. Friction rubs are not always present and may be intermittently heard. ECG changes may reflect inflammatory processes through diffuse ST-segment elevation that is concaved upward without Q waves.[145] The ECG may remain abnormal for days or even weeks. Echocardiography may reveal a pericardial effusion.

Treatment for uncomplicated acute pericarditis consists of relieving symptoms. Rest is helpful during episodes of acute pain. Salicylates and nonsteroidal anti-inflammatory drugs (NSAIDs) reduce inflammation. Combined nonsteroidals and colchicine (prevents fibrosis) is a highly effective regimen.[145] Additional analgesics may be given to relieve pain. Exploring the underlying cause is important. If pericardial effusion develops, aspirating the excessive fluid may be necessary.

Pericardial Effusion

Pericardial effusion, the accumulation of fluid in the pericardial cavity, can occur in all forms of pericarditis. The fluid may be a transudate, such as the serous effusion that develops with left heart failure, overhydration, or hypoproteinemia. More often, however, the fluid is an exudate, which indicates pericardial inflammation like that seen with acute pericarditis, heart surgery, some chemotherapeutic agents, infections, and autoimmune disorders, such as systemic lupus erythematosus.[145,146] (Types of exudate are described in Chapter 7.) If the fluid is serosanguineous, the underlying cause is likely to be tuberculosis, neoplasm, uremia, or radiation. Idiopathic serosanguineous (cause unknown) effusion is possible, however. Effusions of frank blood are generally related to aneurysms, trauma, or coagulation defects. If chyle leaks from the thoracic duct, it may enter the pericardium and lead to cholesterol pericarditis.

Pericardial effusion, even in large amounts, is not necessarily clinically significant, except that it indicates an underlying disorder. The important consideration is whether the fluid creates sufficient pressure to cause cardiac compression, which is a serious condition known as **tamponade**.[145] If an effusion develops gradually, the pericardium can stretch to accommodate large quantities of fluid without compressing the heart. If the fluid accumulates rapidly, however, even a small amount (50 to 100 ml) may cause serious tamponade. The danger is that pressure exerted by the pericardial fluid eventually equals diastolic pressure within the heart chambers, thus preventing chamber filling. The first structures to be affected by tamponade are the right atrium and ventricle, where diastolic pressures are normally lowest. Compression by pericardial fluid interferes with right atrial filling during diastole, resulting in increased venous pressure, systemic venous congestion, and signs and symptoms of right heart failure (distention of the jugular veins, edema, hepatomegaly). Decreased atrial filling leads to decreased ventricular filling, decreased stroke volume, and reduced cardiac output. If the left atrium collapses because of lack of filling, life-threatening circulatory collapse may occur.[145,146] Individuals with cardiac tamponade most often present with dyspnea, tachycardia, jugular venous distention, cardiomegaly, and pulsus paradoxus. Pulsus paradoxus means that the arterial blood pressure during expiration exceeds arterial pressure during inspiration by more than 10 mmHg. This clinical finding reflects impairment of diastolic filling of the left ventricle plus reduction of blood volume within all four cardiac chambers. Presence of a large pericardial effusion or tamponade magnifies the normally insignificant effect of inspiration on intracardiac flow and volume.

Other clinical manifestations of pericardial effusion are distant or muffled heart sounds, poorly palpable apical pulse, dyspnea on exertion, and dull chest pain. A chest x-ray may disclose a "water-bottle" configuration of the cardiac silhouette. An echocardiogram can detect an effusion as small as 20 ml and is considered the most accurate and reliable method of diagnosis, although CT also is commonly used.[146]

Treatment of pericardial effusion or tamponade generally consists of pericardiocentesis (aspiration of excessive pericardial fluid). Pericardiocentesis is diagnostic and therapeutic: the fluid is analyzed to identify the cause of the effusion, and its removal alone may bring dramatic relief from symptoms. Persistent pain may be treated with analgesics, anti-inflammatory medications, or steroids. Surgery may be required if the underlying cause of tamponade is trauma or aneurysm. If an effusion is neoplasm induced, chemotherapeutic agents may be injected into the pericardial space.[146] If the effusion recurs, a pericardial "window" can be created or the individual may require pericardectomy.

Constrictive Pericarditis

Constrictive pericarditis, or **restrictive pericarditis (chronic pericarditis),** was synonymous with tuberculosis years ago, and tuberculosis continues to be an important cause of pericarditis in immunocompromised individuals.[146] In the United States this form of pericardial disease is more often idiopathic or associated with radiation exposure, rheumatoid arthritis, uremia, or CABG. In constrictive pericarditis, fibrous scarring with occasional calcification of the pericardium causes the visceral and parietal pericardial layers to adhere, obliterating the pericardial cavity. The fibrotic lesions encase the heart in a rigid shell (Figure 32-26). Like tamponade, constrictive pericarditis compresses the heart and eventually reduces cardiac output. Unlike tamponade, however, constrictive pericarditis never develops suddenly.

Because the onset of constrictive pericarditis is gradual, clinical manifestations seldom include pulsus paradoxus. Symptoms tend to be exercise intolerance, dyspnea on exertion, fatigue, and anorexia. Clinical assessment shows weight loss, edema, jugular vein distention, and hepatic congestion. Restricted ventricular filling may cause a pericardial knock (early diastolic sound).

ECG findings include T-wave inversions and atrial fibrillation. Chest x-ray often discloses prominent pulmonary vessels and calcification of the pericardium. CT, MRI, and transesophageal echocardiography are used to detect pericardial thickening and constriction. Pericardial biopsy may be needed to determine the etiology.

Initial treatment for constrictive pericarditis consists of dietary sodium restriction, digitalis glycosides, and diuretics to improve cardiac output.[145,146] If these modalities are not successful, surgical excision of the restrictive pericardium is indicated.

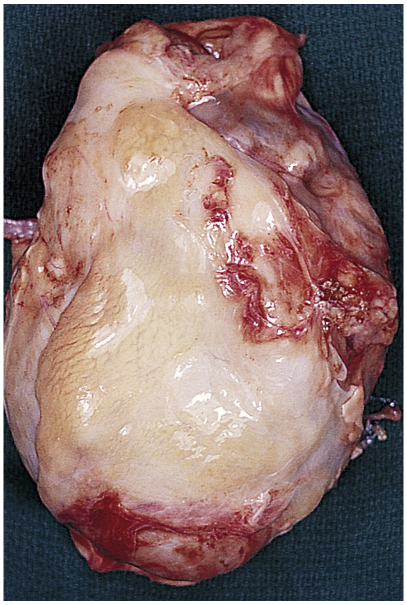

FIGURE 32-26 **Constrictive Pericarditis.** The fibrotic pericardium encases the heart in a rigid shell. (From Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

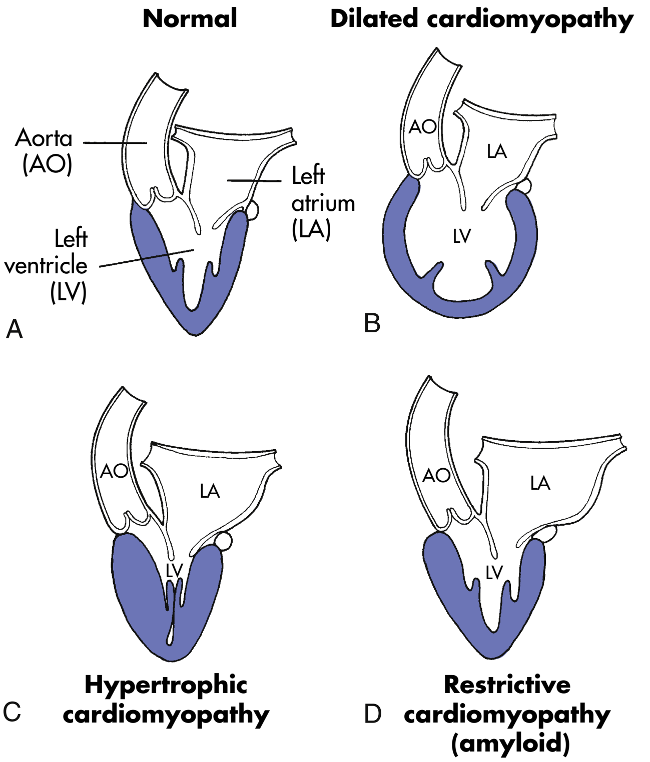

FIGURE 32-27 **Diagram Showing Major Distinguishing Pathophysiologic Features of the Types of Cardiomyopathy. A,** The normal heart. **B,** In the dilated type of cardiomyopathy, the heart has a globular shape, and the largest circumference of the left ventricle is not at its base but midway between apex and base. **C,** In the hypertrophic type of cardiomyopathy the wall of the left ventricle is greatly thickened; the left ventricular cavity is small, but the left atrium may be dilated because of poor diastolic relaxation of the ventricle. **D,** In the restrictive type the left ventricular cavity is of normal size, but again, the left atrium is dilated because of the reduced diastolic compliance of the ventricle. (From Kissane JM, editor: *Anderson's pathology,* ed 9, St Louis, 1990, Mosby.)

Disorders of the Myocardium: The Cardiomyopathies

The **cardiomyopathies** are a diverse group of diseases that affect the myocardium. Most are the result of remodeling caused by the effect of the neurohumoral responses to ischemic heart disease or hypertension on the heart muscle. Cardiomyopathies also can be secondary to inherited disorders, infectious disease, exposure to toxins, systemic connective tissue disease, infiltrative and proliferative disorders, or nutritional deficiencies. Many cases of cardiomyopathy are idiopathic. The cardiomyopathies are categorized as dilated, hypertrophic, or restrictive depending on their tissue characteristics, genomics, and hemodynamic effects (Figure 32-27 and Table 32-8). An individual may display characteristics of more than one type.

Dilated Cardiomyopathy

Dilated cardiomyopathy is characterized by diminished myocardial contractility, which is reflected in diminished systolic performance of the heart. This impaired systolic function leads to increases in intracardiac volume, ventricular dilation, and systolic heart failure (Figure 32-28). This form of cardiomyopathy is usually the result of ischemic heart disease, valvular disease, diabetes, renal failure, hyperthyroidism, alcohol or drug toxicity, peripartum complications, genetic disorder, or infection. Idiopathic dilated cardiomyopathy often has a familial origin with associated alterations in genes coding for contractile proteins, mitochondrial dysfunction, and immune defects.[147,148]

Ischemic cardiomyopathy is the most common and can occur as the direct result of myocardial infarction or can result from repetitive ischemic insults in those with poorly controlled angina.[149] Valvular heart disease causes cardiac chamber volume and pressure overload that can result in long-term myocardial dysfunction. Diabetes and uremia are associated with decreased myocardial contractility and dilated cardiomyopathy. Alcohol can be directly toxic to the myocardium, as can many drugs such as some chemotherapeutic, inotropic, and antidysrhythmic agents. Many nutritional deficiencies can cause cardiomyopathy including niacin, vitamin D, and selenium. Peripartum cardiomyopathy occurs in previously healthy women in the final month of pregnancy and up to 5 months after delivery. Although the incidence is less than 0.1% of pregnancies, morbidity and mortality rates are high at 5% to 32%.[150] Dilated cardiomyopathies also may be the late autoimmune consequences of previous viral infections resulting in myocarditis and subsequent decreases in contractility.[151] Hyperthyroidism may present with atrial fibrillation and dilated cardiomyopathy, which may be reversible with treatment of the thyroid disorder. (Pathophysiologic effects of the cardiomyopathies are summarized in Table 32-8.)

The most common symptoms of dilated cardiomyopathy are dyspnea and fatigue. Pulmonary congestion is expected, although fulminant pulmonary edema is uncommon. Palpitations and associated dysrhythmias may cause dizziness (syncope). Systemic and pulmonary emboli are common complications. Chest pain may be present but it is usually nonspecific and unlike anginal pain.

TABLE 32-8 PATHOPHYSIOLOGIC EFFECTS OF THE CARDIOMYOPATHIES

	TYPE OF CARDIOMYOPATHY		
PATHOPHYSIOLOGY	**DILATED**	**HYPERTROPHIC**	**RESTRICTIVE**
Major symptoms	Fatigue, weakness, palpitations	Dyspnea, angina pectoris, fatigue, dizziness (syncope), palpitations	Dyspnea, fatigue
Cardiomegaly	Moderate to marked	Mild to moderate	Mild
Hypertrophy	Left ventricular myocardium	Left ventricular myocardium and interventricular septum	Left ventricular myocardium
Alterations of chamber volume	Volume increased	Volume decreased, particularly in left ventricle	Volume normal to decreased
Alterations of chamber compliance	Compliance increased	Compliance decreased, particularly in left ventricle	Compliance decreased, particularly in left ventricle
Alterations of systolic function (myocardial contractility)	Contractility decreased in left ventricle	Contractility normal	None
Conduction defects	Intraventricular	Nonspecific	Atrioventricular
Dysrhythmias	Sinoatrial tachycardia; atrial and ventricular dysrhythmias	Atrial and ventricular dysrhythmias	Tachydysrhythmias
Thromboembolism	Systemic or pulmonary	Systemic or pulmonary	Systemic or pulmonary
Associated conditions	Alcoholism, pregnancy, infection, nutritional deficiency, exposure to toxins	Inherited defect of muscle growth and development or hypertension	Infiltrative disease
Eventual cardiovascular event	Left heart failure	Left heart failure	Right heart failure

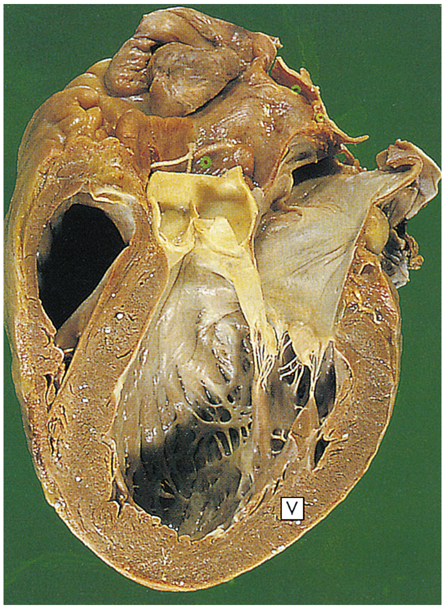

FIGURE 32-28 **Dilated Cardiomyopathy.** The dilated left ventricle has a thin wall *(V)*. (From Stevens A, Lowe JS, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

In the presence of dilated heart failure, blood pressure may be elevated initially; however, hypotension indicates progressive decreases in contractility. Extra heart sounds and cardiac murmurs may be present as well. Echocardiography and MRI can confirm the diagnosis; however, careful evaluation for potentially reversible underlying causes is essential.

General treatment for dilated cardiomyopathy consists of salt restriction and the careful use of vasodilators, diuretics, and inotropic agents. Anticoagulants are given to prevent pulmonary and systemic embolism. Corticosteroids and immunosuppressants can benefit individuals with documented inflammatory disease. Myocardial pacemakers (pacing) can improve cardiac output in many individuals. Cardiac transplantation may be lifesaving. The use of cardiac stem cells to restore myocardial contractility is an area of promising research.[152]

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy refers to two major categories of thickening of the myocardium: (1) hypertrophic obstructive cardiomyopathy (asymmetric septal hypertrophic cardiomyopathy or subaortic stenosis), and (2) hypertensive or valvular hypertrophic cardiomyopathy. These two categories are very different in their etiology, pathophysiology, and clinical presentation.

Hypertrophic obstructive cardiomyopathy is the most common inherited heart defect, occurring in 1 of 500 individuals through autosomal dominant inheritance.[5] It is characterized by thickening of the septal wall (Figure 32-29), which may cause outflow obstruction to the left ventricle outflow tract. Additional changes include abnormalities of collagen deposition and altered contractile proteins in the myocytes.[153] The thickening of the septum results in a hyperdynamic state, especially with exercise. Diastolic relaxation also is impaired and ventricular compliance is decreased. Obstruction of left ventricular outflow can occur when heart rate is increased and intravascular volume is decreased. Individuals complain of angina, syncope, palpitations, and symptoms of MI and left heart failure. Examination may reveal extra heart sounds and murmurs. Echocardiography and cardiac catheterization can confirm the diagnosis.[154] This type of hypertrophic cardiomyopathy is a significant risk for serious ventricular arrhythmias and sudden death. Management includes beta-blockers or verapamil to slow the heart rate, surgical resection of the hypertrophied myocardium, septal ablation, and prophylactic placement of an ICD in high-risk individuals.[155]

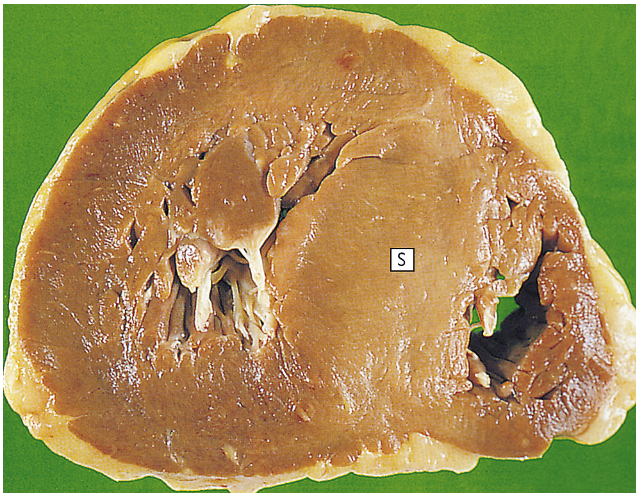

FIGURE 32-29 Hypertrophic Cardiomyopathy. There is marked left ventricular hypertrophy. This often affects the septum *(S)*. (From Stevens A, Lowe JS, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

Hypertensive or valvular hypertrophic cardiomyopathy occurs because of increased resistance to ventricular ejection commonly seen in hypertension or in valvular stenosis (usually aortic). In this case, hypertrophy of the myocytes is an attempt to compensate for increased myocardial workload. Long-term dysfunction of the myocytes develops over time, with first diastolic dysfunction leading eventually to systolic dysfunction of the ventricle (see Heart Failure, p. 1175). Individuals with hypertrophic cardiomyopathy may be asymptomatic or may complain of angina, syncope, dyspnea on exertion, and palpitations. Examination may reveal extra heart sounds and murmurs. Echocardiography and cardiac catheterization can confirm the diagnosis.

Restrictive Cardiomyopathies

Restrictive cardiomyopathy is characterized by restrictive filling and reduced diastolic volume of either or both ventricles with normal or near-normal systolic function and wall thickness.[156] It may occur idiopathically or as a cardiac manifestation of systemic diseases, such as scleroderma, amyloidosis, sarcoidosis, lymphoma, and hemochromatosis, or a number of inherited storage diseases. The myocardium becomes rigid and noncompliant, impeding ventricular filling and raising filling pressures during diastole. The overall clinical and hemodynamic picture mimics and may be confused with that of constrictive pericarditis.

The most common clinical manifestation of restrictive cardiomyopathy is right heart failure with systemic venous congestion. Cardiomegaly and dysrhythmias are common. A thorough evaluation for the underlying cause should be initiated (and may include myocardial biopsy).[156] Treatment is aimed at the underlying cause. Death occurs as a result of heart failure or dysrhythmias.

Disorders of the Endocardium

Valvular Dysfunction

Disorders of the endocardium, the innermost lining of the heart wall, all damage the heart valves, which are made up of endocardial tissue. Endocardial damage can be either congenital or acquired. The acquired forms cause inflammatory, ischemic, traumatic, degenerative, or infectious alterations of valvular structure and function. Structural alterations of the heart valves lead to stenosis, incompetence, or both. Although all four heart valves may be affected, those of the left heart (mitral and aortic semilunar valves) are more commonly affected than those of the right heart (tricuspid and pulmonic semilunar valves).

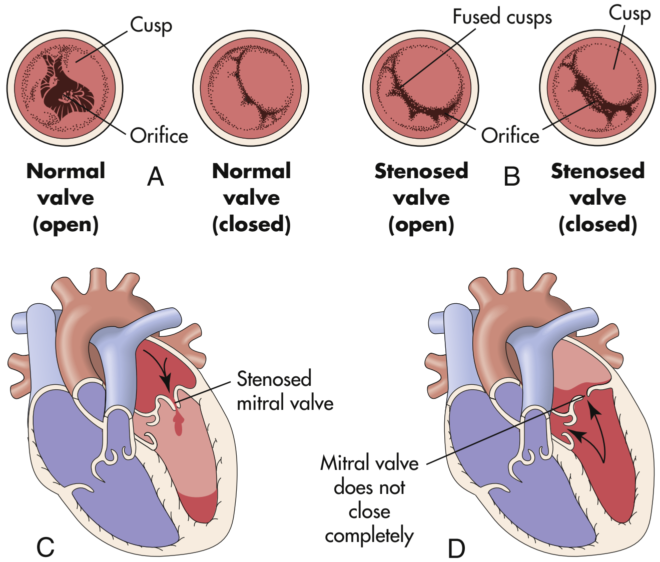

FIGURE 32-30 Valvular Stenosis and Regurgitation. **A,** Normal position of the valve leaflets, or cusps, when the valve is open and closed. **B,** Open position of a stenosed valve *(left)* and open position of a closed regurgitant valve *(right)*. **C,** Hemodynamic effect of mitral stenosis. The stenosed valve is unable to open sufficiently during left atrial systole, inhibiting left ventricular filling. **D,** Hemodynamic effect of mitral regurgitation. The mitral valve does not close completely during left ventricular systole, permitting blood to reenter the left atrium.

In **valvular stenosis** the valve orifice is constricted and narrowed, impeding the forward flow of blood and increasing the workload of the cardiac chamber proximal to the diseased valve (Figure 32-30). Intraventricular or atrial pressure increases in the chamber to overcome resistance to flow through the valve. Increased pressure causes the myocardium to work harder, causing myocardial hypertrophy. In **valvular regurgitation** (also called *insufficiency* or *incompetence*) the valve leaflets, or cusps, fail to shut completely, permitting blood flow to continue even when the valve is supposed to be closed (see Figure 32-30). During systole or diastole some blood leaks back into the chamber proximal to the incompetent valve. Valvular regurgitation increases the volume of blood the heart must pump and increases the workload of the affected heart chamber. Increased volume leads to chamber dilation, and increased workload leads to hypertrophy.

Valvular dysfunction stimulates chamber dilation and/or myocardial hypertrophy, both of which are compensatory mechanisms intended to increase the pumping capability of the heart. Eventually, myocardial contractility is diminished, the ejection fraction is reduced, diastolic pressure increases, and the affected heart chamber fails from overwork. Depending on the severity of the valvular dysfunction and the capacity of the heart to compensate, valvular alterations cause a range of symptoms and some degree of incapacitation (Table 32-9).

TABLE 32-9 CLINICAL MANIFESTATIONS OF VALVULAR STENOSIS AND REGURGITATION

MANIFESTATION	AORTIC STENOSIS	MITRAL STENOSIS	AORTIC REGURGITATION	MITRAL REGURGITATION	TRICUSPID REGURGITATION
Most common cause	Congenital bicuspid valve, degenerative (calcification) changes with aging, rheumatic fever	Rheumatic heart disease	Infective endocarditis; aortic root disease (connective tissue diseases, Marfan syndrome); dilation of the aortic root due to hypertension and aging	Myxomatous degeneration (mitral valve prolapse)	Congenital
Cardiovascular outcome (untreated)	Left ventricular hypertrophy followed by left heart failure; decreased coronary blood flow with myocardial ischemia	Left atrial hypertrophy and dilation with fibrillation, followed by right ventricular failure	Left ventricular hypertrophy and dilation, followed by heart failure	Left atrial hypertrophy and dilation, followed by left heart failure	Right heart failure
Pulmonary effects	Pulmonary edema: dyspnea on exertion	Pulmonary edema: dyspnea on exertion, orthopnea, paroxysmal, nocturnal dyspnea, predisposition to respiratory infections, hemoptysis, pulmonary hypertension, and edema	Pulmonary edema with dyspnea on exertion	Pulmonary edema with dyspnea on exertion	Dyspnea
Central nervous system effects	Syncope, especially on exertion	Neural deficits only associated with emboli (e.g., hemiparesis)	Syncope	None	None
Pain	Angina pectoris	Atypical chest pain	Angina pectoris	Atypical chest pain	Palpitations
Heart sounds	Systolic murmur heard best at the right parasternal second intercostal space and radiating to the neck	Low rumbling diastolic murmur heard best at the apex and radiating to the axilla, accentuated first heart sound, opening snap	Diastolic murmur heard best at the right parasternal second intercostal space and radiating to the neck	Murmur throughout systole heard best at the apex and radiating to the axilla	Murmur throughout systole heard best at the left lower sternal border

Data from Braunwald E, editor: *Heart disease: a textbook of cardiovascular medicine,* ed 7, Philadelphia, 2005, Saunders; Carabello BA, Paulus WJ: Valvular heart disease. In Crawford MH, DiMarco JP, editors: *Cardiology,* London, 2001, Mosby-Wolfe.

In general, valvular disease is diagnosed by echocardiography, which can be used to assess the severity of valvular obstruction or regurgitation before the onset of symptoms. Management almost always includes careful fluid management, valvular repair, or valve replacement with a prosthetic valve followed by long-term anticoagulation.[157] In the case of mechanical valve replacement, lifelong antibiotic prophylaxis prior to invasive procedures is required.[158]

Stenosis

Aortic Stenosis. **Aortic stenosis** is the most common valvular abnormality affecting nearly 2% of adults older than 65 years.[5] The three common causes are: (1) congenital bicuspid valve, (2) calcific degeneration related to aging, and (3) inflammatory damage caused by rheumatic heart disease (less than 10% of cases). Numerous gene abnormalities have been associated with aortic stenosis. Aortic stenosis is also associated with many risk factors for coronary artery disease. In the United States, 29% of adults were found to have degenerative sclerotic aortic valves, and approximately 2% to 5% progress to aortic stenosis.[5,159] Aortic valve degeneration with aging is associated with lipoprotein deposition in the tissue with chronic inflammation and leaflet calcification. Evidence suggests that degenerative aortic stenosis is linked to hyperlipidemia and that its prevalence might be decreased by more aggressive lipid lowering in adults. Disorders in calcium transport, apoptosis of endocardial cells, and decreased nitric oxide synthesis also have been implicated. In aortic stenosis from any cause, the orifice of the aortic semilunar valve narrows, causing diminished blood flow from the left ventricle into the aorta (Figures 32-31). Outflow obstruction increases pressure within the left ventricle as it tries to eject blood through the narrowed opening. Left ventricular hypertrophy develops to compensate for the increased workload. Eventually, hypertrophy increases myocardial oxygen demand that the coronary arteries may not be able to supply. If this occurs, ischemia may cause attacks of angina. Untreated aortic stenosis can lead to dysrhythmias, myocardial infarction, and heart failure.

Aortic stenosis tends to develop gradually. The classic manifestations of aortic stenosis are angina, syncope, and heart failure. Clinical manifestations include decreased stroke volume, reduced systolic blood pressure, and narrowed pulse pressure (difference between systolic and diastolic pressure). Heart rate is often slow, and pulses are faint. Resistance to flow through the stenotic valve gives rise to a crescendo-decrescendo systolic heart murmur heard best at the second intercostal space and may radiate to the neck. Echocardiography is used to follow

FIGURE 32-31 Aortic Stenosis. Mild stenosis in valve leaflets of a young adult. (From Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

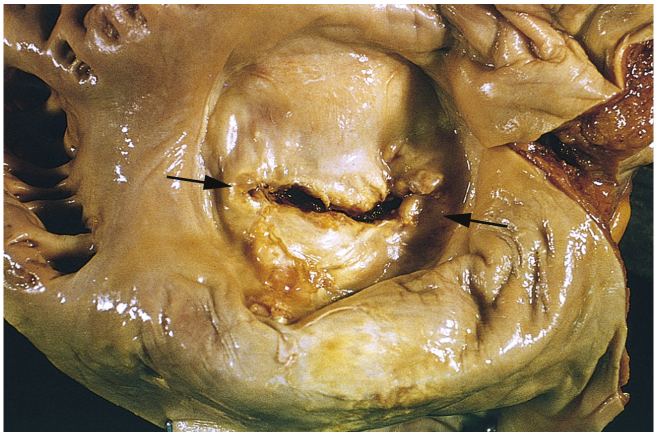

FIGURE 32-32 Mitral Stenosis with Classic "Fish Mouth" (Arrows) Orifice. (From Kumar V, et al: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2010, Mosby.)

valve orifice and cardiac functioning. Medical management with careful monitoring for complications, such as heart failure and myocardial ischemia, may be indicated for selected individuals, but most require valve repair or replacement with a prosthetic valve followed by long-term anticoagulation.[157] Transcatheter aortic valve implantation is used increasingly to avoid major heart surgery in selected individuals.[160] The prognosis is poor once an individual becomes symptomatic from aortic stenosis.[159]

Mitral Stenosis. Mitral stenosis impairs the flow of blood from the left atrium to the left ventricle. Mitral stenosis is most commonly caused by acute rheumatic fever (see p. 1171) and is two to three times more common in women than in men. Congenital mitral valve stenosis is less common and includes a wide range of anatomic variants.[161] Autoimmunity in response to group A beta-hemolytic streptococcal M protein antigens leads to inflammation and scarring of the valvular leaflets. Scarring causes the leaflets to become fibrous and fused and the chordae tendineae cordis becomes shortened (Figure 32-32).

Clinical manifestations depend on the size of the valvular orifice. Impedance to blood flow results in incomplete emptying of the left atrium and elevated atrial pressure as the chamber tries to force blood through the stenotic valve. Continued increases in left atrial volume and pressure cause chamber dilation and hypertrophy. The risk of developing atrial dysrhythmias (especially fibrillation) and dysrhythmia-induced thrombi is high. As mitral stenosis progresses, symptoms of decreased cardiac output occur, especially during exertion. Continued elevation of left atrial pressure and volume causes pressure to rise in the pulmonary circulation. The outcomes of untreated chronic mitral stenosis are pulmonary hypertension, edema, and right ventricular failure.

Blood flow through the stenotic valve gives rise to a rumbling decrescendo diastolic murmur heard best over the cardiac apex and radiating to the left axilla. If the mitral valve is forced open during diastole, it may make a sharp noise called an *opening snap*. The first heart sound (S_1) is often accentuated and somewhat delayed because of increased left atrial pressure. Other signs and symptoms result from pulmonary congestion and right heart failure. Atrial enlargement is demonstrated by chest x-rays and electrocardiography. Mitral stenosis can often be repaired surgically but may require valve replacement in advanced cases.[157]

Regurgitation

Aortic Regurgitation. Aortic regurgitation results from an inability of the aortic valve leaflets to close properly during diastole resulting from abnormalities of the leaflets or the aortic root, or both. It can be congenital (bicuspid valve) or acquired. Acquired aortic regurgitation can be caused by rheumatic heart disease, bacterial endocarditis, syphilis, hypertension, connective tissue disorders (e.g., Marfan syndrome and ankylosing spondylitis), appetite-suppressing medications, trauma, or atherosclerosis. More than a third of cases of aortic regurgitation are idiopathic. The hemodynamic repercussions depend on the size of the "leak." During systole, blood is ejected from the left ventricle into the aorta. If the aortic semilunar valve fails to close completely, some of the ejected blood flows back into the left ventricle during diastole. Volume overload occurs in the ventricle because it receives blood from the left atrium and the aorta during diastole. Over time, the end-diastolic volume of the left ventricle increases and myocardial fibers stretch to accommodate the extra fluid. Compensatory dilation permits the left ventricle to increase its stroke volume and maintain cardiac output. Ventricular hypertrophy also occurs as an adaptation to the increased volume and increased afterload created by the high stroke volume and resultant systolic hypertension. Ventricular dilation and hypertrophy eventually cease to compensate for aortic incompetence, and heart failure develops.

Clinical manifestations include widened pulse pressure resulting from increased stroke volume and diastolic backflow. Turbulence across the aortic valve during diastole produces a decrescendo murmur heard best in the second, third, or fourth intercostal spaces parasternally and may radiate to the neck. Large stroke volume and rapid runoff of blood from the aorta cause prominent carotid pulsations and bounding peripheral pulses (Corrigan pulse). Other symptoms are usually associated with heart failure that occurs when the ventricle can no longer pump adequately. Dysrhythmias and endocarditis are common complications of aortic regurgitation. The severity of

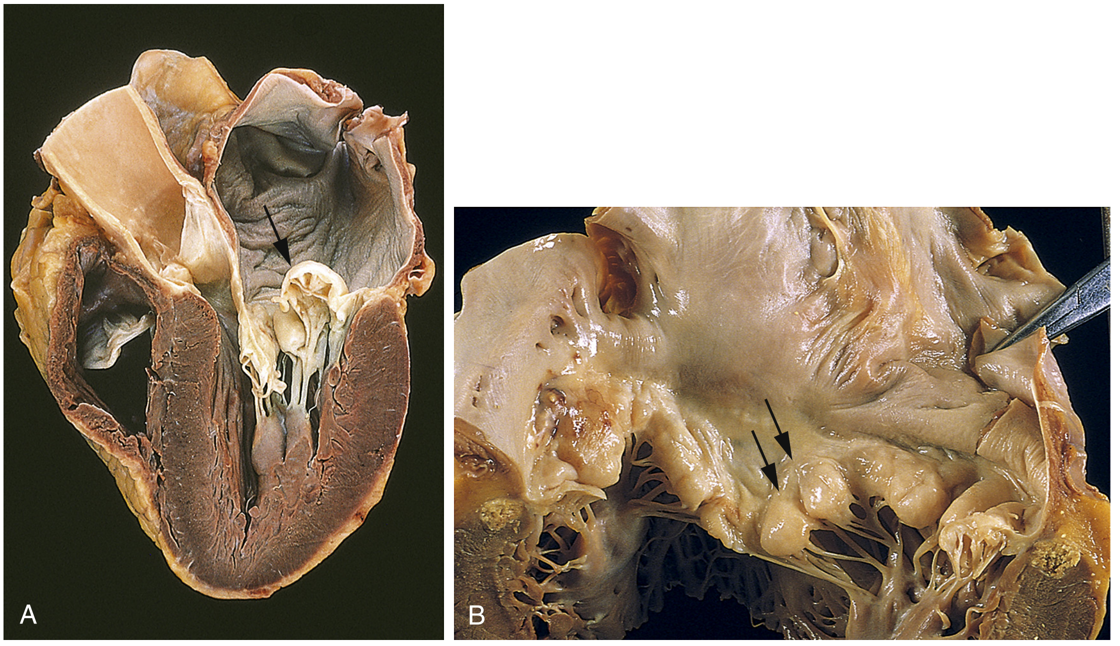

FIGURE 32-33 **Mitral Valve Prolapse. A,** Prolapsed mitral valve. Prolapse permits the valve leaflets to billow back *(arrow)* into the atrium during left ventricular systole. The billowing causes the leaflets to part slightly, permitting regurgitation into the atrium. **B,** Looking down into the mitral valve, the ballooning *(arrows)* of the leaflets is seen. (From Kumar V, et al: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2010, Mosby.)

regurgitation can be estimated by echocardiography, and valve replacement may be delayed for many years through careful use of vasodilators and inotropic agents.[157]

Mitral Regurgitation. **Mitral regurgitation** has a variety of causes. The most common are mitral valve prolapse and rheumatic heart disease. Other causes include infective endocarditis, CAD, connective tissue diseases (Marfan syndrome), and congestive cardiomyopathy. Mitral regurgitation permits backflow of blood from the left ventricle into the left atrium during ventricular systole, giving rise to a loud pansystolic (throughout systole) murmur heard best at the apex that radiates into the back and axilla. Because of increased volume in the left atrium that then enters the ventricle, the left ventricle becomes dilated and hypertrophied to maintain adequate cardiac output. The volume of backflow reentering the left atrium gradually increases, causing atrial dilation and associated atrial fibrillation. As the left atrium enlarges, the valve structures stretch and become deformed, leading to further backflow. As mitral valve regurgitation progresses, left ventricular function may become impaired to the point of failure. Eventually, increased atrial pressure also causes pulmonary hypertension and failure of the right ventricle. Mitral incompetence is usually well tolerated—often for years—until ventricular failure occurs. Most clinical manifestations are caused by heart failure. The severity of regurgitation can be estimated by echocardiography, and surgical repair or valve replacement may become necessary.[157,162] In acute mitral regurgitation caused by MI, surgical repair must be done emergently.

Tricuspid Regurgitation. **Tricuspid regurgitation** is more common than tricuspid stenosis and usually is associated with dilation and failure of the right ventricle secondary to pulmonary hypertension. Rheumatic heart disease and infective endocarditis are less common causes. Tricuspid valve incompetence leads to volume overload in the right atrium and ventricle, increased systemic venous blood pressure, and right heart failure.[163] Pulmonic valve dysfunction can have the same consequences as tricuspid valve dysfunction.

Mitral Valve Prolapse Syndrome. **Mitral valve prolapse syndrome** is a condition in which the anterior and posterior cusps of the mitral valve billow upward (prolapse) into the atrium during systole (Figure 32-33). The most common cause of mitral valve prolapse is myxomatous degeneration of the leaflets in which the cusps are redundant, thickened, and scalloped because of changes in tissue proteoglycans, increased proteinases, and infiltration by myofibroblasts. The chordae tendineae may be elongated, permitting the valve cusps to stretch upward. Mitral regurgitation occurs if the ballooning valve permits blood to leak into the atrium.[164]

Mitral valve prolapse is the most common valve disorder in the United States, with a prevalence estimated at 2.4%.[5] Mitral valve prolapse tends to be most prevalent in young women. Studies suggest an autosomal dominant and X-linked inheritance pattern. Because mitral valve prolapse often is associated with other inherited connective tissue disorders (Marfan syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta), it is thought to result from a genetic or environmental disruption of valvular development during the fifth or sixth week of gestation. There may be a relationship between symptomatic mitral valve prolapse and hyperthyroidism. Other neuroendocrine abnormalities have been suggested, including polymorphisms of the angiotensin II type 1 (AT_1) receptor and alterations in ANS function.[164]

Many cases of mitral valve prolapse are completely asymptomatic. Cardiac auscultation on routine physical examination may disclose a regurgitant murmur or midsystolic click in an otherwise healthy individual, or echocardiography may demonstrate the

condition in the absence of auscultatory findings. Symptomatic mitral valve prolapse can cause palpitations related to dysrhythmias, tachycardia, lightheadedness, syncope, fatigue (especially in the morning), lethargy, weakness, dyspnea, chest tightness, hyperventilation, anxiety, depression, panic attacks, and atypical chest pain. Many symptoms are vague and puzzling and are unrelated to the degree of prolapse. Although severe sequelae—such as chordae rupture, ventricular failure, systemic emboli, and sudden death—are possible, the disorder is actually associated with minimal mortality and morbidity. Most individuals with mitral valve prolapse have an excellent prognosis, do not develop symptoms, and do not require any restriction in activity or medical management. Occasionally, beta-blockers are needed to alleviate syncope, severe chest pain, or palpitations. However, a subset of individuals have an increased risk for complications such as infective endocarditis, cardioembolic stroke, and sudden death. These high-risk individuals can be identified by clinical and echocardiographic findings. If regurgitation is present, medical treatment includes afterload reduction, diuresis, anticoagulation for associated atrial fibrillation, and other medications for heart failure.[164]

Acute Rheumatic Fever and Rheumatic Heart Disease

Rheumatic fever is a systemic, inflammatory disease caused by a delayed immune response to infection by group A beta-hemolytic streptococci.[165] In its acute form rheumatic fever is a febrile illness characterized by inflammation of the joints, skin, nervous system, and heart.[166] If untreated, rheumatic fever can cause scarring and deformity of cardiac structures, resulting in **rheumatic heart disease (RHD).**

The incidence of acute rheumatic fever declined in the United States during the 1960s, 1970s, and early 1980s because of medical and socioeconomic improvements, as well as changes in the virulence of group A streptococci.[167] Because crowding and poor hygiene are environmental risk factors for acute rheumatic fever, the disease continues to be a major cause of death and disability for underprivileged populations.

The acute disease occurs most often in children between 5 and 15 years of age.[165] Because beta-hemolytic streptococcus infection must persist for some time to cause acute rheumatic fever, appropriate antibiotic therapy given within the first 9 days of infection usually prevents rheumatic fever. Initiation of antibiotic therapy 2 weeks after the start of streptococcal infection does not prevent rheumatic fever in susceptible individuals.

Rheumatic fever tends to run in families, lending support to the concept of genetic predisposition, including changes in major histocompatibility antigens.[165] Individuals who have experienced one attack of acute rheumatic fever are more susceptible than the general population to recurrent attacks.

PATHOPHYSIOLOGY. Acute rheumatic fever can develop *only* as a sequel to pharyngeal infection by group A beta-hemolytic streptococci. Streptococcal skin infections do not progress to acute rheumatic fever because the strains of the microorganism that infect the skin do not have the same antigenic molecules in their cell membranes as do those that cause pharyngitis and therefore do not elicit the same kind of immune response. However, both skin infections and pharyngeal infections can cause acute glomerulonephritis.

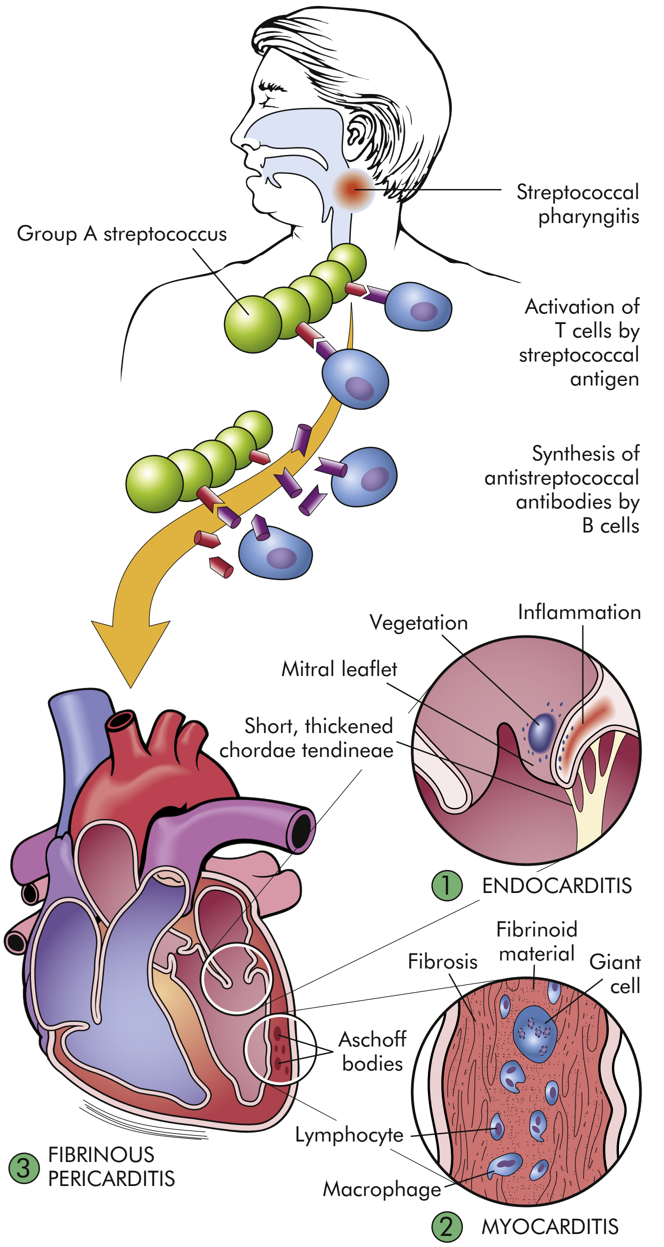

FIGURE 32-34 Pathogenesis and Structural Alterations of Acute Rheumatic Heart Disease. Beginning usually with a sore throat, rheumatic fever can develop only as a sequel to pharyngeal infection by group A beta-hemolytic streptococcus. Suspected as a hypersensitivity reaction, it is proposed that antibodies directed against the M proteins of certain strains of streptococci cross-react with tissue glycoproteins in the heart, joints, and other tissues. The exact nature of cross-reacting antigens has been difficult to define, but it appears that the streptococcal infection causes an autoimmune response against self-antigens. Inflammation is found in various sites including **(1)** endocardium, **(2)** myocardium, and **(3)** pericardium. The most distinctive inflammatory lesions within the heart are called *Aschoff bodies*. The chronic sequelae result from progressive fibrosis because of healing of the inflammatory lesions and the changes induced by valvular deformities. (From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

Acute rheumatic fever affects the heart, joints, CNS, and skin through an abnormal humoral and cell-mediated immune response to the M proteins on the microorganisms that cross-react with normal tissues (Figure 32-34). Antibodies against a streptococci bacterial wall antigen (GlcNAc) display

cross-reactivity against laminin, a protein present in extracellular tissues around heart cells and in the valves. Cardiac myosin is another target antigen. Antibodies also cross-react within neuronal cells triggering dopamine release.[167] These antibodies also affect skin, muscles, and synovial joints.

Autoimmunity and associated intense inflammation result in diffuse, proliferative, and exudative lesions in the connective tissues, especially in the heart, joints, and skin.[167] The inflammation may subside before treatment, leaving behind damage to the heart valves and increasing the individual's susceptibility to recurrent acute rheumatic fever after any subsequent streptococcal infections. Repeated attacks of acute rheumatic fever cause chronic proliferative changes in the previously mentioned organs as a result of scarring, granulomas, and thromboses.[166]

Approximately 10% of cases of rheumatic fever develop RHD.[165] Several genes have been implicated in RHD, including the HLA-DR 1 antigen and HLA-DR 6 antigen, which suggests that genetically determined immune response factors may play a role in the pathogenesis of severe chronic RHD.[5] RHD begins as **carditis,** or inflammation of the heart. Although rheumatic fever can cause carditis in all three layers of the heart wall (endocardium, myocardium, pericardium) (see Chapter 31, Figure 31-2), the primary lesion usually involves the endocardium, which includes the heart valves.[167] Endocardial inflammation causes swelling of the valve leaflets, with secondary erosion along the lines of leaflet contact. Small beadlike clumps of vegetation containing platelets and fibrin are deposited on eroded valvular tissue and on the chordae tendineae (Figure 32-35). (The chordae tendineae anchor the valve leaflets; see Chapter 31, Figure 31-3). The valves lose their elasticity, and the leaflets may adhere to each other. Scarring and shortening of the involved structures occur over time.

If inflammation penetrates the myocardium, localized fibrin deposits develop that are surrounded by areas of necrosis. These fibrinoid necrotic deposits are called *Aschoff bodies.* Pericardial inflammation is usually characterized by serofibrinous effusion within the pericardial cavity.

CLINICAL MANIFESTATIONS. The common symptoms of acute rheumatic fever are fever, lymphadenopathy, arthralgia, nausea, vomiting, epistaxis (nose bleed), abdominal pain, and tachycardia. The major clinical manifestations of acute rheumatic fever (carditis, acute migratory polyarthritis, chorea, and erythema marginatum) usually occur singly or in combination 1 to 5 weeks after streptococcal infection of the pharynx.

Carditis. Carditis occurs a few weeks after the initial infection in about 50% of patients with acute rheumatic fever.[165] The earliest cardiac manifestation of acute rheumatic fever may be a previously undetected murmur caused by mitral or aortic semilunar valve dysfunction. Chest pain is caused by pericardial inflammation. Pericardial effusion produces an audible friction rub. Extra heart sounds, heart block (see p. 1181), atrial fibrillation, and a prolonged PR interval are often associated with chronic rheumatic heart disease. Endocardial inflammation may be manifested years later with serious valvular diseases (stenosis and regurgitation) and recurrent infective endocarditis.

Polyarthritis. Acute migratory polyarthritis (inflammation of more than one joint) occurs in 60% to 80% of individuals with rheumatic fever.[165] Although all of the synovial joints may be involved, the large joints of the extremities are most often affected. Two or more joints are usually involved simultaneously or in succession, with each joint being symptomatic for approximately 2 to 3 days while the overall polyarthritis continues for up to 3 weeks. Exudative synovitis causes heat, redness, swelling, severe pain, and tenderness but no permanent disability. Palpable subcutaneous nodes often develop over bony prominences and along extensor tendons. They do not interfere with joint function and often go unnoticed.

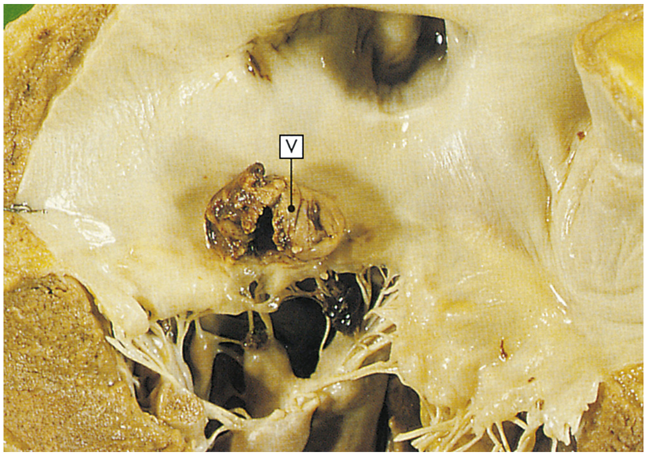

FIGURE 32-35 Valvular Vegetations in Mitral Stenosis. Mitral stenosis and clumps of vegetation *(V)* containing platelets and fibrin. Mitral leaflets are thickened and fused and have clumps of vegetation containing platelets and fibrin. (From Stevens A, Lowe JS, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

Chorea. **Sydenham chorea,** or **St. Vitus dance,** is a disorder of the CNS characterized by sudden, aimless, irregular, involuntary movements. (Chorea is described in Chapter 17.) It is the most common acquired chorea in children and is more common in girls than in boys. The chorea is self-limiting, although severe cases may require the use of dopamine receptor blockers and antiepileptic medications. It resolves within 1 to 6 months and has no permanent neural sequelae.

Erythema Marginatum. **Erythema marginatum** is a distinctive truncal rash that often accompanies acute rheumatic fever. It consists of nonpruritic, pink, erythematous macules that never occur on the face or hands. The rash is transitory and may change in appearance within minutes or hours. Heat (e.g., bathing) darkens the rash. The macules may fade in the center and be mistaken for ringworm.

EVALUATION AND TREATMENT. Criteria for the diagnosis of rheumatic fever have been developed and updated by both the AHA and the World Health Organization[168] (Table 32-10). When correlated with findings from physical assessment, laboratory values lend significant support to the diagnosis of acute rheumatic fever. A throat culture positive for group A beta-hemolytic streptococci can be an important finding when associated with certain physical signs. Cultures may be negative when the rheumatic attack begins, however. Most strains of group A beta-hemolytic streptococci produce a hemolytic factor called *streptolysin-O.* Antibodies against this hemolytic factor increase as an individual's immune system fights the disease. A high or rising antistreptolysin-O (ASO) antibody titer is an accurate means of diagnosing the

TABLE 32-10 JONES CRITERIA (REVISED) FOR DIAGNOSIS OF RHEUMATIC FEVER

CRITERIA	DESCRIPTION
Essential	Evidence of streptococcal infection (increased titer of streptococcal antibodies: antistreptolysin-O [ASO]; positive throat culture for group A streptococci; recent scarlet fever)
Major	Carditis, arthritis, chorea, erythema marginatum, subcutaneous nodules
Minor	*Clinical:* arthralgia, fever *Laboratory:* increased C-reactive protein, increased white blood cell count, increased erythrocyte sedimentation rate *Electrocardiographic*: prolonged PR interval

From Dajani AS et al: *Circulation* 87:302–307, 1993.

presence of a streptococcal infection. Several other antibody tests are sensitive indicators of streptococcal infection. These include antideoxyribonucleotidase (anti-DNase B), antihyaluronidase, and antistreptozyme (ASTZ).

Elevated white blood cell count, erythrocyte sedimentation rate, and CRP indicate inflammation. All three are usually increased at the time cardiac or joint symptoms begin to appear. They are more useful in identifying an acute inflammatory process and suggesting prognosis than in diagnosing acute rheumatic fever. The levels of these tests decrease as the inflammatory process resolves.

Therapy for acute rheumatic fever is aimed at eradicating the streptococcal infection using a 10-day regimen of antibiotics. NSAIDs are used as anti-inflammatory agents for rheumatic carditis and arthritis and help relieve symptoms, but do not prevent complications.[167] Unfortunately there is little evidence that anti-inflammatory medications (including corticosteroids) are effective in treating acute carditis.[169] Serious carditis may require that cardiac glycosides, diuretics, and bed rest be added to the regimen. Surgical repair of damaged valves may be necessary in cases of chronic recurrent rheumatic fever or carditis. Active disease is considered resolved when (1) the murmur has disappeared or cardiac status becomes stable, (2) major manifestations are no longer present, (3) the individual is afebrile, and (4) the erythrocyte sedimentation rate is normal or stabilized. This may take 1 to 6 months.

A rheumatic recurrence will develop in 50% to 65% of children with known rheumatic fever if they have another group A streptococcal infection. Recurrence rates decline with the length of time elapsed since the last infection. Continuous prophylactic antibiotic therapy for as long as 5 years is necessary to prevent recurrence of acute rheumatic fever. Several group A streptococcus vaccines are in development.[165]

Infective Endocarditis

Infective endocarditis is a general term used to describe infection and inflammation of the endocardium, especially the cardiac valves. There are approximately 15,000 new cases of infective endocarditis per year in the United States that account for approximately 1 in 1000 admissions to the hospital. Bacteria are the most common cause of infective endocarditis, especially streptococci, staphylococci and enterococci. Other causes include viruses, fungi, rickettsia, and parasites. Infective endocarditis was once a lethal disease, but morbidity and mortality diminished significantly with the advent of antibiotics and improved diagnostic techniques (Box 32-3).

BOX 32-3 RISK FACTORS FOR INFECTIVE ENDOCARDITIS

- Acquired valvular heart disease (especially mitral valve prolapse)
- Implantation of prosthetic heart valves
- Congenital lesions associated with highly turbulent flow (e.g., ventricular septal defect)
- Previous attack of infective endocarditis
- Intravenous drug use
- Long-term indwelling intravenous catheterization (e.g., for pressure monitoring, feeding, hemodialysis)
- Implantable cardiac pacemakers
- Heart transplant with defective valve

PATHOPHYSIOLOGY. The pathogenesis of infective endocarditis requires at least three critical elements (Figure 32-36):

1. Endocardial damage. Trauma, congenital heart disease, valvular heart disease, and the presence of prosthetic valves are the most common risk factors for endocardial damage that leads to infective endocarditis. Turbulent blood caused by these abnormalities usually affects the atrial surface of atrioventricular valves or the ventricular surface of semilunar valves. Endocardial damage exposes the endothelial basement membrane, which contains a type of collagen that attracts platelets and thereby stimulates sterile thrombus formation on the membrane. This causes an inflammatory reaction (nonbacterial thrombotic endocarditis).
2. Blood-borne microorganism adherence to the damaged endocardial surface. Bacteria may enter the bloodstream during injection drug use, trauma, dental procedures that involve manipulation of the gingiva, cardiac surgery, genitourinary procedures and indwelling catheters in the presence of infection, or gastrointestinal instrumentation, or they may spread from uncomplicated upper respiratory or skin infections. Bacteria adhere to the damaged endocardium using adhesins.
3. Formation of infective endocardial vegetations (Figure 32-37). Bacteria infiltrate the sterile thrombi and accelerate fibrin formation by activating the clotting cascade. These vegetative lesions can form anywhere on the endocardium but usually occur on heart valves and surrounding structures. Although endocardial tissue is constantly bathed in antibody-containing blood and is surrounded by scavenging monocytes and polymorphonuclear leukocytes, bacterial colonies are inaccessible to host defenses because they are embedded in the protective fibrin clots. Embolization from these vegetations can lead to abscesses and characteristic skin changes, such as petechiae, splinter hemorrhages, Osler nodes, and Janeway lesions.

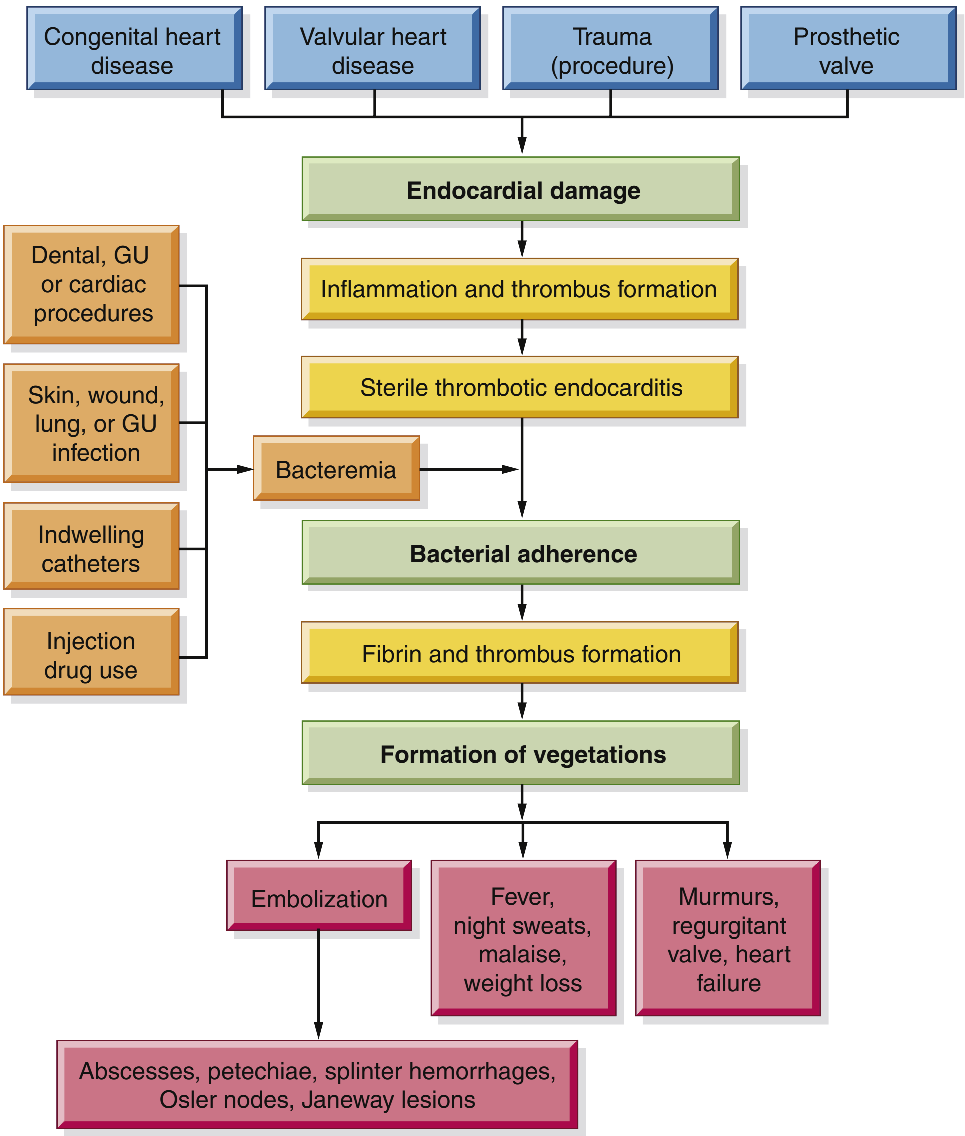

FIGURE 32-36 Pathogenesis of Infective Endocarditis.

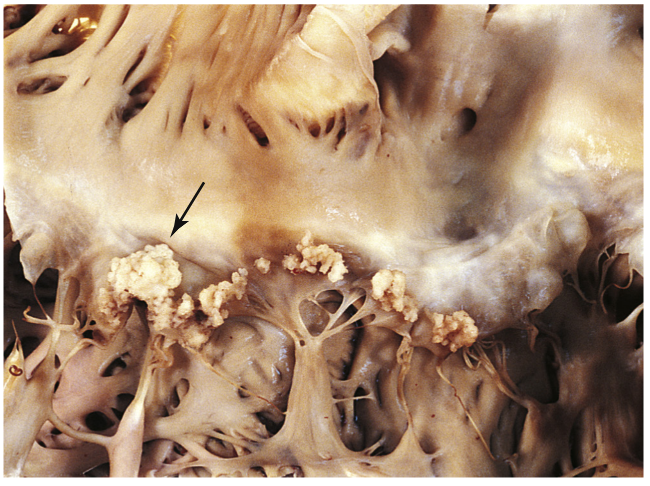

FIGURE 32-37 **Bacterial Endocarditis of Mitral Valve.** Lesion *(arrow)* in combination with old rheumatic valvulitis. (From Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

CLINICAL MANIFESTATIONS. Infective endocarditis may be acute, subacute, or chronic. It causes varying degrees of valvular dysfunction and may be associated with manifestations involving several organ systems (lungs, eyes, kidneys, bones, joints, CNS), making diagnosis exceedingly difficult. Signs and symptoms of infective endocarditis are caused by infection and inflammation, systemic spread of microemboli, and immune complex deposition. The "classic" findings are fever; new or changed cardiac murmur; and petechial lesions of the skin, conjunctiva, and oral mucosa.[170] Characteristic physical findings include Osler nodes (painful erythematous nodules on the pads of the fingers and toes) and Janeway lesions (nonpainful hemorrhagic lesions on the palms and soles). Other manifestations include weight loss, back pain, night sweats, and heart failure. CNS, splenic, renal, pulmonary peripheral arterial, coronary and ocular emboli may lead to a wide variety of signs and symptoms. Sudden onset of severely debilitating symptoms indicates acute disease.

EVALUATION AND TREATMENT. The criteria for the diagnosis of infective endocarditis include persistent bacteremia, new heart murmurs, vascular complications, and appropriate electrocardiographic and echocardiographic findings.[171] If emboli are suggested, organ scans can be performed to confirm their presence. Antimicrobial therapy is generally given for 4 to 6 weeks, beginning with intravenous and ending with oral administration.[170,171] In some cases two different antibiotics are given simultaneously to eliminate the offending microorganism and prevent the development of drug resistance. Other drugs may be necessary to treat left heart failure secondary to valvular dysfunction, and surgical intervention to repair or replace the valve may be required.[171]

In the past, individuals with valvular heart disease received prophylactic antibiotics for dental, genitourinary, or gastrointestinal procedures to prevent infective endocarditis; however, evidence has shown that the risk of endocarditis is low in most individuals. For example, infective endocarditis resulting from dental procedures in individuals with mitral valve prolapse is estimated at only 1 case per 1.1 million dental procedures.[5] In 2008 the recommendations were changed such that only "high risk" individuals (history of infective endocarditis, prosthetic valves, cyanotic congenital heart disease, heart transplant with valvular defect) receive antibiotic prophylaxis, and only in the setting of gingival procedures or in the presence of documented acute gastrointestinal or genitourinary infection.[158]

Cardiac Complications in Acquired Immunodeficiency Syndrome

Individuals infected with HIV and resultant acquired immunodeficiency syndrome (AIDS) are at risk for numerous cardiac complications. Pericardial effusion and left heart failure are the most common complications of HIV infection. Other conditions include cardiomyopathy, myocarditis, tuberculous pericarditis, infective and nonbacterial endocarditis, heart block, pulmonary hypertension, and non-antiretroviral drug-related cardiotoxicity. Malignancies, such as lymphoma and Kaposi sarcoma, are often seen in individuals with AIDS and can affect the heart. Furthermore, treatment with combination antiretroviral therapy (cART) can cause hyperlipidemia and atherosclerotic disease.

MANIFESTATIONS OF HEART DISEASE

Heart Failure

Heart failure is defined as the pathophysiologic condition in which the heart is unable to generate an adequate cardiac output such that there is inadequate perfusion of tissues or increased diastolic filling pressure of the left ventricle, or both, so that pulmonary capillary pressures are increased. It is estimated that nearly 10% of Americans older than age 65 have symptomatic heart failure and approximately 20% of asymptomatic individuals older than age 40 have some evidence of myocardial dysfunction.[5] Ischemic heart disease and hypertension are the most important predisposing risk factors. Other risk factors include age, obesity, diabetes, renal failure, valvular heart disease, cardiomyopathies, myocarditis, congenital heart disease, and excessive alcohol use. Numerous genetic polymorphisms have been linked to an increased risk for heart failure, including genes for cardiomyopathies, myocyte contractility, and neurohumoral receptors. Genetic changes in kinases, phosphatases, and cellular calcium cycling are being explored. Most causes of heart failure result in dysfunction of the left ventricle (systolic and diastolic heart failure). The right ventricle also may be dysfunctional, especially in pulmonary disease (right ventricular failure). Finally, some conditions cause inadequate perfusion despite normal or elevated cardiac output (high-output failure).

Types

Left Heart Failure (Congestive Heart Failure). **Left heart failure,** commonly called **congestive heart failure,** is categorized as heart failure with reduced ejection fraction (systolic heart failure) or heart failure with preserved ejection fraction (diastolic heart failure). These two types of heart failure can occur together in one individual or singly.

Heart Failure with Reduced Ejection Fraction (HFrEF) (Systolic Heart Failure). **Heart failure** with reduced ejection fraction (systolic heart failure) is defined as an ejection fraction of <40% and an inability of the heart to generate an adequate cardiac output to perfuse vital tissues.[5a] Cardiac output depends on the heart rate and stroke volume. Stroke volume is influenced by three major factors: contractility, preload, and afterload (see Chapter 31). Contractility is reduced by diseases that disrupt myocyte activity. Myocardial infarction is the most common cause of decreased contractility; other causes include myocarditis and cardiomyopathies. Secondary causes of decreased contractility, such as myocardial ischemia and increased myocardial workload, contribute to inflammatory, immune, and neurohumoral changes (activation of the SNS and RAAS) that mediate a process called ventricular remodeling. **Ventricular remodeling** results in disruption of the normal myocardial extracellular structure with resultant dilation of the myocardium and causes progressive myocyte contractile dysfunction over time (Figure 32-38). When contractility is decreased, stroke volume falls, and left ventricular end-diastolic volume (LVEDV) increases. This causes dilation of the heart and an increase in preload.

Preload, or LVEDV, increases with decreased contractility or when there is an excess of plasma volume (intravenous fluid

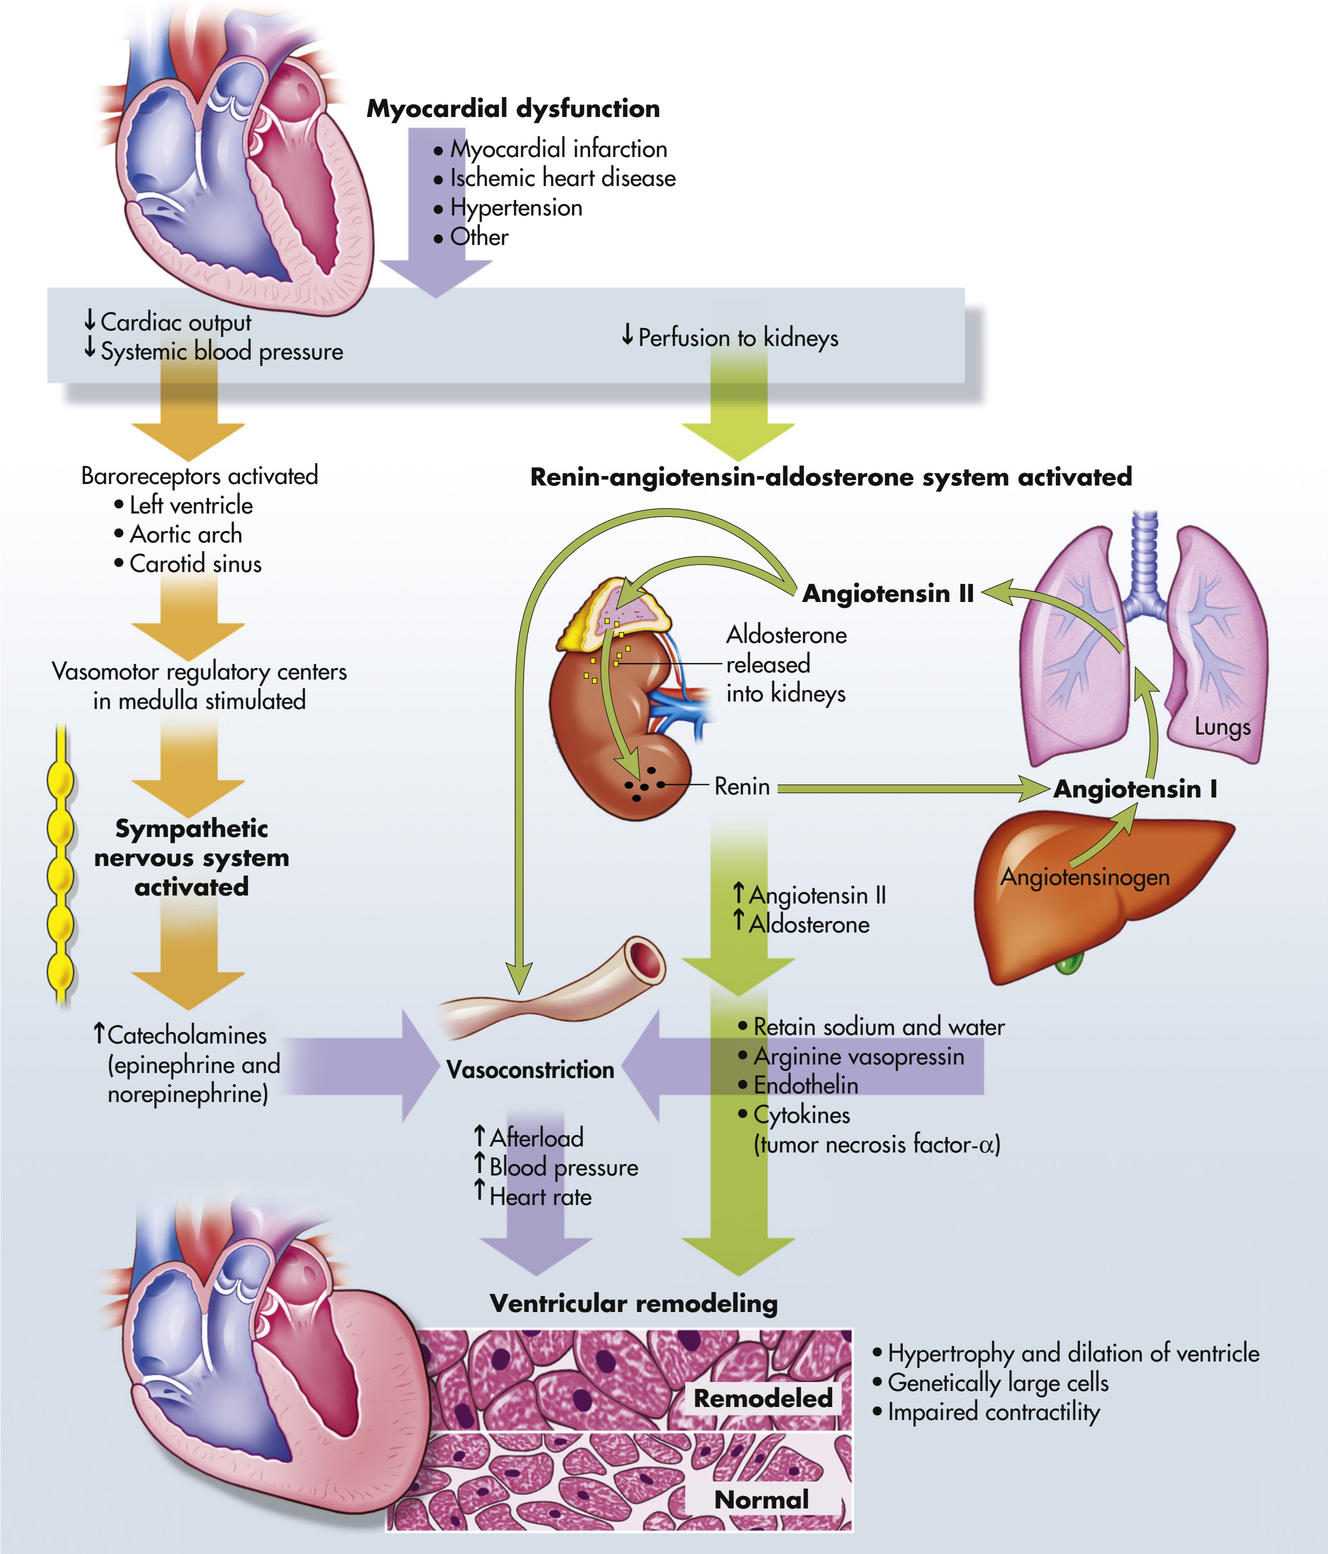

FIGURE 32-38 **Pathophysiology of Ventricular Remodeling.** Myocardial dysfunction activates the renin-angiotensin-aldosterone and sympathetic nervous systems, releasing neurohormones (angiotensin II, aldosterone, catecholamines, and cytokines). These neurohormones contribute to ventricular remodeling. (Redrawn from Carelock J, Clark AP: *Am J Nurs* 101[12]:27, 2001.)

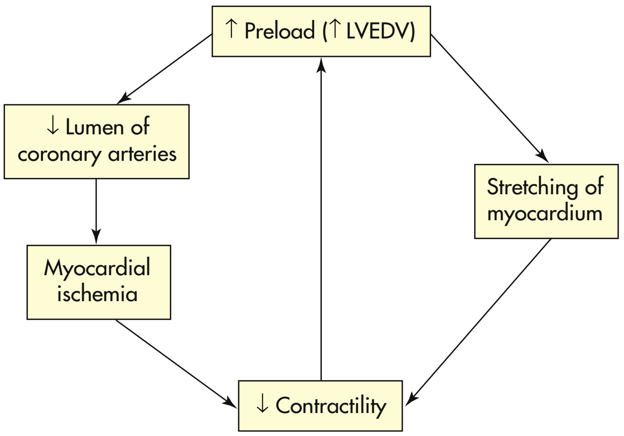

FIGURE 32-39 The Effect of Elevated Preload on Myocardial Oxygen Supply and Demand. *LVEDV,* Left ventricular end-diastolic volume.

administration, renal failure, mitral valvular disease). Increases in LVEDV can actually improve cardiac output up to a certain point, but as preload continues to rise, it causes a stretching of the myocardium that eventually can lead to dysfunction of the sarcomeres and decreased contractility (Figure 32-39).

Increased afterload is most commonly a result of increased peripheral vascular resistance (PVR), such as that seen with hypertension (Figure 32-40). Nearly 75% of cases of heart failure have antecedent hypertension.[5] Although much less common, it also can be the result of aortic valvular disease. With increased PVR, there is resistance to ventricular emptying and more workload for the left ventricle, which responds with hypertrophy of the myocardium. This process differs from the physiologic myocyte response to increased workload (exercise) in which the workload is intermittent rather than sustained, resulting in an increase in muscle mass but no distortion of the cardiac architecture.[172] Sustained afterload leads to pathologic hypertrophy mediated by angiotensin II and catecholamines. This pathologic increase in muscle mass results in an increase in oxygen and energy demand. The myocardium consumes a huge amount of metabolic energy and relies on the efficient production of ATP. This production of ATP depends on the myocytes getting enough fuel, having adequate mitochondrial function, and using an effective creatine kinase system. When demand for energy is greater than the ability of these systems to supply the necessary ATP, contractility of the myocardium is compromised. An energy-starved state develops that further contributes to changes in the myocytes themselves and ventricular remodeling that significantly impairs contractility and therefore ventricular function (see Figure 32-38).[173] Remodeling also results in the deposition of collagen between the myocytes, which can disrupt the integrity of the muscle, decrease contractility, and make the ventricle more likely to dilate and fail.[174] Weakness of the cardiac muscle due to hypertension-induced hypertrophy is called hypertensive hypertrophic cardiomyopathy.

As cardiac output falls, renal perfusion diminishes with activation of the RAAS, which acts to increase PVR and plasma volume, thus increasing afterload and preload further. In addition, baroreceptors in the central circulation detect the decrease in

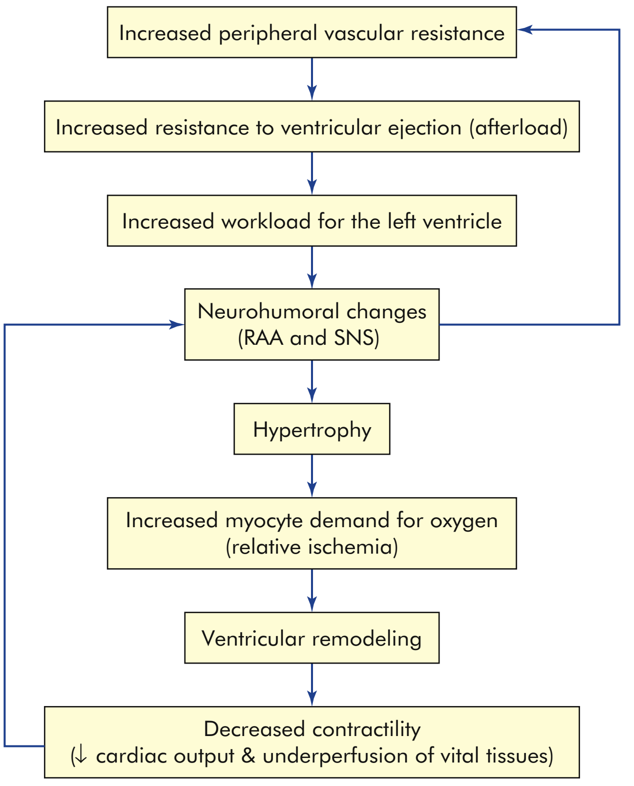

FIGURE 32-40 The Role of Increased Afterload in the Pathogenesis of Heart Failure. *RAA,* Renin angiotensin aldosterone, *SNS,* sympathetic nervous system.

perfusion and stimulate the SNS to cause yet more vasoconstriction and to cause the hypothalamus to produce antidiuretic hormone. This vicious cycle of decreasing contractility, increasing preload, and increasing afterload causes progressive worsening of left heart failure (Figure 32-41).

In addition to these hemodynamic interactions, systolic congestive heart failure is characterized by a complex constellation of neurohumoral, inflammatory, and metabolic processes:

1. *Catecholamines.* Sympathetic nervous system activation initially compensates for a decrease in cardiac output by increasing heart rate and peripheral vascular resistance. However, catecholamines cause numerous deleterious effects on the myocardium, including direct toxicity to myocytes, induction of myocyte apoptosis, myocardial remodeling, down-regulation of adrenergic receptors, facilitation of dysrhythmias, and potentiation of autoimmune effects on the heart muscle.
2. *RAAS*
   a. Angiotensin II (Ang II). Activation of the RAAS causes not only increases in preload and afterload but also direct toxicity to the myocardium (see Figure 32-38). Ang II mediates remodeling of the ventricular wall, contributing to sarcomere death, loss of the normal collagen matrix, and interstitial fibrosis. This leads to decreased contractility, changes in myocardial compliance, and ventricular dilation.
   b. Aldosterone. Aldosterone not only causes salt and water retention by the kidney but also contributes to

myocardial fibrosis, autonomic dysfunction, and dysrhythmias. It also has been implicated in endothelial dysfunction and prothrombotic effects.[175]

3. *Arginine vasopressin.* Arginine vasopressin is also known as antidiuretic hormone and causes both peripheral vasoconstriction and renal fluid retention. These actions exacerbate hyponatremia and edema in heart failure.
4. *Natriuretic peptides.* Atrial and BNPs are increased and may have some protective effect by decreasing preload; however, their compensatory mechanisms are inadequate in heart failure.[176]
5. *Inflammatory cytokines*
   a. Endothelial hormones. Endothelin is a potent vasoconstrictor and is associated with a poor prognosis in individuals with heart failure.
   b. TNF-α and IL-6. TNF-α is elevated in heart failure and contributes to myocardial hypertrophy and remodeling.[177,178] It down-regulates the synthesis of the vasodilator nitric oxide (NO), induces myocyte apoptosis, and may contribute to weight loss and weakness in individuals with heart failure (cardiac cachexia). IL-6 also is elevated in individuals with severe heart failure and cardiogenic shock and may contribute to further deleterious immune activation.

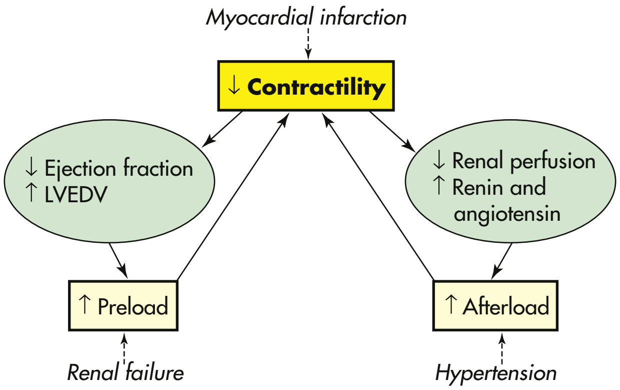

FIGURE 32-41 **The Vicious Cycle of Systolic Heart Failure.** Although the initial insult may be one of primary decreased contractility (e.g., myocardial infarction), increased preload (e.g., renal failure), or increased afterload (e.g., hypertension), all three factors play a role in the progression of left heart failure. *LVEDV,* Left ventricular end-diastolic volume.

6. *Myocyte calcium transport.* Calcium transport into, out of, and within myocytes is critical to normal contractile function. Changes in calcium ion channels, intracellular transport mechanisms in the sarcoplasmic reticulum, and calcium cycling have all been implicated in decreased myocardial contractility and heart failure.[179]
7. *Insulin resistance and diabetes.* Insulin resistance is a likely contributor to, as well as complication of, heart failure. Insulin resistance causes abnormal myocyte fatty acid metabolism and generation of ATP, which contributes to decreased myocardial contractility and remodeling[180] (see What's New? Metabolic Changes in Heart Failure). Heart failure activates the SNS and RAAS, which contribute to insulin resistance. Diabetes contributes to heart failure through disturbed calcium metabolism, oxidative stress, changes in fatty acid and glucose metabolism, and mitochondrial dysfunction. In addition, receptors on myocytes for damaging advanced glycation end-products (RAGE) (see Chapter 22) are up-regulated in injuries to the heart, including ischemia and reperfusion injury. Measurement of levels of RAGE in plasma or serum may correlate with the degree of heart failure.[181] Unfortunately, many of the new medications used to treat diabetes and insulin resistance have deleterious side effects on cardiac functioning; however, newer agents that modify fatty acid metabolism and insulin activity are being explored.[182]

The interaction of these metabolic, neurohumoral, and inflammatory processes results in a gradual decline in myocardial function. Pathologically, the heart muscle exhibits progressive changes in myocyte myofilaments, decreased contractility, myocyte apoptosis and necrosis, abnormal fibrin deposition in the ventricle wall, myocardial hypertrophy, and changes in the ventricular chamber geometry. These changes reduce myocardial function and cardiac output and lead to increased morbidity and mortality. These discoveries have led to the routine use of ACE inhibitors, aldosterone blockers, and beta-blockers in the management of heart failure, which has

WHAT'S NEW?

Metabolic Changes in Heart Failure

The heart is the largest consumer of energy in the body and relies on the efficient production of adenosine triphosphate (ATP). The heart has very little capacity for energy storage. In the failing heart, increased demand for oxygen and energy is coupled with a decreased ability to use fatty acids as an energy source. As a result, there is activation of several genes that alter the ability of myoctyes to use lipids and glucose as fuel sources, the most studied of which are the peroxisome proliferator-activated receptor (PPAR) family of genes. These genes control fatty acid oxidation and are of particular importance in heart failure associated with insulin resistance and diabetes. Energy starvation and high levels of catecholamines associated with heart failure lead to altered fatty acid oxidation and decreased effective ATP generation and use. This results in decreased myocardial contractility and structural changes in the myocardium (remodeling). Increasing knowledge of these mechanisms has led to the exploration of potential therapies for heart failure. For example, PPAR agonists have been shown to enhance fatty acid oxidation, improve endothelial cell function, and decrease myocardial fibrosis and hypertrophy in animal models of heart failure. Unfortunately currently available PPAR-gamma agonists (thiazolidinediones) are contraindicated in worsening heart failure because of increased fluid retention at the renal tubule. Many new potential pharmacologic interventions are under investigation, including trimetazidine, a partial fatty-acid-oxidation inhibitor that may decrease hospitalization for cardiac causes, improve clinical symptoms and cardiac function, and reduce left ventricular remodeling in people with CHF.

WHAT'S NEW?

Brain Natriuretic Peptide and Heart Failure

Brain natriuretic peptide (BNP) is produced and released in response to pressure and volume overload of the cardiac chambers. This occurs in both systolic and diastolic heart failure (HF). BNP causes arterial and venous dilation, natriuresis, and suppression of the renin-angiotensin-aldosterone system and the sympathetic nervous system. BNP inhibits myocardial fibrosis and hypertrophy and enhances diastolic function. There are currently four uses for BNP: three are measures of serum levels of endogenous BNP and one is a therapeutic use for exogenous BNP:

1. *Diagnosis of heart failure:* Significantly elevated serum levels of BNP have a sensitivity ranging from 93% to 98% in diagnosing heart failure in symptomatic patients, and negative predictive values ranging from 92% to 98%, demonstrating BNP ability to rule out heart failure. BNP also can be used to diagnose diastolic heart failure.
2. *Prognosis in HF:* Serum levels of BNP are correlated with the American Heart Association/American College of Cardiology class of heart failure morbidity and mortality, and risk for future acute exacerbations.
3. *Monitoring treatment of HF:* Serum levels of BNP-guided treatment of heart failure reduced total cardiovascular events, mortality, and hospital readmission with heart failure.
4. *Treatment of HF:* Approved in August 2001 by the U.S. Food and Drug Administration, nesiritide is the first of a new class of drugs, human B-type natriuretic peptide (hBNP); it is manufactured from *Escherichia coli* using recombinant deoxyribonucleic acid (DNA) technology. Intravenous administration of nesiritide (recombinant BNP) also improves preload and contractility; however, results of this therapy have been mixed and a new natriuretic peptide (ularitide) is being evaluated. In a limited number of studies, human recombinant ANP (hANP) has been shown to improve pulmonary capillary wedge pressure and cardiac output, but not mortality.

Data from Florea VG, Anand IS: *Heart Fail Clin* 8(2):207–224, 2012; Gassanov N et al: *Eur J Clin Pharmacol* 68(3):223–230, 2012; Januzzi JL Jr: *Arch Cardiovasc Dis* 105(1):40–50, 2012; Kobayashi D et al: *Can J Cardiol* 28(1):102–199, 2012; Richards AM, Troughton RW: *Clin Chem* 58(1):62–71, 2012; Saremi A, Gopal D, Maisel AS: *Exp Rev Cardovasc Ther* 10(2):191–203, 2012; Sato Y, Fujiwara H, Takatsu Y: *J Cardiol* 59(1):1–7, 2012.

resulted in significant decreases in morbidity and mortality.[137] Individuals selected for use of these medications may soon be facilitated through the use of pharmacogenetics that can identify those genotypes most likely to respond favorably to specific treatment options.[183]

EVALUATION. The clinical manifestations of HFrEF are the result of pulmonary vascular congestion and inadequate perfusion of the systemic circulation. Individuals experience dyspnea, orthopnea, cough of frothy sputum, fatigue, decreased urine output, and edema. Physical examination often reveals pulmonary edema (cyanosis, inspiratory crackles, pleural effusions), hypotension or hypertension, an S_3 gallop, and evidence of underlying CAD or hypertension.[184] An ECG and serum troponin should be obtained to evaluate for acute ischemia. A chest x-ray should be obtained to assess heart size and evidence of pulmonary congestion, and echocardiography, to confirm decreased cardiac output and cardiomegaly.[5a] Invasive catheterization to monitor hemodynamics or to document underlying coronary disease may be needed. Serum BNP levels should be measured to assist in diagnosing heart failure and to give some insight into its severity and response to treatment[5a,185] (see What's New? Brain Natriuretic Peptide and Heart Failure). Numerous other biomarkers are emerging that may aid in the diagnosis and management of heart failure.[186]

Management of HFrEF is aimed at interrupting the worsening cycle of decreasing contractility, increasing preload, and increasing afterload, as well as blocking the neurohormonal mediators of myocardial toxicity.[187] The acute onset of left heart failure is most often the result of acute myocardial ischemia and must be managed in conjunction with the underlying coronary disease. Oxygen, nitrates, and morphine administration improve myocardial oxygenation and help relieve coronary spasm while lowering preload through systemic venodilation. Diuretics reduce preload and are the mainstay of therapy. Intravenous inotropic drugs, such as dobutamine and milrinone, increase contractility and can help raise the blood pressure in hypotensive individuals; however, long-term use is associated with a high mortality.[188] Calcium-sensitizing inotropic drugs (e.g., levosimendan) have shown promise for acute heart failure in selected individuals.[189] ACE inhibitors (which reduce preload and afterload) and intravenous beta-blockers (which reduce myocardial demand) have been found to reduce mortality but must be used with caution in hypotensive individuals. Intravenous administration of nesiritide (recombinant BNP) also improves preload and contractility; however, results of this therapy have been mixed and new natriuretic peptides (human recombinant ANP and ularitide) are being evaluated.[190,191] Individuals with severe systolic failure because of myocardial ischemia may benefit from acute coronary bypass or PCI. Those with refractory hypotension may be supported with the intra-aortic balloon pump (IABP) until they can be taken safely to the operating room; the IABP is positioned in the aorta just distal to the aortic valve and is inflated during diastole to improve coronary perfusion and deflated during systole to reduce afterload.

Management of **chronic left heart failure** also relies on increasing contractility and reducing preload and afterload. In all patients with reduced ejection fraction, ACE inhibitors and beta blockers are indicated to reduce mortality.[5a,137] Salt restriction, loop diuretics, and aldosterone-blockers such as spironolactone and eplerenone are effective in reducing preload and improving outcomes.[192,193] ACE inhibitors reduce preload and afterload and have been shown to significantly reduce mortality in chronic left heart failure. ARBs do not improve morbidity or mortality in individuals with heart failure and should be used only in those who do not tolerate ACE inhibitors.[194] Beta-blockers, especially some of the newer drugs, such as bisoprolol, improve symptoms and increase survival.[195] Catheter-based renal sympathetic denervation is

WHAT'S NEW?

Gene Therapy for Heart Failure

The effectiveness and safety of recent gene therapy trials for heart failure have led to an explosion of interest in these innovative methods for restoring cardiac function. The most studied of the potential gene targets include sarcoendoplasmic reticulum calcium ATPase (SERCA2a) and S100A1, which affect intracellular myocyte calcium handling. Another exciting target is adenylyl cyclase 6 (AC6), the enzyme catalyzing cAMP formation and beta-adrenergic receptor function. Other targets include SDF1/CXCR4 complex, which promotes homing of stem cells to infarcted myocardium, microRNAs, and genes that code for critical neurohumoral factors, including insulin-like growth factor-1 (IGF-1), growth hormone, and B-type natriuretic peptide. Gene delivery vectors fall into one of two categories: nonviral or viral. Nonviral gene delivery vectors are safe and have minimal immunogenicity, but do not appear to be efficient at delivering the genes to the tissues. Viral vectors are more efficient at delivering genes to cells, but safety concerns persist. Today the viruses most widely used for cardiovascular gene transfer are adenovirus, sendai virus, and adeno-associated virus (AAV). These viruses exhibit fairly good cardiotropism, and various methods are being explored for delivering these gene vectors most efficiently to the myocardium, including antegrade or retrograde coronary infusion, intravenous infusion, direct myocardial injection, and pericardial injection. It is clear that the future will reveal many new and potentially lifesaving gene therapies for individuals with intractable heart failure.

being explored for heart failure.[196] The inotropic drug digoxin may be considered in some individuals, especially those with atrial fibrillation. Statins are not indicated for the treatment of heart failure unless other comorbid conditions (e.g., CAD) are present. Anticoagulants and antithrombotics may be indicated in selected individuals, particularly those with intracardiac thrombi or atrial fibrillation. Although many individuals with left heart failure die suddenly from dysrhythmias, prophylactic administration of antidysrhythmics has not been shown to improve survival. In individuals with sustained ventricular tachycardia, amiodarone or ICDs are indicated. Cardiac resynchronization therapy is proving to be an important modality in selected individuals.[197] Coronary bypass surgery or PCI may improve perfusion to ischemic myocardium (hibernating myocardium) and improve cardiac output. Other types of surgical intervention that improve ventricular geometry may be considered. Heart transplant may be the only remaining option. Experimental therapies, including gene and stem cell therapies, are being explored[198,199] (see What's New? Gene Therapy for Heart Failure).

Diastolic Heart Failure. **Diastolic heart failure** (also called heart failure with preserved ejection fraction) can occur singly or along with systolic heart failure. Isolated diastolic heart failure is defined as pulmonary congestion despite a normal stroke volume and cardiac output. It is the cause of approximately 50% of all cases of left heart failure and is more common in women. The major causes of diastolic dysfunction include hypertension-induced myocardial hypertrophy and myocardial ischemia with resultant ventricular remodeling. Hypertrophy and ischemia cause a decreased ability of the myocytes to actively pump calcium from the cytosol, resulting in impaired relaxation. Other causes include aortic valvular disease, mitral valve disease, pericardial diseases, and cardiomyopathies. Diabetes also increases the risk for diastolic dysfunction. Like systolic heart failure, diastolic failure is characterized by sustained activation of the RAAS and the SNS.

Two areas of pathophysiologic changes in the ventricle have been identified in diastolic dysfunction: decreased compliance of the left ventricle and abnormal diastolic relaxation (lusitropy). Decreased ventricular compliance has been linked to changes in myocardial structure such as that seen with molecular alterations in collagen, which forms the extracellular matrix for myocytes. Another recently identified structural change is because of abnormalities in an intracellular protein component of the myocyte cytoskeleton called titin. Abnormal lusitropy is caused by changes in calcium transport from myocytes and may be related to the activity of sarcoplasmic reticulum–calcium adenosine triphosphatase (ATPase).[200] The resultant noncompliant and poorly lusitropic ventricle cannot accept filling with blood without significant resistance and an increase in wall tension. Thus HFpEF occurs because a normal LVEDV is associated with an increased LVEDP. The resultant increase

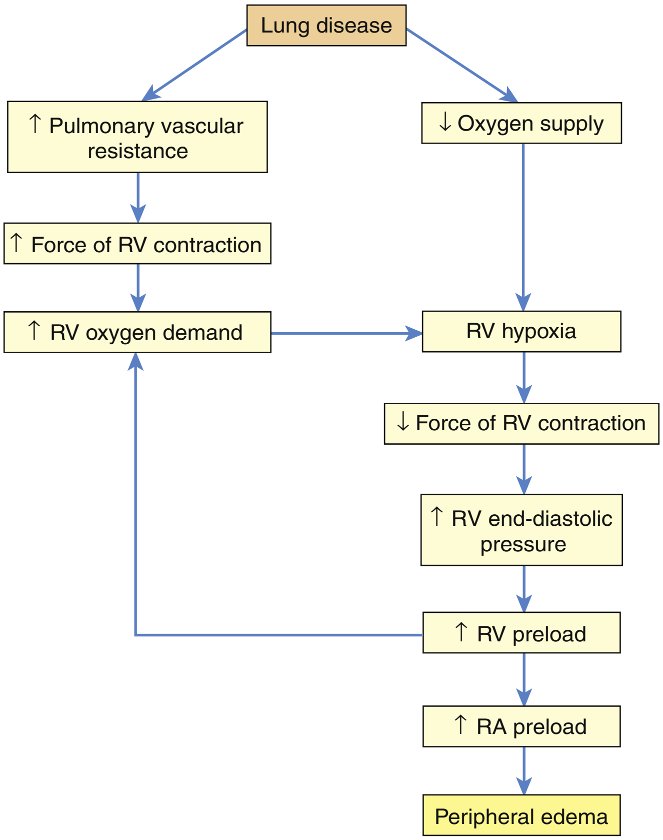

FIGURE 32-42 **Right Heart Failure (Cor Pulmonale) Caused By Lung Disease.** The presence of peripheral edema in cor pulmonale is caused by lung disease. *RA,* Right atrial; *RV,* right ventricular.

in left atrial pressure is then reflected back into the pulmonary circulation and results in pulmonary edema. The increase in pressure is made worse when ventricular filling is rapid so symptoms worsen with tachycardia (e.g., with exercise).

Individuals with diastolic dysfunction most often present with dyspnea on exertion and fatigue. If diastolic dysfunction is severe, there may be evidence of pulmonary edema (inspiratory crackles on auscultation, pleural effusions). Pulmonary hypertension and right ventricular failure may develop.[201] Late in diastole, atrial contraction with rapid ejection of blood into the noncompliant ventricle may give rise to an S_4 gallop. Electrocardiography often reveals evidence of left ventricular hypertrophy, and chest x-ray shows pulmonary congestion without cardiomegaly (Table 32-11).There also may be evidence of underlying coronary disease, hypertension, or valvular disease. Diagnosis is based on three factors: signs and symptoms of heart failure, normal left ventricular ejection fraction, and evidence of diastolic dysfunction. The diagnosis is initially made by echocardiography, which demonstrates poor ventricular filling with normal ejection fractions.[202] Management is aimed at improving ventricular relaxation and prolonging diastolic filling times to reduce diastolic pressure. Physical training (aerobic and weight training) improves endurance and quality of life.[203] Beta-blockers, ACE inhibitors, ARBs, and aldosterone blockers have been used with varying success,[204,205] however current guidelines focus on treating hypertension or valvular disease.[5a] Inotropic drugs are not indicated in isolated diastolic heart failure because contractility and ejection fraction are not affected. Outcomes for individuals with HFpEF can be as poor as those with systolic heart failure, and there has been little improvement in prognosis despite numerous new treatment trials.

Right Heart Failure. **Right heart failure** is defined as the inability of the right ventricle to provide adequate blood flow into the pulmonary circulation at a normal central venous pressure. It most often results from left heart failure when the increase in left ventricular filling pressure that is reflected back into the pulmonary circulation is severe enough.[206] As pressure in the pulmonary circulation rises, the resistance to right ventricular emptying increases. The right ventricle is poorly prepared to compensate for this increased workload and will dilate and fail. When this happens, pressure will rise in the systemic venous circulation, resulting in jugular venous distention, peripheral edema, and hepatosplenomegaly. Treatment relies on management of the left ventricular dysfunction as just outlined. When right heart failure occurs in the absence of left heart failure, it is caused most commonly by pulmonary hypertension resulting from diffuse hypoxic pulmonary disease such as chronic obstructive pulmonary disease (COPD), cystic fibrosis, and ARDS[207] (Figure 32-42). The mechanisms for this type of right ventricular dysfunction *(cor pulmonale)* are discussed in Chapter 35. Finally, right heart failure can result from right ventricular MI, cardiomyopathies, and pulmonic valvular disease.

High-Output Failure. **High-output failure** is the inability of the heart to adequately supply the body with blood-borne nutrients, despite adequate blood volume and normal or elevated myocardial contractility. In high-output failure the

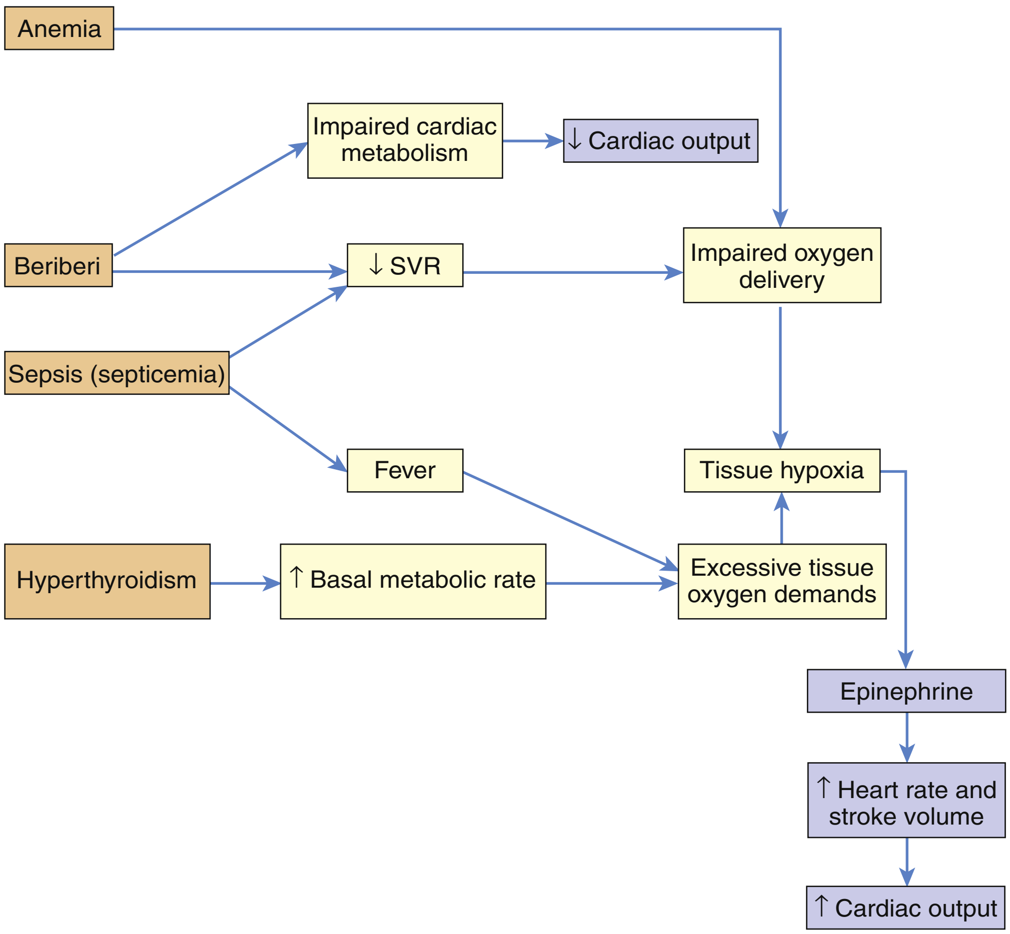

FIGURE 32-43 High-Output Failure. *SVR,* Systemic vascular resistance.

heart increases its output but the body's metabolic needs are still not met. Common causes of high-output failure are anemia, septicemia, hyperthyroidism, and beriberi (Figure 32-43).

Anemia decreases the oxygen-carrying capacity of the blood (see Chapter 28). Metabolic acidosis occurs as the body's cells switch to anaerobic metabolism (see Chapter 3). In response to metabolic acidosis, heart rate and stroke volume increase in an attempt to circulate blood faster. If anemia is severe, however, even maximum cardiac output does not supply the cells with enough oxygen for metabolism.

In septicemia, disturbed metabolism, bacterial toxins, and the inflammatory process cause systemic vasodilation and fever. Faced with a lowered systemic vascular resistance (SVR) and an elevated metabolic rate, cardiac output increases to maintain blood pressure and prevent metabolic acidosis. In overwhelming septicemia, however, the heart may not be able to raise its output enough to compensate for vasodilation. Body tissues show signs of inadequate blood supply despite a very high cardiac output.

Hyperthyroidism accelerates cellular metabolism through the actions of elevated levels of thyroxine from the thyroid gland. This may occur chronically (thyrotoxicosis) or acutely (thyroid storm). Because the body's increased demand for oxygen threatens to cause metabolic acidosis, cardiac output increases. If blood levels of thyroxine are high and the metabolic response to thyroxine is vigorous, even an abnormally elevated cardiac output may be inadequate.

In the United States, beriberi (thiamine deficiency) usually is caused by malnutrition secondary to chronic alcoholism. Beriberi actually causes a mixed type of heart failure. Thiamine deficiency impairs cellular metabolism in all tissues, including the myocardium. In the heart, impaired cardiac metabolism leads to insufficient contractile strength. In blood vessels, thiamine deficiency leads mainly to peripheral vasodilation, which decreases SVR. Heart failure ensues as decreased SVR triggers increased cardiac output, which the impaired myocardium is unable to deliver. The strain of demands for increased output in the face of impaired metabolism may deplete cardiac reserves until low-output failure begins.

Dysrhythmias

A dysrhythmia, or arrhythmia, is a disturbance of heart rhythm. Normal heart rhythms are generated by the SA node and travel through the heart's conduction system, causing the atrial and ventricular myocardium to contract and relax at a regular rate that is appropriate to maintain circulation at various levels of physical activity (see Chapter 31). Dysrhythmias range in severity from occasional "missed" or rapid beats to serious disturbances that impair the pumping ability of the heart, contributing to heart failure and death. Dysrhythmias can be caused by either an abnormal rate of impulse generation (Table 32-12) by the SA node or other pacemaker or the abnormal conduction of impulses (Table 32-13) through the heart's conduction system, including the myocardial cells themselves.

TABLE 32-12 **DISORDERS OF IMPULSE FORMATION**

TYPE	ELECTROCARDIOGRAM	EFFECT	PATHOPHYSIOLOGY	TREATMENT
Sinus bradycardia	P rate 60 or less PR interval normal QRS for each P	Increased preload Decreased mean arterial pressure	Hyperkalemia: slows depolarization Vagal hyperactivity: unknown Digoxin toxicity common Late hypoxia: lack of adenosine triphosphate (ATP)	If hypotensive, treat cause and support Follow with sympathomimetics, cardiotonics, and pacer Vagolytics
Simple sinus tachycardia	P rate 100-150 PR interval normal QRS for each P	Decreased filling times Decreased mean arterial pressure Increased myocardial demand	Catecholamines; rise in resting potential, calcium influx Fever: unknown Early failure and lung disease: hypoxic cell metabolism Hypercalcemia	Oxygen, bed rest Calcium channel blockers
Premature atrial contractions (PACs) or beats*	Early P waves that may have changed morphology PR interval normal QRS for each P	Occasional decreased filling time and mean arterial pressure	Electrolyte disturbances: decrease in all phases Hypoxia and elevated preload: cell membrane disturbances Hypercalcemia	Treat underlying cause Digoxin
Sinus dysrhythmias	Rate varies P-P regularly irregular, short with inspiration, long with exhalation PR interval normal QRS for each P	Variable filling times Variable mean arterial pressures Variable oxygen demand	Unknown Common in young children and young adults	None
Atrial tachycardia (includes premature atrial tachycardia if onset is abrupt)	P rate 151-250P morphology may differ from sinus PPR interval normal P:QRS ratio variable	Decreased filling time Decreased mean arterial pressure Increased myocardial demand	Same as PACs: leads to increased atrial automaticity, atrial reentry Digoxin toxicity: common	Control ventricular rate Digoxin, calcium channel blockers, vagus stimulation Pace to override
Atrial flutter*	P rate 251-300; morphology may vary from sinus P PR interval usually not observable P:QRS ratio variable	Decreased filling time Decreased mean arterial pressure	Same as atrial tachycardia Aging	Same as atrial tachycardia Synchronous cardioversion
Atrial fibrillation*	P rate >300 and usually not observable No PR interval QRS rate variable and rhythm irregular	Same as atrial flutter	Same as atrial tachycardia Aging	Same as atrial tachycardia
Idiojunctional rhythm	P absent or independent QRS normal, rate 41-59, regular	Decreased cardiac output from loss of atrial contribution to ventricular preload Decreased mean atrial pressure as a result of bradycardia	Atrial and sinus bradycardia, standstill, or block	Same as sinus bradycardia
Junctional bradycardia	P absent or independent QRS normal, rate 40 or less	Same as idiojunctional rhythm	Same as idiojunctional rhythm Vagal hyperactivity	Same as sinus bradycardia
Premature junctional contractions (PJCs) or beats	Early beats without P waves QRS morphology normal	Decreased cardiac output from loss of atrial contribution to ventricular preload for that beat	Hyperkalemia (6-5.4 mEq/L) Hypercalcemia, hypoxia, and elevated preload (see PACs)	Same as PACs
Accelerated junctional rhythm	P absent or independent QRS morphology normal, rate 60-99	Decreased cardiac output from loss of atrial contribution to ventricular preload	Same as PJCs	Same as PACs
Junctional tachycardia	P absent or independent QRS morphology normal, rate 100 or more	Decreased cardiac output from loss of atrial contribution to ventricular preload Increased myocardial demand because of tachycardia	Same as PJCs	Same as PACs
Idioventricular rhythm†	P absent or independent QRS >0.11 and rate 20-39	Same as idiojunctional rhythm	Sinus, atrial, and junctional bradycardia, standstill, or block	Same as sinus bradycardia

Continued

TABLE 32-12 DISORDERS OF IMPULSE FORMATION—cont'd

TYPE	ELECTROCARDIOGRAM	EFFECT	PATHOPHYSIOLOGY	TREATMENT
Ventricular bradycardia†	P absent or independent QRS >0.11 and rate 60-21	Same as idiojunctional rhythm	Same as idiojunctional rhythm	Same as sinus bradycardia
Agonal rhythm/ electromechanical dissociation†	P absent or independent QRS >0.11 and rate 20 or less	Absent or barely present cardiac output and pulse Not compatible with life	Depolarization and contraction not coupled: electrical activity present with little or no mechanical activity Usually caused by profound hypoxia	Vigorous pharmacology aimed at restoring rate and force Usually ineffective May attempt to pace
Ventricular standstill or asystole†	P absent or independent QRS absent	No cardiac output Not compatible with life	Profound ischemia, hyperkalemia, acidosis	Same as agonal rhythm, including electrical defibrillation
Premature ventricular contractions (PVCs) or depolarizations*	Early beats with P waves QRS occasionally opposite in deflection from usual QRS	Same as PJCs	Same as PJCs, including aging and induction of anesthesia Impulse originates in cell outside normal conduction system and spreads through intercalated disks	Pharmacology to change thresholds, refractory periods; reduce myocardial demand, increase supply Removal of cause
Accelerated ventricular rhythm	P absent or independent QRS >0.11 and rate 41-99	Same as accelerated junctional rhythm	Same as PVCs	Same as PVCs
Ventricular tachycardia†	P absent or independent QRS >0.11 and rate 100 or more	Same as junctional tachycardia	Same as PVCs	Same as PVCs, including electrical cardioversion
Ventricular fibrillation†	P absent QRS >300 and usually not observable	Same as ventricular standstill	Same as PVCs Rapid infusion of potassium	Same as PVCs including electrical defibrillation

*Most common in adults.
†Life threatening in adults.

TABLE 32-13 DISORDERS OF IMPULSE CONDUCTION

TYPE	ELECTROCARDIOGRAM	EFFECT	PATHOPHYSIOLOGY	TREATMENT
Sinus block	Occasionally absent P, with loss of QRS for that beat	Occasional decrease in cardiac output Increase in preload for the following beat	Local hypoxia, scarring of intra-atrial conduction pathways, electrolyte imbalances Increased atrial preload	Conservative Usually do not progress in severity Pharmacologic treatment includes vagolytics, sympathomimetics, pacing
First-degree block*	PR interval >0.2	None	Same as sinus block Hyperkalemia (>7 mEq/L) Hypokalemia (<3.5 mEq/L) Formation of myocardial abscesses in endocarditis	Conservative Discovery and correction of cause
Second-degree block, Mobitz I, or Wenckebach*	Progressive prolongation of PR interval until one QRS is dropped Pattern of prolongation resumes	Same as sinus block	Hypokalemia (<3.5 mEq/L) Faulty cell metabolism in atrioventricular (AV) node Severity increases as heart rate increases Supports theory that AV node is fatiguing Digoxin toxicity, beta-blockade Coronary artery disease (CAD), myocardial infarction (MI), hypoxia, increased preload, valvular surgery and disease, diabetes	Same as sinus block
Second-degree block or Mobitz II	Same as sinus block	Same as sinus block	Hypokalemia (<3.5 mEq/L) Faulty cell metabolism below AV node Antidysrhythmics, cyclic antidepressants CAD, MI, hypoxia, increased preload, valvular surgery and disease, diabetes	More aggressively than Mobitz I because block can progress to type III Pacemaker after pharmacologic treatment

TABLE 32-13 DISORDERS OF IMPULSE CONDUCTION—cont'd

TYPE	ELECTROCARDIOGRAM	EFFECT	PATHOPHYSIOLOGY	TREATMENT
Third-degree block[†]	P waves present and independent of QRS No observed relationship between P and QRS Always AV dissociation	Same as idiojunctional rhythm	Hypokalemia (<3.5 mEq/L) Faulty cell metabolism low in bundle of His MI, especially inferior wall, as nodal artery interrupted; results in ischemia of AV node	Pharmacologic until pacemaker inserted Temporary pacing if caused by inferior MI because ischemia usually resolves
Atrioventricular dissociation	P waves present and independent of QRS, but not always because of block (e.g., ventricular tachycardia) AV dissociation not always third-degree block	Decreased cardiac output from loss of atrial contribution to ventricular preload Variable effect on myocardial demand, depending on ventricular rate	May result from third-degree block or accelerated junctional or ventricular rhythm, or be caused by sinus, atrial, and junctional bradycardias	Treat according to cause Pacemaker or reducing rate of AV or ventricular discharge, or increasing rate of sinus or AV node discharge
Ventricular block	QRS >0.11 R-S-R' in V_1, V_2, V_5, V_6	None	Faulty cell metabolism in right and left bundle branches RBBB more common than LBBB because of dual blood supply to left bundle branch Congestive heart failure, mitral regurgitation, especially anterior MI, because of infarct of fascicles Left anterior hemiblock more common than left posterior hemiblock, since posterior fascicles have dual blood supply	Isolated right bundle branch block (RBBB) or left bundle branch block (LBBB) or hemiblock not treated If acute and/or associated with acute anterior MI, treated with permanent pacer and vigorous pharmacology
Aberrant conduction	QRS >0.11	None unless ventricular rate abnormalities present	Conduction of impulse through intercalated disks because conduction system transiently blocked because of hypoxia, electrolyte imbalances, digoxin toxicity, excessively rapid rates of discharge	Correct underlying cause
Preexcitation syndromes (Wolff-Parkinson-White and Lown-Ganong-Levine)	P present with QRS for each P PR interval >0.12 and QRS >0.11 because of presence of delta wave in PR interval	None	Congenital presence of accessory pathways (bundle of Kent and fiber of Mahaim) that conduct very rapidly and bypass the AV node, causing early ventricular depolarization in relation to atrial depolarization Prone (reason unknown) to tachycardias and atrial fibrillation that can result in very rapid ventricular rates	Aimed at lining up refractory periods of accessory pathway and AV node to prevent reentry May slow rate with pharmacology May surgically cut pathways
Ventricular block	QRS >0.11 R-S-R' in V_1, V_2, V_5, V_6	None	Faulty cell metabolism in right and left bundle branches RBBB more common than LBBB because of dual blood supply to left bundle branch Congestive heart failure, mitral regurgitation, especially anterior MI, because of infarct of fascicles Left anterior hemiblock more common than left posterior hemiblock, because posterior fascicles have dual blood supply	Isolated RBBB or LBBB or hemiblock not treated If acute and/or associated with acute anterior MI, treated with permanent pacer and vigorous pharmacology

SUMMARY REVIEW

Diseases of the Veins

1. Varicosities are areas of veins in which blood has pooled, usually in the saphenous veins. Varicosities may be caused by damaged valves as a result of trauma to the valve or by chronic venous distention involving gravity and venous constriction.
2. Chronic venous insufficiency is inadequate venous return over a long period that causes pathologic ischemic changes in the vasculature, skin, and supporting tissues.
3. Venous stasis ulcers follow the development of chronic venous insufficiency and probably develop as a result of the borderline metabolic state of the cells in the affected extremities.
4. DVT occurs in individuals who have venous stasis (immobility, age, left heart failure), spinal cord injury, vein wall damage (trauma, intravenous medications), or hypercoagulable states (pregnancy, oral contraceptives, malignancy, genetic coagulopathies).
5. DVT is often asymptomatic but may lead to fatal pulmonary emboli; prevention and careful assessment in individuals at risk are crucial.

Diseases of the Arteries

1. Hypertension is a sustained elevation of the systemic arterial blood pressure resulting from increases in cardiac output or total peripheral resistance, or both. Hypertension can be primary (without known cause) or secondary (caused by disease or drugs). Systolic hypertension is the most significant factor in causing target organ damage.
2. The risk factors for hypertension include a positive family history; male gender; advanced age; black race; obesity; high sodium intake; low potassium, calcium, and magnesium intake; diabetes mellitus; labile blood pressure; cigarette smoking; and heavy alcohol consumption.
3. Primary hypertension is the result of extremely complicated interactions of genetics and the environment mediated by a host of neurohumoral effects. These genes interact with diet, smoking, age, and the other risk factors to cause chronic changes in vasomotor tone and blood volume.
4. The most frequently cited theories of the pathogenesis of primary hypertension include overactivity of the SNS; overactivity of the RAAS; alterations in other neurohumoral mediators of blood volume and vasomotor tone such as ANP, BNP, and adrenomedullin; inflammation; a complex interaction involving insulin resistance and endothelial function; and obesity-related hormonal changes.
5. Clinical manifestations of hypertension result from damage of organs and tissues outside the vascular system. These include heart disease, renal disease, CNS problems, and retinal changes.
6. Hypertension is managed pharmacologically, using diuretics, adrenergic blockers, calcium channel blockers, ACE inhibitors, and Ang II receptor blockers. Nonpharmacologic methods include cessation of smoking, dietary modifications, and exercise.
7. Orthostatic hypotension is a drop in blood pressure that occurs on standing. The compensatory vasoconstriction response to standing is altered by a marked vasodilation and blood pooling in the muscle vasculature.
8. Orthostatic hypotension may be acute or chronic. The acute form is caused by a delay in the normal regulatory mechanisms. The chronic forms are secondary to a specific disease or are idiopathic.

SUMMARY REVIEW—cont'd

9. The clinical manifestations of orthostatic hypotension include fainting and may involve cardiovascular symptoms, as well as impotence and bowel and bladder dysfunction.
10. An aneurysm is a localized dilation of a vessel wall to which the aorta is particularly susceptible.
11. A thrombus is a clot that remains attached to a vascular wall.
12. An embolus is a mobile aggregate of a variety of substances that occludes the vasculature. Sources of emboli include thrombi, air, amniotic fluid, bacteria, fat, and foreign matter.
13. The most common sources of arterial thrombotic emboli from the heart are mitral and aortic valvular disease and atrial fibrillation. Tissues affected include the lower extremities, the brain, and the heart.
14. Emboli to the central organs cause tissue death in lungs, kidneys, and mesentery.
15. The generation of air emboli requires a connection between the vascular compartment and a source of air. These emboli cause ischemia and necrosis when a vessel is totally blocked.
16. Amniotic fluid may be forced into the bloodstream and generate an embolus during the labor and delivery of pregnancy.
17. Aggregates of bacteria in the vasculature may be large enough to form an embolus.
18. Fat emboli are caused mainly by trauma to the long bones, either through defective fat metabolism after trauma or through the release of fat globules from bone marrow exposed by fracture.
19. The introduction of foreign matter into the vasculature can occur with trauma and also can occur in a hospital setting in which intravenous and intra-arterial lines are being used.
20. Vasospastic disorders include Raynaud disease, involving arterioles of the extremities; variant angina, involving coronary arteries; and Buerger disease, involving arteries of the hands and feet.
21. Atherosclerosis is a form of arteriosclerosis and is the leading cause of coronary artery and cerebrovascular disease.
22. Atherosclerosis is an inflammatory disease that begins with endothelial injury and progresses through several stages to become a fibrotic plaque.
23. Traditional risk factors include age, family history, gender, smoking, dyslipidemia, hypertension, and diabetes.
24. Novel risk factors include elevated CRP, increased serum fibrinogen, oxidative stress, infection, and periodontal disease.
25. Once a plaque has formed it can rupture, resulting in thrombosis and vasoconstriction that leads to obstruction of the lumen and inadequate perfusion of distal tissues.
26. PAD is atherosclerosis of arteries that perfuse the limbs, especially the lower extremities.
27. PAD is often asymptomatic but can present with intermittent claudication (pain in leg on walking). Treatment includes risk factor reduction and antiplatelet therapy.
28. CAD is spasm or occlusion of the coronary arteries and is most often the result of atherosclerotic lesions that limit the flow of blood to the heart.
29. Many risk factors contribute to the onset and escalation of CAD, including advanced age, male gender (younger than age 60), hypertension, dyslipidemia (including elevated Lp[a]), diabetes mellitus, smoking, obesity, sedentary lifestyle, psychosocial factors, elevated CRP, and possibly infectious agents.
30. CAD results in an imbalance between coronary supply of blood and myocardial demand for oxygen and nutrients such that reversible myocardial ischemia or irreversible infarction may result.
31. Reversible myocardial ischemia presents clinically in several ways. Chronic coronary obstruction results in recurrent predictable chest pain called *stable angina.* Abnormal vasospasm of coronary vessels results in unpredictable chest pain called *Prinzmetal angina.* Myocardial ischemia that does not cause detectable symptoms is called *silent ischemia.*
32. Stable angina is evaluated by noninvasive techniques of assessing coronary flow with or without exercise (stress ECG, thallium, or SPECT). Management may include lifestyle changes, vasodilators, antithrombotics, PCI, or CABG surgery.
33. When there is sudden coronary obstruction because of thrombosis formation over a ruptured atherosclerotic plaque, the acute coronary syndromes result. Unstable angina causes reversible myocardial ischemia and is a harbinger of impending infarction. MI results when prolonged ischemia causes irreversible damage to the heart muscle. Sudden cardiac death can occur in any of the acute coronary syndromes.
34. Unstable angina occurs because of transient episodes of thrombotic vessel occlusion and vasoconstriction at the site of plaque damage, with return of perfusion before significant myocardial necrosis occurs. This must be managed aggressively with antithrombotic agents to prevent MI.
35. When coronary blood flow is interrupted for an extended period, myocyte necrosis occurs; this is called MI. Pathologically, there are two major types of myocardial infarction: subendocardial infarction and transmural infarction. In addition to myocyte necrosis, other changes in the heart with MI include hibernating, stunning, and remodeling of the myocardium.
36. Acute coronary syndromes are assessed by measuring serum enzymes, such as creatinine kinase and troponins, as well as looking for characteristic changes in the ECG. Those individuals at highest risk for complications present with ST-segment elevations on the ECG (STEMI) and require immediate intervention. Smaller subendocardial infarctions are not associated with ST-segment elevations (non-STEMI) but suggest that additional myocardium is still at risk for recurrent ischemia and infarction. Management may include thrombolytic drugs, antithrombotic drugs, vasodilators, PCI, or immediate surgery.

SUMMARY REVIEW—cont'd

37. Dysrhythmias, congestive heart failure, and sudden death are the most common complications of the acute coronary syndromes.

Disorders of the Heart Wall

1. Inflammation of the pericardium (pericarditis) may result from innumerable sources (infection, drug therapy, tumors). Pericarditis presents with symptoms that are physically troublesome, but in and of themselves they are not life threatening.
2. Fluid may collect within the pericardial sac (pericardial effusion). Cardiac function may be severely impaired if a large volume of fluid accumulates rapidly.
3. Cardiomyopathies are a diverse group of primary myocardial disorders that are poorly understood. The cardiomyopathies are categorized as dilated (congestive), restrictive (rigid and noncompliant), and hypertrophic (asymmetric). Size of the cardiac muscle walls and chambers may increase or decrease, depending on the type of cardiomyopathy, thereby altering contractile activity.
4. Hemodynamic integrity of the cardiovascular system depends to a great extent on properly functioning cardiac valves. Congenital or acquired disorders that result in stenosis or incompetence or both can structurally alter the valves.
5. Characteristic heart sounds, cardiac murmurs, and systemic complaints assist in determining which valve is abnormal. If severely compromised function exists, a prosthetic heart valve may be surgically implanted to replace the faulty one.
6. Mitral valve prolapse is a common finding, especially in young women. Although not grossly abnormal, the mitral valve leaflets do not position themselves properly during systole. Mitral valve prolapse may be a completely asymptomatic condition or it may result in severe subjective symptoms. Afflicted valves may be at greater risk for developing infective endocarditis.
7. Rheumatic fever is an inflammatory disease that results from a delayed autoimmune response to a streptococcal infection. The disorder usually resolves without sequelae if treated early.
8. Severe or untreated cases of rheumatic fever may progress to rheumatic heart disease, a potentially disabling cardiovascular disorder.
9. Infective endocarditis is a general term for infection and inflammation of the endocardium, especially the cardiac valves. A wide range of conditions predisposes one to the development of this disorder. In the mildest cases, valvular function may be slightly impaired by vegetations that collect on the valve leaflets. If infective endocarditis is left unchecked, severe valve abnormalities, chronic bacteremia, and systemic emboli may occur as vegetations break off the valve surface and travel through the bloodstream. Antibiotic therapy can limit the extent of this disease.
10. HIV is associated with cardiac abnormalities, including myocarditis, endocarditis, pericarditis, and cardiomyopathy. Left heart failure is the most common clinical manifestation.

Manifestations of Heart Disease

1. Heart failure is an inability of the heart to supply the metabolism with adequate circulatory volume and pressure.
2. Left heart failure can be categorized as systolic heart failure or diastolic heart failure.
3. Systolic heart failure is defined as an inability of the heart to generate an adequate cardiac output to perfuse vital tissue.
4. Cardiac output depends on the heart rate and stroke volume. Stroke volume is influenced by contractility, preload, and afterload. MI is the most common cause of decreased contractility. Myocardial ischemia results in ventricular remodeling that causes progressive myocyte contractile dysfunction over time.
5. Preload LVEDV is increased when there is decreased contractility or excess plasma volume.
6. Increased afterload is most commonly the result of increased peripheral vascular resistance. This increase in resistance decreases ventricular emptying and makes more workload for the left ventricle, resulting in hypertrophy and ventricular remodeling. The vicious cycle of decreasing contractility, increasing preload, and increasing afterload causes progressive worsening.
7. Neurohumoral mechanisms of CHF include abnormalities in the SNS, RAAS, arginine vasopressin, natriuretic peptides, inflammatory cytokines, and myocyte metabolism.
8. The clinical manifestations of left heart failure are the result of pulmonary vascular congestion and inadequate systemic perfusion.
9. Management of left heart failure relies on increasing contractility and reducing preload and afterload.
10. Diastolic heart failure can occur singly or with systolic heart failure. The major causes of diastolic dysfunction include hypertension-induced myocardial hypertrophy and ischemia with resultant ventricular remodeling.
11. Right heart failure can result from left heart failure and/or diffuse hypoxic pulmonary disease, such as COPD, cystic fibrosis, and ARDS (these mechanisms are discussed in Chapter 35).
12. High output failure is the inability of the heart to adequately supply the body with blood-borne nutrients despite adequate volume and normal or elevated myocardial contractility. Common causes are anemia, septicemia, hyperthyroidism, and beriberi.
13. A dysrhythmia (arrhythmia) is a disturbance of heart rhythm. Dysrhythmias range in severity from occasional missed beats or rapid beats to disturbances that impair myocardial contractility and are life threatening.
14. Dysrhythmias can occur because of an abnormal rate of impulse generation or the abnormal conduction of impulses.

• Review Questions and Answers

CHAPTER OUTLINE

Cardiovascular disease in children can be classified as congenital or acquired heart disease. Congenital heart disease is the most common. The diagnosis and management of congenital heart defects continue to improve with the use of fetal echocardiography, early interventional catheterization, and refined surgical repair. Acquired heart defects in children continue to present challenges to the practitioner; although guidelines for diagnosing acquired defects are available, work is needed in developing standards of treatment and long-term follow-up.

DEVELOPMENT OF THE CARDIOVASCULAR SYSTEM

Developmental Anatomy

Embryology

Cardiogenesis begins at approximately 3 weeks of gestation; however, most cardiovascular development occurs between the fourth and seventh weeks.[1] The heart arises from the mesenchyme and begins development as an enlarged blood vessel with a large lumen and a muscular wall (Figure 33-1, *A*). Initially, two lateral endocardial heart tubes fuse to form a single structure (Figure 33-1, *B*). During the fifth week of gestation, the midsection of this tube begins to grow faster than its ends. This single heart tube elongates and rotates to the right (D-loop formation), creating a bulboventricular loop by approximately the twenty-eighth day[1] (Figure 33-1, *C*). Also at this time the first fetal heart contractions occur. At this stage the primitive heart structures include a common atrium; common ventricle; the sinus venosus, which eventually evolves into the superior and inferior venae cavae; the bulbus cordis, which eventually evolves into the ventricular outflow tracts; and the truncus arteriosus, which eventually yields the main pulmonary artery (PA) and aorta (Figure 33-1, *D*). By the fourth week of gestation, cardiovascular septation, ventricular development, aortic arch evolution, and circulation begin.

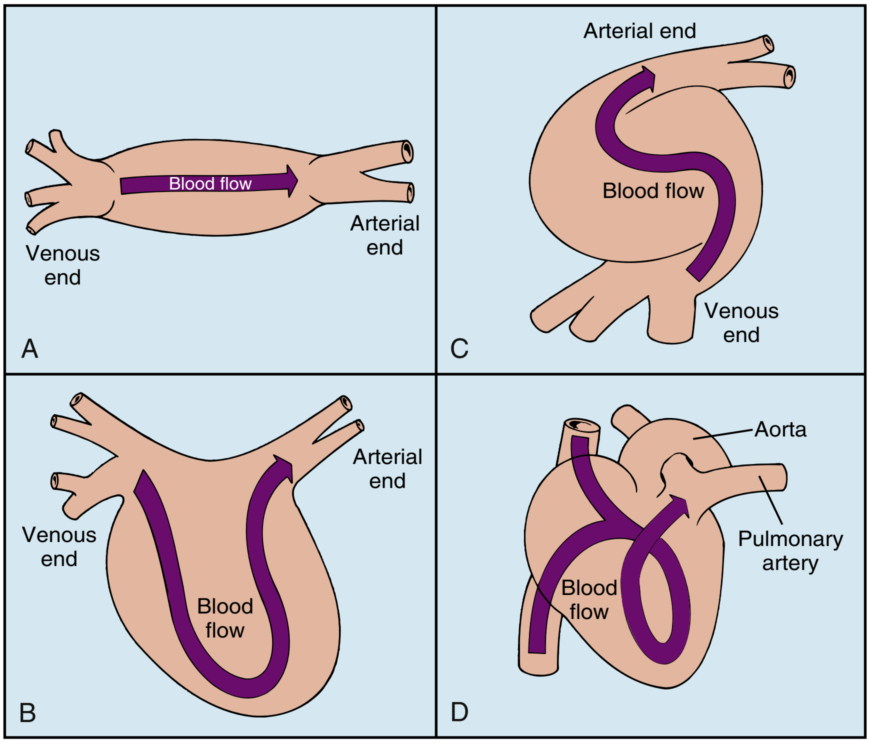

FIGURE 33-1 Embryologic Development of the Heart. **A,** The earliest heart structure consists of a muscular tube with a large lumen. About the fifth week of gestation, the tube, **B,** bulges and, **C,** twists until, **D,** the ends come together and fuse.

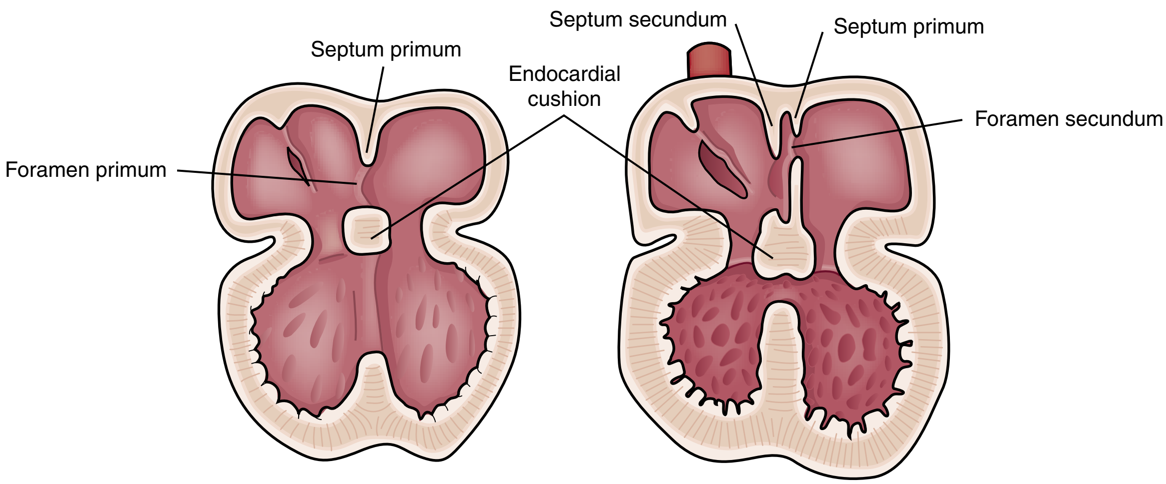

FIGURE 33-2 Development of the Cardiac Septa.

Cardiac Septation

Separation first begins when collections of mesenchymal cells cause the endocardial lining of the heart to bulge into the internal lumen. These changes, known as **endocardial cushions,** are instrumental in closing the lower portion of the atrial septum, dividing the atrioventricular (AV) canals into the right and left AV orifices, and forming the upper portion of the interventricular septum. Altered formation of the endocardial cushions can result in ostium primum atrial septal defects, inlet ventricular septal defects (VSDs), malformation of the AV valves, or a complete AV defect (also known as atrioventricular septal defect).[2]

Atrial septation begins when two thin membranelike structures, known as the **septum primum** and the **septum secundum,** grow toward the area of the endocardial cushions (Figure 33-2). The septum primum forms along the posterior wall of the common atrium and grows downward toward the center portion of the heart. The gap between the two structures, known as the **ostium primum,** normally closes by extensions from the endocardial cushions. At the time of closure, fenestrations or openings develop in the superior portion of the septum primum, creating the **ostium secundum.** Failure of the septum primum to fuse with the endocardial cushions results in an ostium primum defect in the atrial septum near the AV valve area.

The septum secundum is also a fenestrated, membranelike structure located anteriorly that grows toward the endocardial

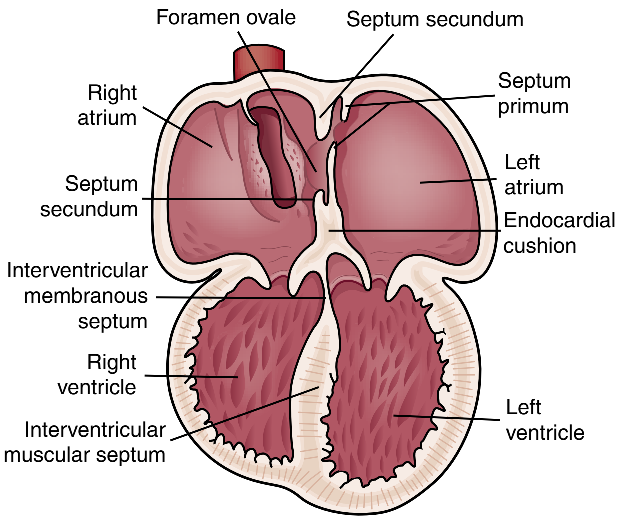

FIGURE 33-3 Septal Development of the Heart.

cushions. During fetal development this structure does not completely fuse with the endocardial cushions to achieve complete atrial septal closure. The nonfused septum secundum and ostium secundum result in the formation of a flapped orifice known as the **foramen ovale,** which allows the right-to-left shunting necessary for fetal circulation. Altered development in any of these structures can lead to an atrial septal defect.

Ventricular septation develops when the muscular ridge located at the apex, the endocardial tissue, and the bulbar ridges in the bulbus cordis fuse (Figure 33-3). Closure of the interventricular septum ensures communication between the right ventricle (RV) and the PA and between the left ventricle (LV) and the aorta. Further evolution of the endocardial tissue gives rise to the membranous ventricular septum and the AV valves. The conal portion of the ventricular septum that separates the aorta from the PA forms from the **bulbus cordis.**

When the single primitive heart tube begins to form the D-loop, the venous and arterial poles of the heart are fixed, resulting in torsion within the anterosuperior region of the loop, known as the *truncus arteriosus*. This torsion creates a spiral ridgelike structure or septum within the truncus arteriosus that divides it into the PA and the aorta. The semilunar valves evolve from tubercles after this division is complete.

Before this division occurs, however, two large arteries form at the distal end of the truncus arteriosus. Over time they give rise to a series of arterial vessels, collectively called the six aortic arches. By the fifth week of gestation, the first two pairs disappear and the third eventually evolves into the common carotid artery, the external carotid artery, and part of the internal carotid artery. The fourth pair of aortic arches will form part of the true aortic arch and the proximal segment of the right subclavian artery. The fifth pair disappears; however, the sixth pair yields the proximal and branch pulmonary arteries within the lung parenchyma and the ductus arteriosus.

Swellings in the conal region at the base of the main trunk separate the right ventricular outflow (pulmonary outflow) tract from the left ventricular outflow (aortic outflow) tract. The conus also contributes to complete closure of the interventricular septum, and normal reabsorption of the subaortic conal region ensures rotation of the great arteries so that the aorta is posterior and to the right of the PA and the PA is anterior and to the left of the aorta. Despite division of the truncus arteriosus and separation of the right and left outflow tracts, a communication exists between the aorta and the PA known as the **ductus arteriosus.**

In order to deliver maximally oxygenated blood to the developing brain, fetal circulation differs from the adult pattern by the presence of alternate pathways known as fetal shunts (Figure 33-4). Fetal oxygenation occurs in the placenta instead of the fetal lungs. The fetal lungs are not aerated, although the fetus does make breathing motions.

In utero the fetus receives blood carrying oxygen and nutrients from the placenta through the umbilical vein. Fetal arterial oxygen tension is much lower than that found in the postnatal period—approximately 20 to 30 torr (mmHg pressure). Yet, despite this hypoxemic state, tissue hypoxia does not occur because of high fetal cardiac output and high fetal hemoglobin levels. The blood travels to the liver, where a portion enters the portal and hepatic circulation; approximately half the flow is diverted away from the liver through the ductus venosus and into the inferior vena cava. Because the blood received from the inferior vena cava yields a higher pressure, blood entering the right atrium (RA) from the inferior vena cava is shunted through the foramen ovale and into the left atrium (LA) and is then pumped through the LV and into the aorta. Approximately two thirds of the blood flows to the head and upper extremities. Because this blood is mainly from the placenta, the brain and coronary arteries receive the blood with the highest oxygen concentration. The remaining blood flows into the descending aorta.

Less-saturated blood, with an oxygen tension of 15 to 19 torr, returns from the upper body, head, neck, and arms and travels from the superior vena cava into the RA. A small portion of this blood flows into the RV and out the PA and enters the nonfunctioning lungs. Most of the blood, however, bypasses the lungs by flowing through the ductus arteriosus and into the descending aorta. Blood from the descending aorta returns to the placenta through two umbilical arteries.[1]

The nonaerated lungs and low oxygen tension induce vasoconstriction, creating high pulmonary vascular resistance. This is transmitted to the right side of the heart and the PAs. Conversely, fetal systemic resistance is low because of the large-volume placenta and ductus arteriosus. Therefore, because blood flow follows the path of least resistance, high pulmonary resistance diverts most of the blood flow into the PA, through the ductus arteriosus, and into the aorta. From there it travels into the low-resistance placenta.

Transitional Circulation

At birth a series of circulatory changes occur that affect blood flow, vascular resistance, and oxygen tension. The most important change that takes place in the circulation is the shift of gas exchange from the placenta to the lungs. In addition, alterations in pressure and volume of blood flowing through the heart chambers functionally close the ductus arteriosus, ductus

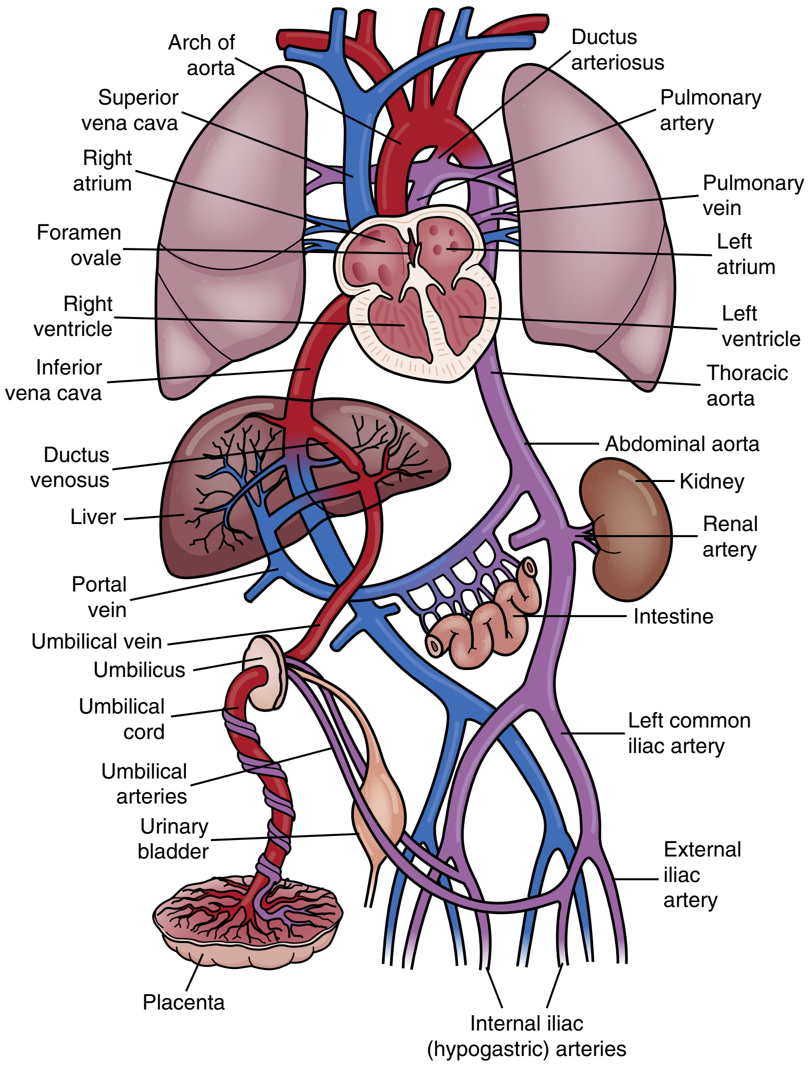

FIGURE 33-4 **Fetal Circulation.** Circulation of the fetus reflects the fact that oxygenation of fetal blood does not take place in the lungs, but rather in the placenta. Therefore, the pulmonary circulatory system is essentially "bypassed." Instead of traveling from the right heart to the lungs, as occurs after birth, most blood entering the right heart passes through the ductus arteriosus and into the systemic circulation.

venosus, and foramen ovale. A decrease of pulmonary vascular resistance and an increase of systemic vascular resistance lead to changes in the size and shape of the heart chambers.

Clamping of the umbilical cord and expansion of the lungs at birth shift gas exchange from the placenta to the lungs. Removal of the low-resistance placenta from circulation also causes an immediate increase in systemic vascular resistance to about twice that before birth. Conversely, pulmonary vascular resistance decreases because of expansion of the lungs, which result from the infant's respirations and exposure to more oxygen-rich blood.

Closure of Fetal Shunts

Once the umbilical cord is clamped, the umbilical arteries and vein, which comprise the cord, vasoconstrict and undergo fibrous changes. Therefore, blood flow through the ductus venosus falls instantly; absence of fetal shunting through this vessel usually occurs within the first 7 days of life. Once the ductus venosus closes, its remnants form the **ligamentum venosum,** or round ligament of the liver.

Increased pulmonary venous return and decreased inferior vena cava return cause functional closure of the foramen ovale within the first month of life. In the fetus the foramen ovale is held open by the blood flow from the higher-pressure right side, reflecting pulmonary vascular resistance, to the lower-pressure area on the left side of the heart, reflecting systemic vascular resistance. At birth the pressure gradients reverse (left atrial pressure exceeds right atrial pressure by a small degree), causing the valve flaps of the foramen ovale to close. Functional closure occurs by the adherence of these flaps to the atrial septum. Anatomic closure occurs within the first month of life after deposition of fibrin tissue and cell products permanently seals the flaps closed. Until this occurs, any condition that stimulates an increase in the right-sided pressures or causes dilation of the RA can reopen the foramen ovale. Conditions in which a patent foramen ovale may continue past the first month of life include pulmonary hypertension, RV failure, and tricuspid atresia.

The ductus arteriosus closes more gradually. Increased oxygen saturation in the systemic arterial blood is thought to be

the major stimulus causing vasoconstriction of the ductus arteriosus. In addition, a decrease in the amount of endogenous prostaglandins promoting dilation and the release of vasoactive substances stimulate further ductal closure. Vasoconstriction of the ductal medial smooth muscle shortens and thickens the intima of the ductal wall within 15 to 18 hours after birth. Permanent closure is complete 10 to 21 days after birth. Fibrous tissue adheres to the remaining structure, and the ductus arteriosus eventually evolves into the ligamentum arteriosum. Conditions that involve low arterial oxygen saturations, such as cyanotic heart disease, decreased medial muscle layer within the ductus, or increased levels of circulating vasodilating substances in the blood, may delay or prevent ductal closure.[3]

Postnatal Development

Compared to the adult, the infant's cardiopulmonary system is proportionally larger in relation to body surface area. The infant's heart points at a transverse angle, but as the lungs and heart mature, the heart shifts lower in the chest and is rotated at a more oblique angle. Unlike the adult heart, the newborn heart has RV dominance with a thickened RV wall. This is because of the high pulmonary vascular resistance in the fetal circulation that subjects the RV to high afterload, which in turn causes the right ventricular myocardium to become as thick and strong as the LV myocardium.

After birth the right ventricular myocardium becomes less dominant as pulmonary vascular resistance drops. As systemic vascular resistance increases, the left ventricular myocardium becomes thicker. By 1 month of age, the newborn's ventricles are approximately equal in weight. As the child grows, the heart size increases accordingly. The weight of the heart doubles during the first year of life and increases six times that by 9 years of age.[3]

Postnatal changes involve a rise in arterial oxygen tension and an increase in alveolar oxygenation that stimulates vasodilation, resulting in a decrease in pulmonary vascular resistance. During the first 2 to 9 weeks of life, the inner medial linings of the small pulmonary arterioles become thinner in response to decreased pulmonary arterial pressure. This increased diameter of the pulmonary vessels, along with further development of the pulmonary bed in response to lung growth, results in a decrease in pulmonary vascular resistance. By 2 months of age, pulmonary resistance may approximate adult levels. During the neonatal period the pulmonary vascular bed remains hyperactive. Adverse conditions, such as alveolar hypoxia, acidosis, and hypothermia, may trigger pulmonary vasoconstriction and lead to pulmonary hypertension.

Postnatal Hemodynamics

As stated, systemic vascular resistance begins to rise once the placenta is removed from the circulation. Normal levels in the infant range from approximately 10 to 15 Wood units × body surface area (in square meters) and gradually increase to 15 to 30 Wood units × body surface area (in square meters) by childhood.[4] Likewise, the systolic pressure is low in the full-term newborn (approximately 39 to 59 mmHg), reflecting the low systemic vascular resistance. As the systemic vascular resistance increases, the LV becomes more developed and the systolic pressure rises steadily until it equals adult levels once the child reaches puberty.

The heart rate of the newborn ranges from 100 to 180 beats/minute, which gradually decreases as the child grows. Similarly, the newborn's cardiac output is high, which is a reflection of the fetal circulation described earlier. Oxygen consumption doubles at birth; to maintain adequate oxygen delivery, the cardiac output also remains high. These changes, however, cause minimal cardiac reserve in the newborn. Additional stressors could increase oxygen demands and result in acute deterioration. By 2 months of age, oxygen consumption decreases by half. As the newborn grows, stroke volume steadily increases while the heart rate decreases, thus maintaining cardiac output.[2]

Postnatal Circulation

Postnatal circulation allows the lungs to oxygenate the venous blood and allows fully saturated blood to be delivered to the systemic circulation. Desaturated blood returning from the superior vena cava, inferior vena cava, and coronary veins enters the RA and is pumped to the RV through the tricuspid valve. The RV then pumps the blood through the pulmonic valve to the PA; the blood flows to the lungs, where it is oxygenated. The oxygenated blood returns from the lungs through the pulmonary veins and enters the LA, which pumps blood to the LV through the mitral valve. The LV then pumps blood through the aortic valve and into the aorta. The coronary arteries receive the saturated blood along with delivery to the systemic circulation.

CONGENITAL HEART DEFECTS

Congenital heart disease is the leading cause of death, excluding prematurity, during the first year of life.[5] It is estimated that as many as 35% of deaths caused by congenital heart defects occur in the first year of life and that one third of children born with congenital heart disease will die as a result of their cardiac disease (Box 33-1). There are more than 35 documented types

BOX 33-1 ENDOCARDITIS RISK

Until 2008 it was common to prescribe an antibiotic to be administered before dental, gastrointestinal, or genitourinary procedures for almost all children with congenital heart defects. This practice started in the 1950s and continued until a committee of the American Heart Association (AHA) reviewed all of the major literature related to infectious endocarditis (IE), a serious and sometimes fatal condition in which the heart valves become infected with bacteria. The AHA committee concluded that: (1) IE is more likely to result from bacteremia from daily activities, such as brushing one's teeth, than from procedures; (2) prophylaxis was not effective in preventing IE; (3) there are significant risks to giving antibiotics; and (4) good oral health and hygiene is most important in the prevention of IE. Current recommendations suggest administration of prophylactic antibiotics before dental procedures only to the most high-risk children and adults: those with prosthetic cardiac valves, cyanotic congenital heart disease, repaired heart defects for the first 6 months after the procedure, repaired heart defects with certain residual defects, and those with previous IE. The best thing we as healthcare providers can teach our patients and their parents is to take excellent care of their teeth!

Data from Nishimura RA et al: *Circulation* 118(8):887–896, 2008.

of congenital heart defects, and the frequency of occurrence in the United States is on the rise. Although researchers have not determined the reason for this increase, one explanation is that it may be the result of improved methods of detection.[6]

The underlying cause of congenital heart disease is known in only 10% of cases. Several factors place the fetus at risk for developing congenital heart disease, including prenatal, environmental, and genetic factors. Among the prenatal factors are maternal rubella, maternal insulin-dependent diabetes, maternal alcoholism, maternal age (older than 40 years), maternal phenylketonuria, and maternal hypercalcemia (Table 33-1). The use of some drugs during pregnancy is associated with an above-average incidence of congenital heart disease. Examples of these drugs include thalidomide, lithium, phenytoin (Dilantin), and warfarin. The incidence of heart defects also has been found to be higher in stillbirths, spontaneous abortions, and low-birth-weight or small-for-gestational-age infants.[2] In general, the likelihood of unaffected parents having a child with congenital heart disease is about 1% with a recurrence risk of 2% to 6%.

Genetic factors also have been implicated in the development of congenital heart disease, although the mechanism of causation is often multifactorial. Recent progress, accelerated through the Human Genome Project, has resulted in the rapid identification of some genes causing congenital heart disease.[5]

ETIOLOGY. The etiology of most congenital heart disease is unknown. Early epidemiologic studies report a multifactorial influence to be the cause of up to 90% of cardiac anomalies, with a recurrence rate of 2% to 6%.[2] Associated risk factors include maternal, gestational, and familial conditions. (Maternal risk factors are discussed in the previous section.) Exposure to teratogens in utero also may be a risk factor. Likewise, fetal exposure to active maternal infections, such as rubella, herpesvirus, coxsackievirus B5, and cytomegalovirus, may be a risk.

Chromosomal aberrations account for about 6% of all congenital heart defects (Table 33-2). Many genetic and hereditary diseases are associated with congenital heart defects, although the mechanism of causation is unknown (Table 33-3). As many as 50% of infants with trisomy 21 have a congenital heart defect, either an AV canal defect or a VSD. Extracardiac defects are noted in as many as 35% of infants with cardiac lesions. Prospective studies using chromosomal analysis have suggested that congenital cardiac malformations may be the result of a single gene defect.[5]

Because of improved screening methods, surgical interventions, and management, children with congenital heart defects are now surviving into adulthood and bearing children of their own. Studies report a 5% to 15% incidence of congenital heart disease in offspring of a parent having a congenital heart lesion. If two siblings have a congenital cardiac anomaly, the recurrence risk is 9%, and if three siblings have a congenital cardiac anomaly, the rate jumps to a 50% chance that the next child also will have a cardiovascular malformation.

TABLE 33-1 ENVIRONMENTAL FACTORS AND ASSOCIATED CONGENITAL HEART DEFECTS

CAUSE	TYPE OF CONGENITAL HEART DEFECT
Infection	
Intrauterine	Patent ductus arteriosus (PDA), pulmonary stenosis, coarctation of aorta
Systemic viral	PDA, pulmonary stenosis, coarctation of aorta
Rubella	PDA, pulmonary stenosis, coarctation of aorta
Coxsackie B5	Endocardial fibroelastosis
Herpesvirus Cytomegalovirus (HCMV)	Can infect endothelial cells and vascular endothelium
Radiation	Studies of cancer survivors reveal radiation can cause atherosclerosis; myocardial, endocardial, and pericardial disease; conduction disturbances; and endothelial vessel disease
Metabolic Disorders	
Diabetes	Ventricular septal defect (VSD), cardiomegaly, transposition of the great vessels
Phenylketonuria (PKU)	Coarctation of the aorta, PDA
Hypercalcemia	Supravalvular aortic stenosis, pulmonic stenosis; aortic hyperplasia
Drugs	
Thalidomide	No specific lesion
Alcohol	Tetralogy of Fallot, atrial septal defect (ASD), VSD
Lithium	Exact effect not known
Phenytoin	Embryonic dysrhythmia and valvular heart disease
Warfarin	ASD and PDA
Peripheral Conditions	
Increased maternal age	VSD, tetralogy of Fallot (relationship unclear)
Antepartal bleeding	Various defects (relationship unclear)
Prematurity	PDA, VSD
High altitude	PDA, ASD (increased incidence)

Classification of Congenital Heart Defects and Associated Conditions

There are more than 35 different types of congenital anomalies that can be classified into 4 categories based on blood flow pattern: (1) lesions increasing pulmonary blood flow; (2) lesions decreasing pulmonary blood flow; (3) obstructive lesions, in which right- or left-sided outflow tract obstructions curtail or prohibit blood flow out of the heart; and (4) mixing lesions, in which desaturated blood and saturated blood mix within the chambers or great arteries of the heart (Table 33-4). By classifying lesions in this way, the clinical manifestations, as well as associated sequelae, are more predictable.

Associated conditions and their clinical manifestations are lesion dependent. The two most common conditions associated with congenital heart disease are heart failure (HF) and hypoxemia. Lesions increasing pulmonary blood flow include

TABLE 33-2 GENETIC FACTORS AND CONGENITAL HEART DEFECTS

CHROMOSOMAL ABERRATIONS OR SYNDROME	INCIDENCE OF DEFECTS	TYPE OF DEFECT
Trisomy 13	80%	Ventricular septal defect (VSD), atrial septal defect (ASD), patent ductus arteriosus (PDA), anomalous pulmonary venous connection, bicuspid aorta, overriding aorta
Trisomy 18	90%	VSD, PDA, patent foramen ovale, bicuspid aortic valve, dextrocardia
Down syndrome	12-44%	Endocardial cushion defects, VSD, PDA, ASD, transposition of great vessels, tetralogy of Fallot, persistent truncus arteriosus, coarctation of aorta, endocardial fibroelastosis
Cri du chat syndrome	20%	PDA, mixed defects
Turner syndrome	20-40%	Coarctation of aorta, pulmonary stenosis, subaortic and aortic stenosis, PDA, septal defects

Data from Doyle EF, Rutkowski M: *Cardiovasc Clin* 2:1, 1970.

TABLE 33-3 DISORDERS COEXISTENT WITH CONGENITAL HEART DEFECTS

DISORDER	ASSOCIATED CARDIOVASCULAR DEFECT
Connective Tissue Disorders	
Marfan syndrome	Aortic or mitral regurgitation, aortic aneurysm
Hurler syndrome	Pseudoatherosclerosis
Hunter syndrome	Pseudoatherosclerosis, hypertension
Osteogenesis imperfecta	Incompetent aortic valve
Complex Syndromes	
Kartagener syndrome	Dextrocardia
Holt-Oram syndrome	Atrial septal defect (ASD), ventricular septal defect (VSD)
Ellis–van Creveld syndrome	Defect or absence of atrial septum
Laurence-Moon-Biedl syndrome	Tetralogy of Fallot, single ventricle, transposition of aorta
Inborn Errors of Metabolism	
Pompe disease	Cardiomegaly, left heart failure, supraventricular tachycardia
Homocystinuria	Thromboembolic episodes, pulmonic and aortic regurgitation
Phakomatosis	
Neurofibromatosis (von Recklinghausen disease)	Hypertension, pheochromocytoma
von Hippel–Lindau disease	Hypertension, pheochromocytoma
Sturge-Weber-Dimitri disease	Anomalies of carotid and meningeal arteries
Vascular Malformations	
Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia)	Atrioventricular fistula, telangiectasia
Milroy disease (lymphedema)	Hypoplasia or lymphatic vessels

Data from Doyle EF, Rutkowski M: *Cardiovasc Clin* 2:1, 1970.

defects that allow blood flow to shunt from the high-pressure left side to the lower-pressure right side, resulting in pulmonary congestion. Lesions that cause decreased pulmonary blood flow are generally complex and result in cyanosis. Obstructive lesions increase the pressure needed to eject the blood from the ventricles. The two types of obstructive lesions are right-sided lesions that may result in hypoxemia and cyanosis, and left-sided lesions that may result in HF. Mixing lesions are variable in their physiology and clinical manifestations.

Heart Failure

Heart failure (HF), sometimes called congestive heart failure (CHF), is classified as an acquired condition. HF occurs when the heart is unable to maintain sufficient cardiac output to meet the metabolic demands of the body. HF can occur as the result of decreased myocardial function or excessive metabolic demands. The most common causes of HF in infancy and childhood are cardiomyopathy or the result of poor ventricular function. Table 33-5 lists the congenital heart defects that cause HF by age. Pulmonary overcirculation from large left-to-right shunts (mixing) is often called CHF but is not usually associated with decreased ventricular function and failure to meet metabolic demands. However, the clinical manifestations are similar, such as failure to thrive (FTT), tachypnea, tachycardia, and respiratory tract infections.

PATHOPHYSIOLOGY. In general, the pathophysiologic mechanisms of HF in infants and children are very similar to those

TABLE 33-4 CLASSIFICATION OF CONGENITAL HEART DEFECTS

CLASSIFICATION	SHUNT DIRECTION	PRESENTATION	SPECIFIC DEFECTS
Lesions increasing pulmonary blood flow	Left to right	Acyanotic congestive heart failure	Patent ductus arteriosus, atrial septal defect, ventricular septal defect, complete atrioventricular canal defect
Lesions decreasing pulmonary blood flow	Right to left	Cyanotic	Tetralogy of Fallot, tricuspid atresia
Obstructive lesions*	None	Low cardiac output Shock	Coarctation of the aorta, hypoplastic left heart syndrome, aortic stenosis, pulmonary stenosis
Mixed lesions†	Variable	Variable	Transposition of the great arteries, total anomalous pulmonary venous connection, truncus arteriosus

*If patent ductus arteriosus closes, newborns with hypoplastic left heart syndrome, coarctation of the aorta, or critical aortic stenosis will present with shock. Newborns with aortic stenosis or pulmonary stenosis may have only mild symptoms depending on severity of stenosis.
†Transposition of the great arteries and truncus arteriosus will present with cyanosis as patent ductus arteriosus closes. Total anomalous pulmonary venous connection usually presents with congestive heart failure.

TABLE 33-5 CONGENITAL HEART DEFECTS CAUSING HEART FAILURE

AGE	CONGENITAL HEART DEFECT
Time of birth	Hypoplastic left heart syndrome Volume overload caused by tricuspid regurgitation (rare) Arteriovenous fistula
Birth to 1 week	Hypoplastic left heart syndrome Aortic atresia Transposition of the great vessels with ventricular septal defect (VSD) Coarctation of the aorta Total anomalous pulmonary venous connection (TAPVC) with obstruction Patent ductus arteriosus (PDA) in premature infants
First 4 weeks	Coarctation of the aorta TAPVC Large left-to-right shunt caused by VSD, PDA in premature infants Tricuspid atresia All previously mentioned defects
4 to 6 weeks	Transposition of the great vessels with VSD Large left-to-right shunt caused by endocardial cushion defect
6 weeks to 6 months	VSD
6 months	Endocardial fibroelastosis Persistent truncus arteriosus with large left-to-right shunt

in adults. The same compensatory mechanisms are activated in the face of inadequate cardiac output. An acute decrease in blood pressure stimulates stretch receptors and baroreceptors in the aorta and carotid arteries, which in turn stimulate the sympathetic nervous system. With the release of catecholamines and the stimulation of β receptors, heart rate and the force of myocardial contraction increase. Venous smooth muscle tone also increases, which increases return of venous blood to the heart. Sympathetic stimulation also decreases blood flow to the kidneys, skin, spleen, and extremities so that maximum flow to the brain, heart, and lungs can be maintained. Decreased blood flow to the kidneys causes the release of renin, angiotensin, and aldosterone. If chronic, this cycle results in retention of sodium and fluid by the kidneys, which in turn increases volume in the circulatory system.

These neurohumoral and hemodynamic changes create abnormal ventricular wall stress and cause the myocardium to hypertrophy. The myocardial fibers also stretch to accommodate the increased volume. Hypertrophy and fiber stretch temporarily increase contractility and hence the force of ventricular contraction. These mechanisms eventually fail to maintain cardiac output as HF progresses. A review of the Frank-Starling law of the heart (see Chapter 31) is useful for an understanding of the cycle of compensation and decompensation that occurs in HF.

CLINICAL MANIFESTATIONS. Symptomatic HF in children has many causes. It is not usually necessary to determine if it is right- or left-sided HF. When assessing a child with HF, a combination of symptoms generally is present. Pulmonary overcirculation is the predominant cause associated with congenital defects.

HF in infants is manifested as poor feeding and sucking, often leading to failure to thrive (FTT). Dyspnea, tachypnea, and diaphoresis may be accompanied by retractions, grunting, and nasal flaring. Wheezing, coughing, and rales are rare even with significant HF. Common skin changes, such as pallor or mottling, are often present.

Hepatomegaly (enlargement of the liver) is atypically attributable to systemic venous congestion. In infants the normal liver is soft, sharp-edged, and palpable 1 to 2 cm below the costal margin. However, the absence of hepatomegaly does not rule out HF.

Periorbital edema and weight gain without caloric increase are uncommon manifestations of right ventricular failure in infants. Peripheral edema, which is a common finding in adults, is rare in infants and young children and more often signifies renal disease rather than cardiac disease. The clinical manifestations of HF are listed in Box 33-2.

EVALUATION AND TREATMENT. A thorough physical examination with an emphasis on cardiac and pulmonary findings often will reveal the degree of HF. Plotting the child's growth (height, weight, head circumference) is an important method for monitoring a child's health. Infants with HF and pulmonary overcirculation usually have low weight with normal length and head

BOX 33-2 CLINICAL MANIFESTATIONS OF HEART FAILURE

IMPAIRED MYOCARDIAL FUNCTION	PULMONARY CONGESTION	SYSTEMIC VENOUS CONGESTION
Tachycardia	Tachypnea	Weight gain
Sweating (inappropriately)	Dyspnea	Hepatomegaly
Decreased urinary output	Retractions (infants)	Peripheral edema (rare)
Fatigue	Flaring nares	Ascites
Weakness	Exercise intolerance	Neck vein distention (rare in children)
Restlessness	Orthopnea	
Anorexia	Cough, hoarseness	
Pale, cool extremities	Cyanosis	
Weak peripheral pulses	Wheezing (rare)	
Decreased blood pressure	Grunting	
Gallop rhythm		
Cardiomegaly		

From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children,* ed 9, St Louis, 2011, Mosby.

circumference. FTT is usually the result of increased metabolic expenditure relative to caloric intake. An electrocardiogram (ECG) should be performed to determine the presence of dysrhythmias or hypertrophy. A chest radiograph is useful in assessing the presence of cardiomegaly and signs of increased pulmonary circulation.

Treatment is aimed at decreasing cardiac workload and increasing the efficiency of heart function. Medical management initially consists of diuretics, such as furosemide. Depending on the degree of HF, other diuretics can be used in combination with furosemide to counteract potassium losses. Agents that reduce afterload, such as angiotensin-converting enzyme (ACE) inhibitors and beta-blockers, have recently been used to further manage severe HF.[2,3] Caloric supplementation is routinely prescribed.

Hypoxemia

Heart defects that allow desaturated blood to enter the systemic system without passing through the lungs result in hypoxemia and cyanosis. Hypoxemia occurs when arterial oxygen tension is below normal and results in low oxygen arterial saturations and cellular function alteration. **Cyanosis,** a blue discoloration of the mucous membranes and nail beds, results from deoxygenated hemoglobin in a concentration of at least 5 g/dl of blood or from arterial saturations less than 85%.[2,4] Anemia may mask the signs of hypoxemia, whereas children who are polycythemic with a normal arterial saturation may appear cyanotic. Older children who have an unrepaired septal defect with a left-to-right shunt may become cyanotic because of pulmonary vascular changes secondary to increased pulmonary blood flow. Because of these progressive pulmonary vascular changes, pulmonary vascular resistance increases to exceed or equal vascular resistance, resulting in a reversal of shunting known as **Eisenmenger syndrome.** Three types of defects cause hypoxemia and cyanosis:

1. Lesions that cause right ventricular outflow tract obstruction and shunting from the right side of the heart to the left side, as in tetralogy of Fallot (see p. 1207)
2. Defects involving the mixing of saturated and unsaturated blood within the heart chambers, as in a univentricular heart (also referred to as a single ventricle)
3. Defects in children with transposition of the great arteries (see p. 1214), in which two parallel circulations exist and survival depends on the existence of a patent ductus arteriosus or septal defect

CLINICAL MANIFESTATIONS. Infants with mild hypoxemia may show signs of cyanosis only occasionally when stressed; otherwise, they may exhibit near-normal age-projected growth and development. Infants with severe hypoxemia may display signs of feeding intolerance, poor weight gain, tachypnea, and dyspnea. Children with chronic hypoxemia are small for their age, may display cognitive and motor skill delays, experience shortness of breath with exertion, fatigue easily, and have exercise intolerance. Acute, severe hypoxemia will lead to tissue hypoxia, metabolic acidosis, hyperventilation, poor perfusion, and eventually shock.

In response to chronic hypoxemia, polycythemia occurs as the body generates additional red blood cells to increase the oxygen-carrying capacity of the blood. In some infants, however, microcytic anemia may result because of limited stores of iron. Polycythemia and the associated platelet dysfunction also place children at risk for thromboembolic events, especially infants with severe cyanosis and iron deficiency anemia. In addition to the 2% risk of cerebrovascular accidents, there is a small chance that children with right-to-left shunting will develop a brain abscess.[4] Clubbing of the nail beds occurs because of chronic tissue hypoxemia and polycythemia.

Defects Increasing Pulmonary Blood Flow

Cardiac lesions that increase pulmonary blood flow include defects that involve septal abnormalities or communications between the great arteries. These allow the shunting of blood from the high-pressure left side to the lower-pressure right side. Infants with left-to-right shunts are acyanotic and, depending on the degree of shunting, may develop signs and symptoms of CHF. Children with significant left-to-right shunts left untreated are at risk for development of irreversible pulmonary hypertension.

Patent Ductus Arteriosus

The **patent ductus arteriosus (PDA)** is a vessel located between the junction of the main and left pulmonary arteries and the lesser curvature of the descending aorta, usually just distal to the left subclavian artery (Figure 33-5, *A*). During fetal circulation the PDA allows blood to shunt from the PA to the aorta. At birth, once the placenta is removed and the lungs are expanded, the PDA will start to constrict within the first hours of life. Closure of the PDA in full-term infants is usually noted between 15 hours of life and 2 weeks of age.[7] As an isolated defect, PDA occurs in

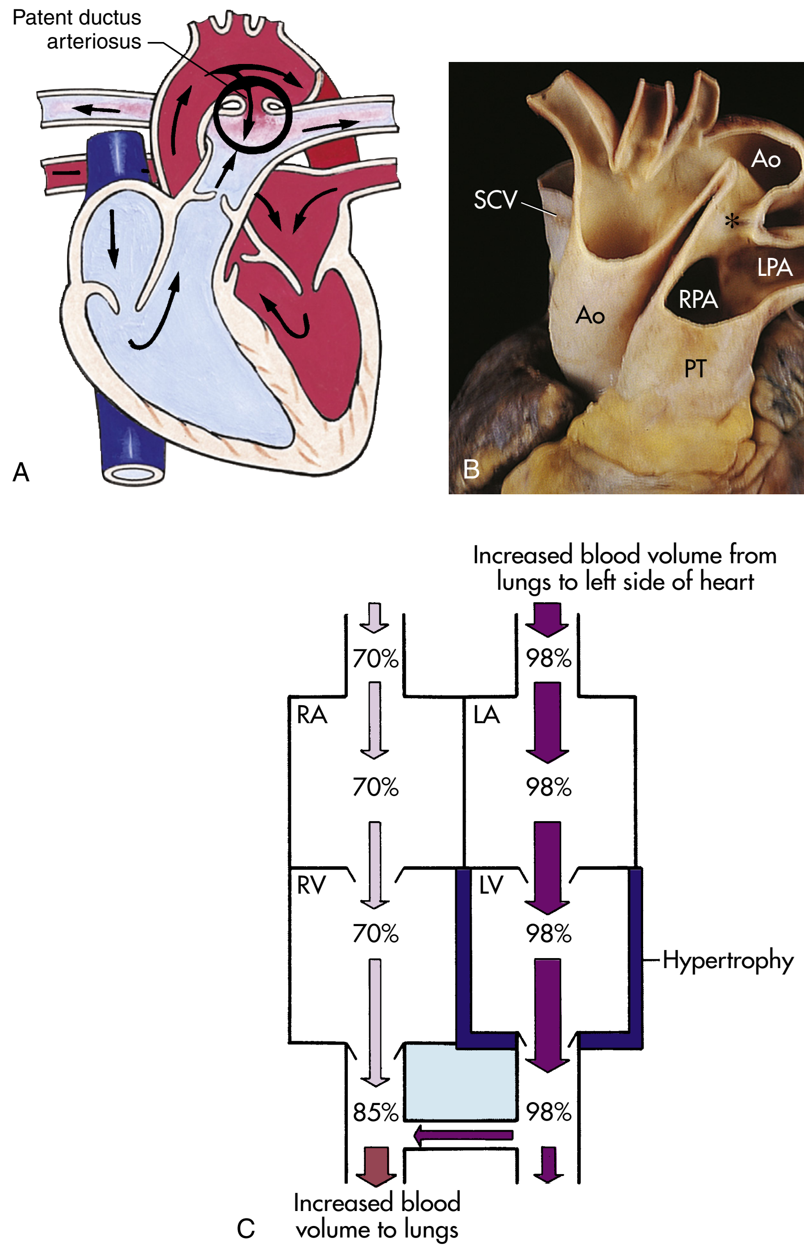

FIGURE 33-5 Patent Ductus Arteriosus (PDA). **A,** PDA with left-to-right shunt. **B,** PDA *(asterisk)* in an adult with pulmonary hypertension. **C,** Changes in oxygen saturation, left ventricular volume, and the myocardium caused by left-to-right shunt through a PDA. *Ao,* Aorta; *LA,* left atrium; *LPA,* left pulmonary artery; *LV,* left ventricle; *PT,* pulmonary trunk; *RA,* right atrium; *RPA,* right pulmonary artery; *RV,* right ventricle; *SCV,* subclavian vein. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby; **B** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

5% to 10% of all congenital cardiac defects. Studies have shown that the incidence of PDA is high in premature infants.[8]

PATHOPHYSIOLOGY. Failure of the PDA to close results in persistent patency of the ductus arteriosus. The hemodynamic effects of PDA depend on the size of the lumen and the resistance in the pulmonary and systemic circulations. At birth the pulmonary and systemic vascular resistances are almost equal and are reflected in the PA and aorta, respectively; therefore, shunting is minimal. However, as pulmonary vascular resistance falls, a reversal of fetal shunting occurs. Blood now begins to shunt left to right, from the aorta to the PA. The hemodynamic effect is increased pulmonary blood flow, resulting in increased pulmonary venous return to the LA and LV with increased workload on the left side of the heart. The increased workload is caused by increased pulmonary venous return to the LA and, potentially, an increase in right ventricular pressure if pulmonary vascular changes occur in response to the increased blood flow, leading to an increase in pulmonary vascular pressure (see Figure 33-5, *B*).

CLINICAL MANIFESTATIONS. If pulmonary vascular resistance has fallen, infants with PDA will characteristically have a continuous-machinery type murmur heard best at the left upper sternal border throughout systole and diastole. If the PDA is significant, the infant also will have bounding pulses,

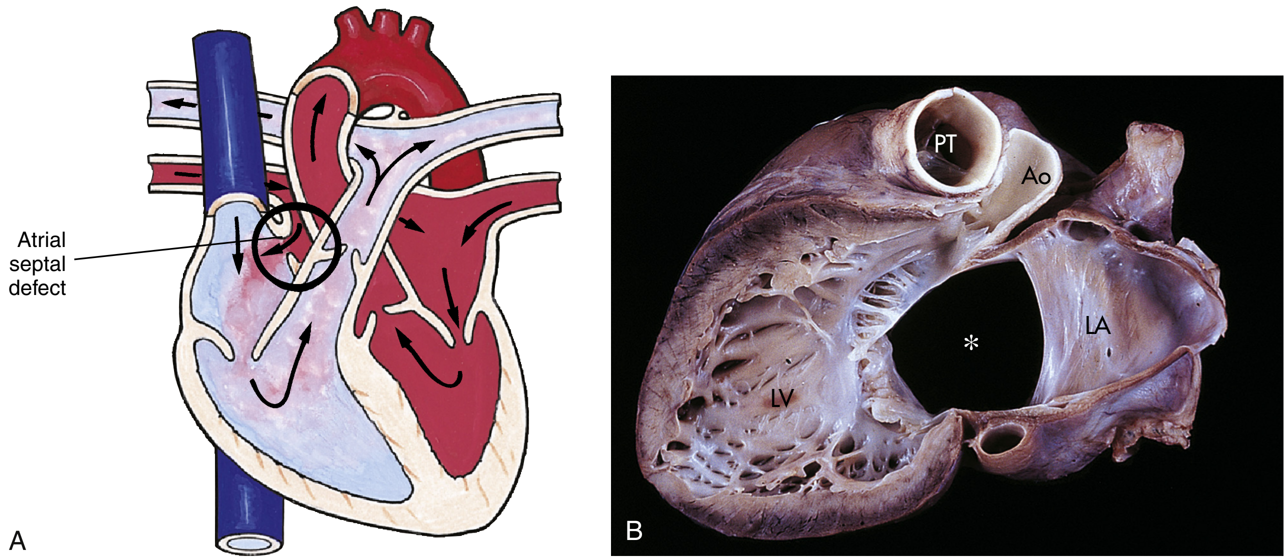

FIGURE 33-6 Atrial Septal Defect (ASD). **A,** Abnormal opening between the atria causing blood from the higher-pressure left atrium to flow into the lower-pressure right atrium. **B,** Complete ASD *(asterisk)* form in children. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *PT,* pulmonary artery trunk. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby; **B** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

an active precordium, a thrill upon palpation, and signs and symptoms of pulmonary overcirculation. Infants with a small PDA will usually remain asymptomatic.

EVALUATION AND TREATMENT. Chest radiograph will reveal cardiomegaly and increased pulmonary vascular markings. An ECG may demonstrate ventricular enlargement, particularly on the left, but in most cases it is within the normal range. Echocardiography and auscultation confirm the diagnosis based on the characteristic continuous-machinery type of murmur.

PDA closure in asymptomatic children with a murmur is recommended by 2 years of age because of the risk of subacute bacterial endocarditis. No treatment is recommended for small PDA in the absence of a murmur or other cardiac conditions. Premature infants who develop respiratory distress are initially given indomethacin, a prostaglandin inhibitor, to close the duct. If this is unsuccessful, surgical ligation and division may be warranted.

Historically the most widely used method for PDA closure is surgical closure involving ligation and division of the ductus with complete closure in nearly 100% of cases. Mortality associated with surgical intervention nears 0%; however, there continues to be some morbidity associated with the approach through a left thoracotomy incision.

Several other options for PDA closure are available depending on the size of the child and the PDA. Many specialists perform interventional closure of the PDA during catheterization. The catheter is advanced into the ductal opening whereby multiple coils or other devices are placed into the lumen that prohibit flow through the duct. The greatest advantages to this procedure are the avoidance of a surgical procedure and thoracotomy pain and a brief observation stay in the hospital.

Another option is closure through video-assisted thoracoscopic surgery. This procedure involves making three small incisions in the left lateral wall, through which a probe is inserted. A clip is then placed around the vessel to occlude it. An advantage of this procedure over open surgical procedures is that there is less associated morbidity because of the avoidance of a thoracotomy incision.[8]

Atrial Septal Defect

An **atrial septal defect (ASD)** is an abnormal communication between the atria (Figure 33-6, *A* and *B*). Although it is an isolated lesion, it is the fourth most common congenital heart defect, occurring in 5% to 10% of all congenital cardiac defects. The three major types are: (1) an ostium primum defect, an opening found low in the septum that may be associated with AV valve abnormalities, especially mitral insufficiency; (2) an ostium secundum defect, an opening in the center of the septum (this is the most common type of atrial defect); and (3) a sinus venosus defect, an opening that occurs high up in the atrial septum near the superior vena cava and RA junction. This defect is often associated with partial anomalous pulmonary venous connection.

PATHOPHYSIOLOGY. Although the pressure difference between the two atria is minimal, the ASD allows blood to be shunted from left to right because of the slightly higher pressure of the left atrial chamber and lower pulmonary vascular resistance as compared with systemic vascular resistance. Right atrial and ventricular enlargement develops as a result of left-to-right shunting. Children with ASD are generally asymptomatic and rarely display signs of pulmonary overcirculation. Moderate to large ASDs allow an increase in pulmonary blood flow and, over time, pulmonary vascular changes can occur that may, although rarely, result in pulmonary hypertension.

CLINICAL MANIFESTATIONS. Because most children with ASD are asymptomatic, diagnosis usually is made during a routine physical examination by the auscultation of a crescendo-decrescendo systolic ejection murmur that reflects increased

blood flow through the pulmonary valve. The location of the murmur is between the second and third intercostal spaces along the left sternal border. A wide fixed splitting of the second heart sound is also characteristic of ASD, reflecting volume overload to the RV, causing prolonged ejection time and delay of pulmonic valve closure.

EVALUATION AND TREATMENT. In most cases an echocardiogram is sufficient to confirm the diagnosis of an ASD. A chest radiograph may reveal cardiomegaly and increased pulmonary vascular markings in an asymptomatic child. An ECG may demonstrate right-axis deviation and diastolic overload of the RV manifested as right ventricular hypertrophy.[2]

ASD closure, generally before the child reaches school age, results in improved health later in life. If left unrepaired, right ventricular compliance decreases with age, and pulmonary hypertension and right ventricular hypertrophy may occur, placing the person at risk for the development of HF, atrial dysrhythmias, or embolic events later in life. Surgical closure is one method of closure and involves a pericardial patch or suture closure of the defect, depending on the size of the opening. Repair is done through a midsternal approach with the use of cardiopulmonary bypass. Minimally invasive techniques are being used on near–adult-sized patients. Sinus venosus defects require a slightly different approach that consists of a synthetic patch to close the opening and baffle the anomalous right pulmonary venous drainage to the LA. Operative mortality associated with ASD closure is near 0%, with minimal morbidity.[7,9,10] Device closure performed in the catheterization laboratory is becoming a routine alternative to open surgical procedures.[7]

Ventricular Septal Defect

A **ventricular septal defect (VSD)** is an abnormal communication between the ventricles (Figure 33-7, *A*). VSDs are the most common type of congenital heart lesion and account for 25% to 33% of all congenital heart defects. The four types of VSDs are based on location in the septum. The perimembranous type, which occurs in the outflow tract of the LV immediately below the aortic valve, is the most common type, accounting for up to 80% of all VSDs that require treatment. Muscular VSDs, which occur low or anterior in the ventricular septum between the trabeculae (see Figure 33-7, *B*) are most likely to close spontaneously and are difficult to close surgically because of their location low in the ventricular apex. Most muscular VSDs are hemodynamically insignificant and require no medical or surgical treatment. Supracristal VSDs (also called outlet VSD) occur in the right ventricular outflow tract or infundibulum, below the pulmonary valve. AV canal or inlet VSDs occur posterior and inferior to the membranous system, beneath the septal cusp of the tricuspid valve and inferior to the papillary muscles of the conus.

PATHOPHYSIOLOGY. The direction of shunting in a child with a VSD is from the high-pressure left side to the lower-pressure right side. The amount of shunting depends on the size of the defect and the degree of pulmonary vascular resistance. Small VSDs present increased resistance to shunting and limit blood flow through the defect; thus the degree of pulmonary vascular congestion and ventricular chamber enlargement is minimal (see Figure 33-7, *C*).

After 1 to 2 weeks of life, when pulmonary vascular resistance has decreased, moderate-sized to large VSDs allow a large amount of shunting from left to right. The shunted blood flows directly out the RV outflow tract and into the PA rather than remain in the RV cavity (see Figure 33-7, *D*). Therefore, the main PA, LA, and LV all enlarge. LV hypertrophy occurs to effectively pump the additional volume. Pulmonary overcirculation accounts for the symptoms associated with a large VSD in most cases.

Over time the pulmonary bed also undergoes changes because of increased pulmonary blood flow caused by the left-to-right shunting. The smooth muscle layer in the arteriolar walls thickens and proliferation of the intimal layer occurs. The effect of these changes is a decrease in the diameter of the pulmonary vessels, which increases the resistance to blood flow. If the pulmonary vascular resistance is severely increased these changes eventually become irreversible, and pulmonary vascular resistance continues to rise. In some cases it exceeds systemic vascular resistance, causing the shunt through the VSD to reverse direction. Deoxygenated blood now flows into the systemic circulation, and cyanosis occurs, a phenomenon known as *Eisenmenger syndrome*.

CLINICAL MANIFESTATIONS. Clinical manifestations in children with VSDs depend on the age of the child, size of the defect, and level of pulmonary vascular resistance. Newborns with small VSDs are relatively asymptomatic. Initially no murmur is present because the newborn's high pulmonary vascular resistance causes equalization of the pressures between both ventricles. Once pulmonary vascular resistance has dropped, left-to-right shunting occurs, creating a murmur. Infants with large VSDs display symptoms of HF and poor weight gain. Adults who develop pulmonary vascular obstructive disease as a result of unrepaired VSD will be cyanotic and have clubbing.

On physical examination a loud, harsh, holosystolic murmur and systolic thrill can be detected at the left lower sternal border. The intensity of the murmur reflects the pressure gradient across the VSD. An apical diastolic rumble may be present with a moderate to large defect, reflecting increased flow across the mitral valve.

EVALUATION AND TREATMENT. ECG and chest radiographs reflect the amount of shunting through the defect. The ECG of an individual with a small VSD may be normal, whereas the ECG of an individual with a large VSD may reveal biventricular hypertrophy and LA enlargement. Chest roentgenographic findings are significant for cardiomegaly and increased pulmonary vascular markings; again, the severity is directly related to the magnitude of shunting. An echocardiogram identifies the position, size, direction of shunting, and dimensions of the LA, LV, and RV chambers. It also can provide an estimate of PA and RV pressures. Cardiac catheterization may be performed to determine hemodynamics and, in some instances, the location of other defects and additional VSDs.

Many VSDs spontaneously close during the first year of life.[2] Infants with symptoms of HF and poor weight gain despite medical management should have their VSD corrected as soon as possible. Left-to-right shunting with a pulmonary flow/systemic flow (Q_p/Q_s) ratio of greater than 2:1 or evidence of

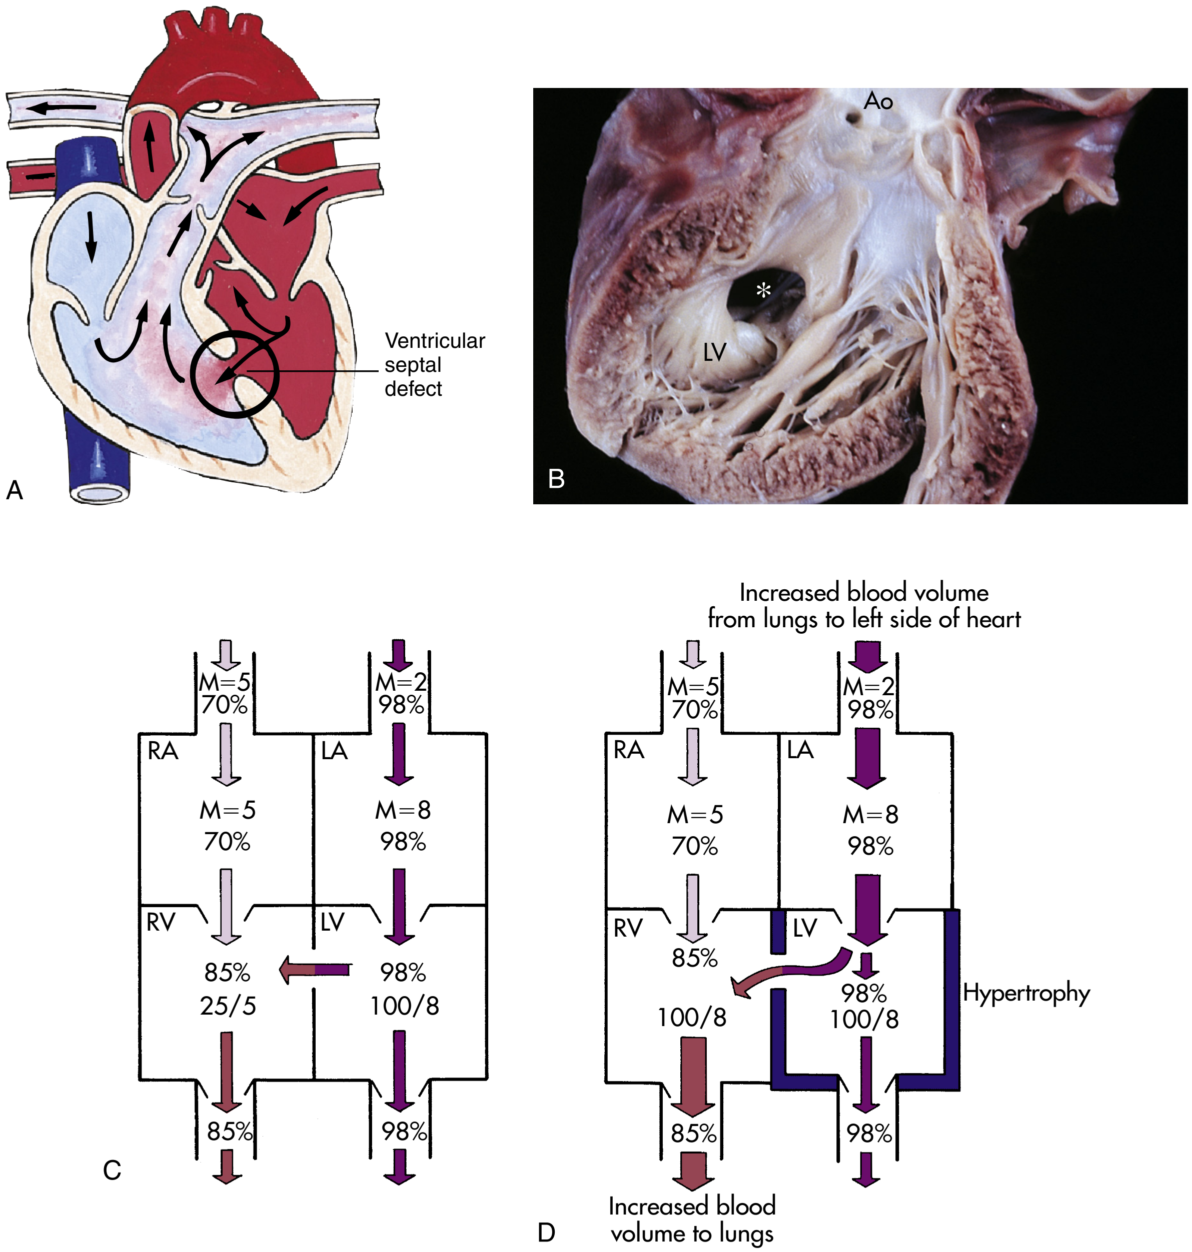

FIGURE 33-7 **Ventricular Septal Defects (VSDs). A,** VSD with left-to-right shunt. **B,** Muscular *(asterisk)* defect (opened left ventricle). **C,** Hemodynamics of a small VSD with left-to-right shunt. Mean *(M)* indicates mean of pressure; systolic/diastolic pressures are in mmHg; and percentages indicate oxygen saturation. **D,** Hemodynamics of a large VSD with left-to-right shunt. Like the shunting that occurs in preductal coarctation of the aorta, the shunting pictured here causes left ventricular overload and hypertrophy. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby; **B** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

elevated pulmonary vascular resistance are indications for closure. Closure of the VSD at this time is to prevent the development of pulmonary vascular obstructive disease.

Placement of a PA band to decrease the amount of pulmonary blood flow was initially used as a palliative procedure but is now rarely used unless the presence of an additional lesion makes complete repair difficult. Patch closure, using a synthetic material or pericardium, is accomplished through a sternotomy and with the use of cardiopulmonary bypass. A transatrial approach is preferable to a right ventriculotomy because of the increased incidence of conduction disturbances associated with ventriculotomy. Contraindications for VSD closure include evidence of pulmonary vascular obstructive disease or Eisenmenger syndrome.[2,7] Occlusion devices for VSD closure performed in the cardiac catheterization laboratory are now in early clinical use.[7,11]

Atrioventricular Canal Defect

An **atrioventricular canal (AVC) defect** results from nonfusion of the endocardial cushions during fetal life, yielding abnormalities in both the atrial and ventricular septa and the AV valves

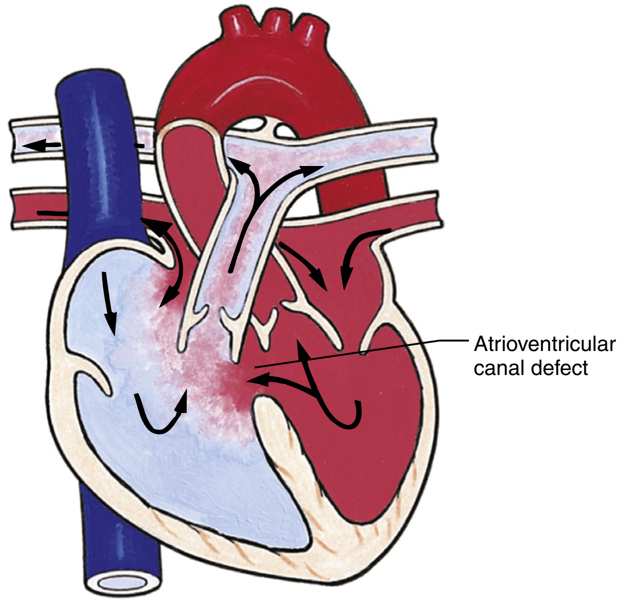

FIGURE 33-8 Atrioventricular Canal Defect. (From Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby.)

(Figure 33-8). This defect accounts for as many as 5% of all congenital heart defects, and approximately 30% of AVC defects occur in children with Down syndrome.[7] The three types of AVC defects are based on the cardiac components involved. **Complete AVC (CAVC) defects** consist of an inlet VSD, a primum type of ASD, and defects in both the mitral and tricuspid valves. **Partial AVC (PAVC) defects** consist of a primum type of ASD and a cleft in the septal or anterior leaflet of the mitral valve. **Transitional AVC (TAVC) defects** involve partial fusion of the endocardial cushions, resulting in variable AV valve abnormalities.[7]

PATHOPHYSIOLOGY. Hemodynamic abnormalities seen in AVC defects depend on the components of the lesion and the level of pulmonary vascular resistance. Shunting is minimal during the neonatal period when pulmonary vascular resistance is high. However, once pulmonary vascular resistance drops, left-to-right shunting occurs through the septal defects, resulting in increased pulmonary blood flow and HF.

PAVC defects mimic the hemodynamics of secundum ASD in which the left-to-right shunting through the primum ASD causes RA and RV dilation and increased pulmonary blood flow. The mitral regurgitation that occurs, caused by the cleft mitral valve, is usually hemodynamically insignificant.

CAVC defects reflect the hemodynamics of an ASD and a VSD, resulting in biatrial and biventricular enlargement. RA and RV volume overload occurs because of shunting through the primum ASD and tricuspid regurgitation. Likewise, LA and LV volume overload occurs because of shunting through the VSD, increased pulmonary venous return, and mitral regurgitation.

CLINICAL MANIFESTATIONS. Children with PAVC defects are generally asymptomatic. Findings on physical examination are similar to those of secundum ASD with the addition of a holosystolic, regurgitant murmur of mitral regurgitation at the apex. At 4 to 12 weeks of age, when pulmonary vascular resistance drops, children with CAVC defects usually begin to show symptoms of HF. Physical findings are similar to those found in individuals with VSDs with the addition of a holosystolic murmur radiating to the back and apex, reflecting mitral regurgitation. A mid-diastolic rumble at the left lower sternal border or apex reflects relative stenosis of the mitral or tricuspid valve from increased flow. Infants with CAVC may have signs of HF and frequent respiratory tract infections.

EVALUATION AND TREATMENT. The ECG generally demonstrates a superior left-axis deviation (−90 to −180 degrees), first-degree AV block, and RV hypertrophy or right bundle branch block. The ECG of CAVC defects also may show LV hypertrophy. Chest radiograph shows cardiomegaly, increased pulmonary vascular markings, and a prominent main PA. Echocardiography allows visualization of the components of the defect, including continuity between the AV valves, their sizes, and chordal attachments. Cardiac catheterization may be electively performed and can confirm the location of septal defects, AV valve abnormalities, degree of left-to-right shunting, and presence of pulmonary hypertension.

Timing of surgical repair depends on the severity of symptoms, degree of shunting, and level of pulmonary vascular resistance. The trend is to perform complete repair between 3 and 6 months after birth to avoid the development of pulmonary vascular changes. Surgical repair is performed through a midsternotomy implementing a one- or two-patch repair to close the septal defects and repair the involved AV valves. Mortality has declined below 10% unless the child is a newborn, has severe AV valve incompetence, or has a small LV (unbalanced AV canal). Postoperative complications include heart block, dysrhythmias, or mitral regurgitation requiring further surgical intervention or valve replacement.[7,12]

Defects Decreasing Pulmonary Blood Flow

Defects decreasing pulmonary blood flow involve obstruction to pulmonary blood flow and septal communications. Because of RV outflow tract obstruction, right-sided pressures exceed left-sided pressures, resulting in right-to-left shunting. Children with these defects have hypoxemia and cyanosis.

Tetralogy of Fallot

Tetralogy of Fallot (TOF) consists of four defects: a large VSD that is high in the septum, an overriding aorta that straddles the VSD, pulmonary stenosis (PS), and RV hypertrophy (Figure 33-9, *A* and *B*). It is the most common cyanotic congenital heart defect and accounts for 10% of all defects.[2]

PATHOPHYSIOLOGY. TOF develops during two phases of embryologic growth: (1) during the division of the truncus arteriosus by the spiral septum in the third or fourth week of gestation, and (2) during the division of the ventricles between the fourth and eighth weeks of gestation. Normally as these events progress, the truncal septum fuses with the bulbar ridges and in turn with the endocardial cushions. The membranous portion of the interventricular septum grows upward to meet the endocardial cushions, and ultimately all of these tissues unite to complete the interventricular septum.

The embryologic error that causes TOF is not definitively known, but two theories have been proposed.[1] The first is that the truncus arteriosus divides unevenly, resulting in great vessels of unequal size. The second theory proposes that infundibular overgrowth in the RV is the major developmental anomaly. Defects in ventricular septation also occur, producing the large VSD, which allows the aorta to override the VSD.

The pathophysiology associated with TOF varies widely, depending primarily on the degree of pulmonary stenosis, the size of the VSD, and the pulmonary and systemic resistance to flow. Because the VSD is usually large, pressures are equal in the RV and LV. Therefore, the major determinant of shunt direction through the VSD is the difference between pulmonary and systemic vascular resistance (see Figure 33-9, *C*). Infants who have little or no right-to-left shunting are acyanotic and are known as "pink tets." They may have a net left-to-right shunt similar to a large VSD. If pulmonary vascular resistance is higher than systemic resistance, the shunt is from right to left. Because many factors can alter the balance between pulmonary and systemic resistance, shunt direction is not necessarily constant.

Pulmonary stenosis decreases blood flow to the lungs and, consequently, the amount of oxygenated blood that returns to the left heart. If blood also shunts from right to left through the VSD, deoxygenated blood mixes with the oxygenated blood returning from the lungs. The result is low oxygen saturation (hypoxemia) in the systemic circulation. The body attempts

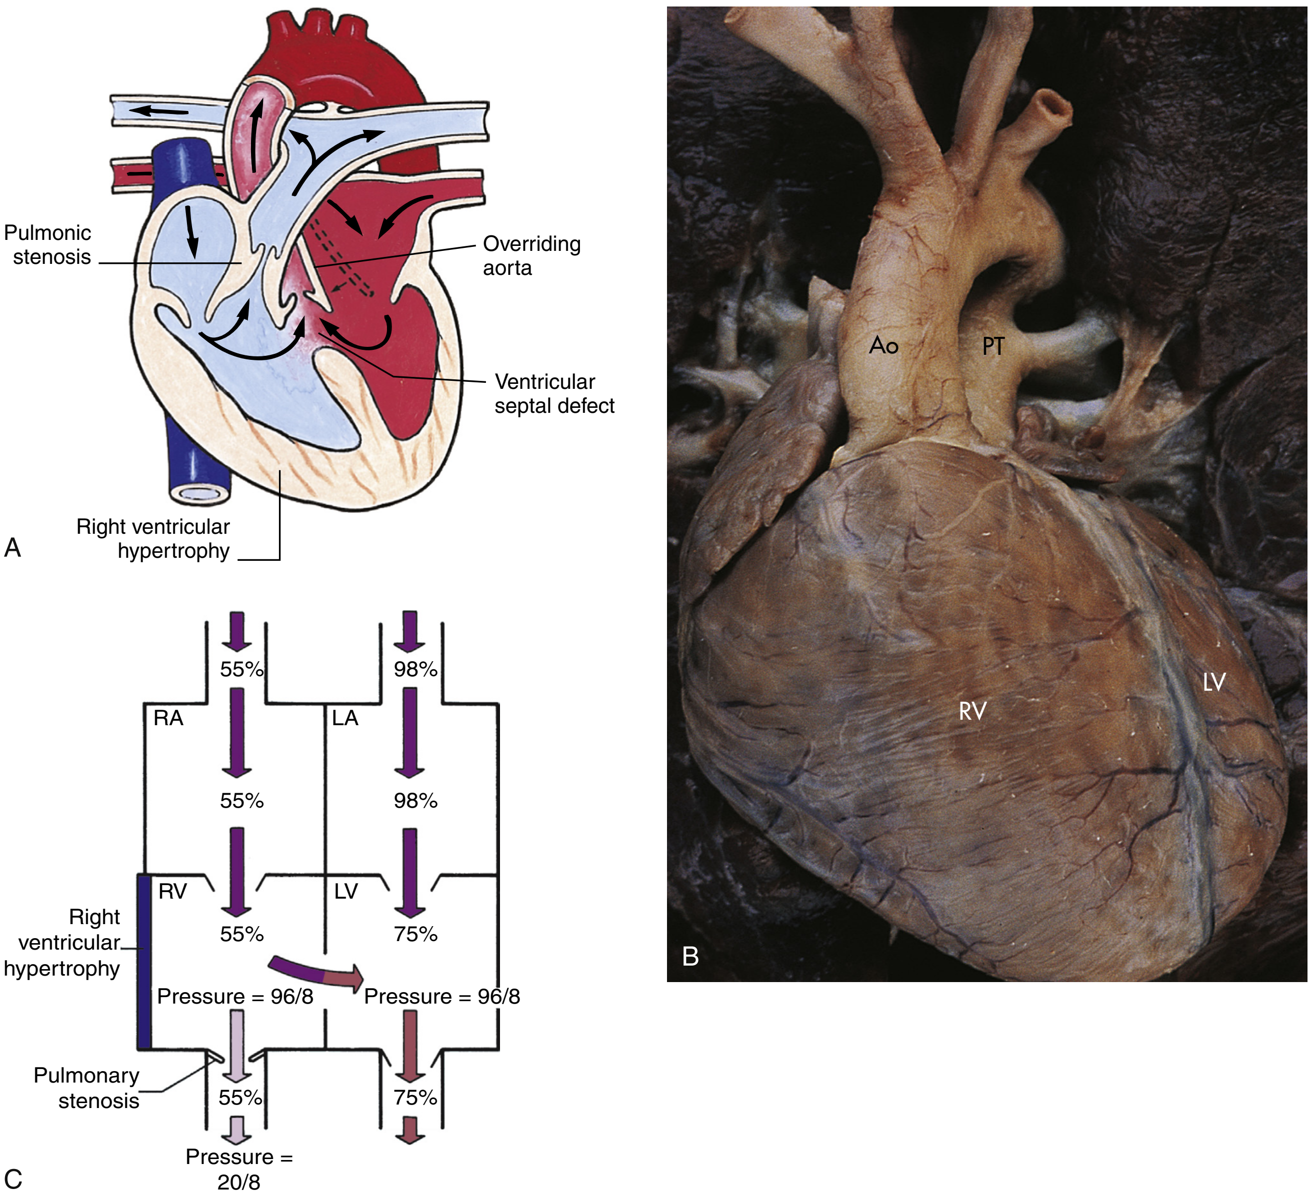

FIGURE 33-9 **Tetralogy of Fallot. A,** Anatomic defects in tetralogy of Fallot. **B,** Complete transposition of the aorta and pulmonary artery. **C,** Hemodynamics of tetralogy of Fallot with right-to-left shunt. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *PT,* pulmonary artery trunk; *RA,* right atrium; *RV,* right ventricle. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby; **B** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

to compensate for chronic hypoxemia by producing more red blood cells (thereby causing polycythemia) and by increasing blood flow to the lungs through collateral bronchial vessels in long-standing cases.

CLINICAL MANIFESTATIONS. In cases with decreased pulmonary flow through the right ventricular outflow tract as long as the ductus arteriosus remains open, the newborn's pulmonary blood flow may be adequate. As the ductus closes, however, cyanosis becomes apparent. Chronic hypoxemia causes clubbing of the fingers and toes (see Chapter 35).

A rare manifestation of TOF is the sudden onset of dyspnea, cyanosis, and restlessness, sometimes called a *hypercyanotic spell* or a "*tet spell,*" that generally occurs with crying and exertion. The cause of these episodes is unknown, but it is theorized that the RV outflow tract goes into spasm or the systemic resistance drops suddenly. In either case the relative or actual increase in pulmonary vascular resistance increases the right-to-left shunt and the cyanosis. Hypercyanotic spells are often the event that initiates surgical intervention. If the spells are frequent or do not terminate spontaneously, they are considered a medical-surgical emergency.[7]

Infants with TOF may have difficulty with feeding because the exertion required increases hypoxia, and therefore they experience slow growth and FTT. Most infants with TOF grow normally.

Squatting is a spontaneous compensatory mechanism used by older children with unrepaired TOF to alleviate hypoxic spells. Squatting and its variants increase systemic resistance while decreasing venous return to the heart from the inferior vena cava. The decrease of systemic return makes relatively more oxygenated blood available to the body. The increase of systemic resistance also reverses the shunt through the VSD to a left-to-right shunt, which has the effect of increasing pulmonary blood flow. Through both of these mechanisms, squatting temporarily decreases the degree of hypoxemia. It is uncommon to witness this because most cases are surgically corrected in early infancy.

The typical heart murmur of TOF is a pulmonary systolic ejection murmur caused by the obstruction in the outflow tract, which creates turbulence during systole. More obstruction to flow (e.g., smaller orifice for the flow of blood) produces a louder murmur. This explains why the murmur often disappears during a hypoxic spell, when obstruction increases and pulmonary blood flow decreases to a minimal amount. The second heart sound seems to be single, but in fact it is not. The pulmonary component is very soft and delayed and usually is not heard, although it is present. The enlarged RV may cause the left side of the chest to be more prominent, and a "heave" also may be palpated.

EVALUATION AND TREATMENT. The ECG indicates RV hypertrophy. Chest radiographic examination shows that the heart is shaped like a boot (upturned apex because of a small main PA) and that pulmonary vascular markings are decreased. Echocardiograms and angiograms enable the clinician to see the size and position of the VSD, the stenotic pulmonary infundibulum or valve, the smaller-than-normal PA, and the overriding aorta. Measurements made during cardiac catheterization (electively done in rare cases) demonstrate equal systemic pressure in the RV and LV, decreased pressure in the PA distal to the obstruction, and low oxygen saturation in the aorta if there is right-to-left shunting.

The current practice is to repair TOF before 1 year of age. Triggers for repair include increasing cyanosis and hypercyanotic spells. Palliative procedures include the placement of a pulmonary-to-systemic artery shunt known as the Blalock-Taussig shunt to increase pulmonary blood flow or a modification of the shunt using prosthetic graft material placed from either the subclavian or the innominate artery to the PA. These shunts may cause PA distortion but may be necessary in a very small symptomatic child. Corrective repair involves patch closure of the VSD, resection of infundibular or valvular stenosis, and patch augmentation of the RV outflow tract. The procedure is done through a median sternotomy while the child is on cardiopulmonary bypass. The operative mortality is less than 5%. Complications include dysrhythmias and occasionally heart block. Many children require further surgery to relieve recurrent pulmonary stenosis or treat severe pulmonary insufficiency.[13]

Tricuspid Atresia

Tricuspid atresia consists of an imperforate tricuspid valve, resulting in no communication between the RA and RV (Figure 33-10). This defect accounts for 2% to 3% of congenital heart defects and is the third most common cyanotic heart defect. Tricuspid atresia is a combination of defects, including the imperforate tricuspid valve as well as a septal defect, hypoplastic or absent RV, enlarged mitral valve and LV, and varying degrees of pulmonic stenosis. Tricuspid atresia also may be associated with transposition of the great vessels. The most common type of tricuspid atresia involves a hypoplastic RA with decreased pulmonary blood flow, ASD, VSD, and normally related great vessels.[2]

PATHOPHYSIOLOGY. Systemic blood returns through the superior and inferior venae cavae to the RA. Venous return flows through the ASD into the LA, mixing with blood returning from the pulmonary circulation. The blood then enters the LV. Most of this blood passes into the systemic circulation through the aorta, but varying amounts flow through the VSD into the hypoplastic RV and to the lungs. Pulmonary circulation depends on the presence of a VSD and the presence of a functioning RV of reasonable capacity. If the RV is absent, the pulmonary valve is usually imperforate as well. If this is the case, a PDA is necessary to ensure that some blood flows into the pulmonary circulation.[7]

Pulmonary circulation also depends on the relationship between pulmonary and systemic vascular resistance. As long as pulmonary resistance is lower than systemic resistance, blood flows through the VSD from left to right, feeding the pulmonary circulation. If pulmonary resistance rises above systemic resistance, pulmonary blood flow will be significantly diminished.

CLINICAL MANIFESTATIONS. Some degree of central cyanosis is common in tricuspid atresia, depending on the amount of pulmonary blood flow. Growth failure also is common. Children experience exertional dyspnea, tachypnea, and hypoxemia. Long-term effects of hypoxia are polycythemia and clubbing.

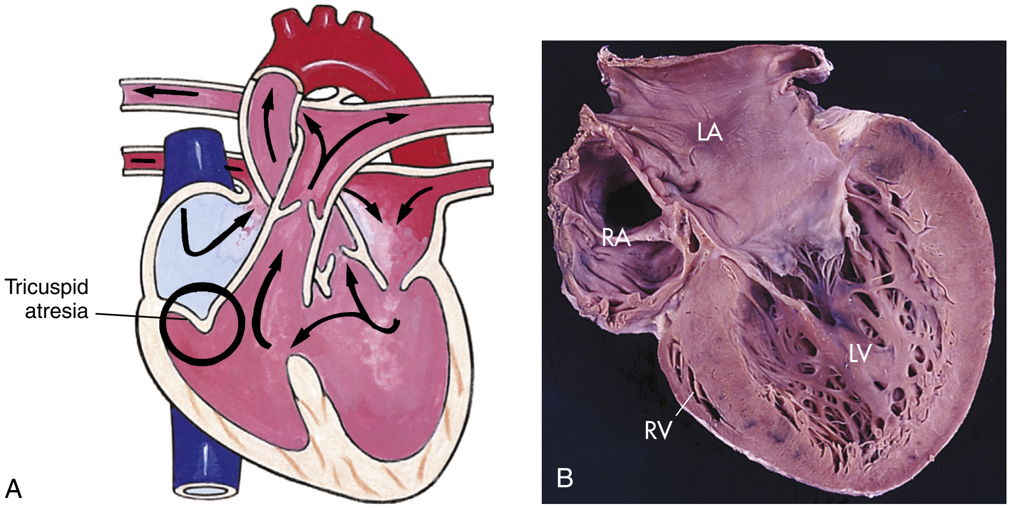

FIGURE 33-10 Tricuspid Atresia. **A,** No communication from the right atrium to the right ventricle. **B,** Tricuspid atresia with absent right atrioventricular connection with a hypoplastic right ventricle (four-chamber view). *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby; **B** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

These children also may display hypercyanotic spells. Hepatomegaly may be present if the ASD is restrictive or CHF occurs as a result of increased pulmonary blood flow.

The murmur heard with tricuspid atresia may have several components. The VSD causes a systolic regurgitant murmur; the murmur is likely to be softer and shorter as the VSD enlarges. A narrowly split second heart sound caused by decreased pulmonary blood flow may be present, or the second heart sound may be single if there is pulmonary atresia.

EVALUATION AND TREATMENT. Chest radiographic examination shows a heart size that is normal or slightly increased. ECG usually shows RA, LA, and LV hypertrophy with left-axis deviation. Echocardiography and cardiac catheterization, if performed, depict left-to-right shunting at the ventricular level, inability of blood flow to enter the RV from the absent tricuspid opening, and the presence of associated defects.

Newborns with ductal dependent pulmonary blood flow are immediately given prostaglandins to maintain adequate pulmonary perfusion. Initial surgical intervention involves the placement of a Blalock-Taussig shunt (or its modification). If the ASD is restrictive, a Rashkind procedure (balloon atrial septostomy) may be performed during catheterization. Children who experience increased pulmonary blood flow may require the placement of a PA band. Corrective repair involves closing the septal defects, removing the previous shunts or band, and connecting the superior and inferior venae cavae to the PA to separate the pulmonary systemic circulation (Fontan procedure and its modifications). Postoperative complications include pleural effusions, elevated pulmonary vascular resistance, LV dysfunction, and dysrhythmias.[13]

Obstructive Defects

Obstructive defects are conditions in which anatomic stenosis (narrowing) in either the right or the left outflow tract causes obstruction to blood flow and results in a pressure load on the ventricles. The gradient reflects the severity of the narrowing; the higher the gradient the more obstruction to flow and more afterload on the ventricle. The location is classified according to the location of the narrowing in relation to the valve. Valvular stenosis refers to stenosis of the valve itself; subvalvular indicates that the obstruction is below the valve or in the ventricular outflow tract; and supravalvular is the area above the valve in the great artery. The great vessel itself can be narrowed and the site of obstruction can be the same as that in coarctation of the aorta. The obstructive defects include coarctation of the aorta, aortic stenosis, pulmonary stenosis, and hypoplastic left heart syndrome. Symptoms associated with the defect depend on the site and severity of stenosis.

Coarctation of the Aorta

Coarctation of the aorta (COA) is a narrowing of the lumen of the aorta that impedes blood flow. This defect accounts for 8% to 10% of all congenital heart defects. COA is almost always in a juxtaductal position, although it can occur anywhere between the origin of the aortic arch and the bifurcation of the aorta in the lower abdomen. About 50% of individuals with COA have a bicuspid aortic valve (Figure 33-11).[2]

PATHOPHYSIOLOGY. COA may develop because of abnormal contractile ductal tissue that constricts at the time of ductal closure. COA causes a condition in which there are higher pressures proximal to the site of stenosis and lower pressures distal to the site. In preductal COA the RV acts as a systemic pump, sending unoxygenated blood through the ductus into the descending aorta below the coarctation (Figure 33-12). In postductal COA the RV cannot pump enough blood through the ductus to the descending aorta because of pressure caused by the narrowed aorta. Systolic pressure increases in the ascending aorta and LV and decreases in the descending aorta beyond the COA (Figure 33-13). In long-standing COA, collateral circulation, which involves small arteries arising from the subclavian arteries, joins intercostal arteries that flow into the descending aorta. These collateral vessels bypass the COA and supply blood to the lower extremities. The direction of shunting

through the ductus, if present, depends on the pressure difference between the PA and aorta and the location of the ductus. When blood pressure is greater in the aorta than in the PA, blood flow through the ductus will be left to right toward the lungs, resulting in increased pulmonary venous return to the left side of the heart. This may place an additional strain on the LA and LV, leading to increased volume and workload. With time, LV hypertrophy develops because of increased afterload and obstruction to flow caused by the coarctation. HF also may develop.

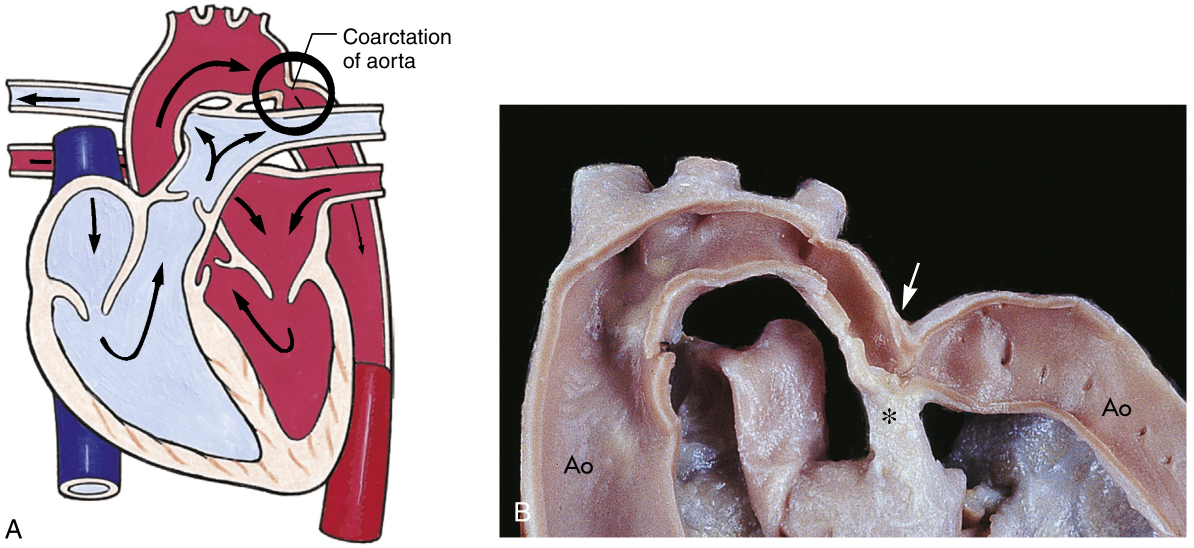

FIGURE 33-11 **Postductal and Preductal Coarctation of the Aorta. A,** Postductal coarctation occurs distal to ("after") the insertion of the closed ductus arteriosus into the aortic arch. Preductal coarctation occurs proximal to ("before") insertion of the patent ductus arteriosus. The coarctation consists of a flap of tissue that protrudes from the tunica media of the aortic wall. **B,** Coarctation of the aorta with typical indentation of the aortic wall *(arrow)* opposite the ductal arterial ligament *(asterisk). Ao,* Aorta. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby; **B** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

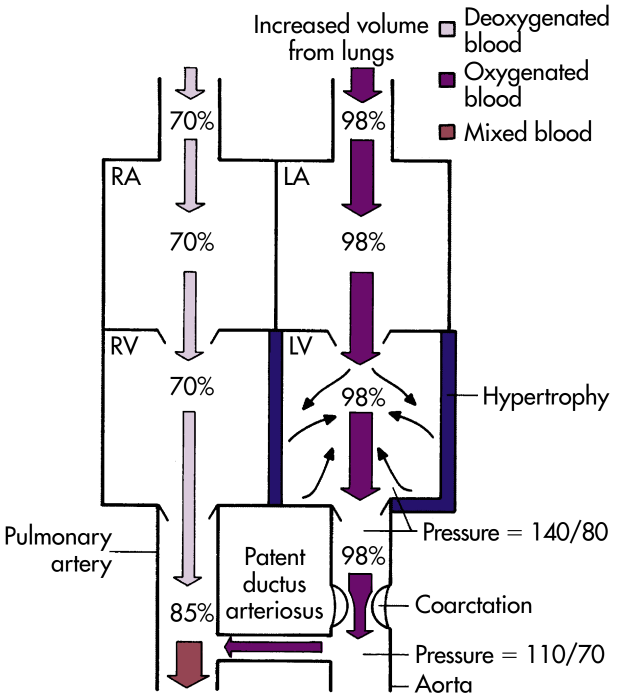

FIGURE 33-12 **Hemodynamics of Preductal Coarctation of the Aorta with a Patent Ductus Arteriosus.** The left-to-right shunt through the ductus arteriosus increases the volume of blood in the pulmonary circulation. Afterload *(small black arrows)* is increased in the left heart by increased return from the lungs and decreased ventricular outflow caused by the coarctation. The outcome is heart failure. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

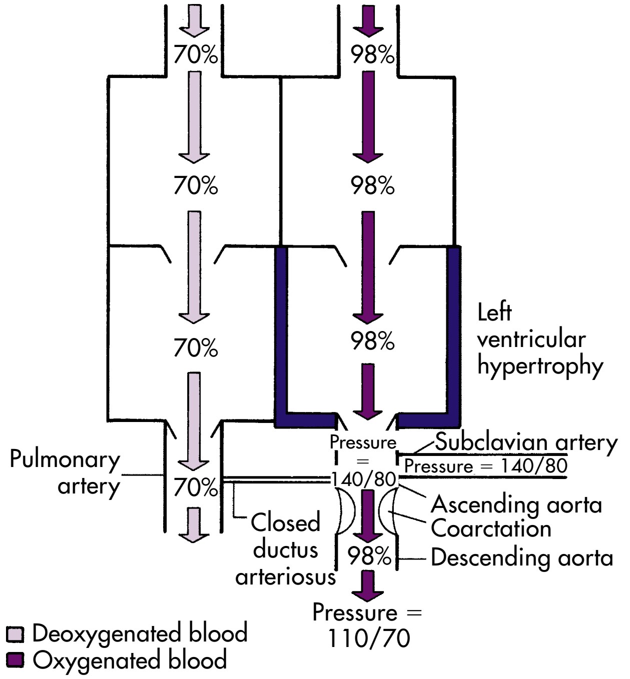

FIGURE 33-13 **Hemodynamics of Postductal Coarctation of the Aorta.** Blood pressure increases in the ascending aorta and subclavian artery and decreases in the descending aorta. These pressure changes eventually occur in the parts of the systemic circulation served by arteries that branch from the aorta before and after the coarctation.

CLINICAL MANIFESTATIONS. Clinical manifestations vary depending on the severity of the coarctation and age of presentation. In newborns the onset of symptoms depends on the timing of ductal closure after a fall in pulmonary vascular resistance, the location of the COA, and the presence of associated defects. The newborn usually presents with CHF symptoms. Once the ductus closes, these infants will deteriorate rapidly from the development of hypotension, acidosis, and shock. Older children may not be diagnosed until hypertension is noted. Hypertension is noted in the upper extremities with decreased or absent pulses in the lower extremities. Children may have cool, mottled skin and occasionally leg cramps during exercise. A systolic ejection murmur, heard best at the left interscapular area, is caused by rapid blood flow through the narrowed area.

EVALUATION AND TREATMENT. A chest radiograph shows an enlarged heart with congested lung fields in newborns. Rib notching between the fourth and eighth ribs may be seen in children older than 5 years, reflecting erosion of the ribs as a result of enlarged collateral vessels from the ascending aorta to the descending aorta, bypassing the coarctation. An ECG may be normal or reveal LV hypertrophy. An echocardiogram will confirm the diagnosis and rule out other intracardiac defects. Cardiac catheterization and/or magnetic resonance imaging (MRI) is performed only if the echocardiogram is inconclusive.

The first step in treatment of the symptomatic infant is stabilization, which may require prostaglandin administration, mechanical ventilation, and inotropic support to maintain adequate cardiac output. Once this is achieved, surgical intervention is indicated. Surgical repair for infants younger than 1 year consists of either a subclavian flap aortoplasty technique to enlarge the constricted area or a resection with end-to-end anastomosis of the arch segments. Depending on the arch morphology, a modification of this procedure enlarges the aorta beyond the area of constriction. For children older than 1 year, surgical repair consists of resection with end-to-end anastomosis.[13] Cardiopulmonary bypass is not required because of the extracardiac nature of the lesion, and the approach is accomplished through a left thoracotomy.

Postoperative complications include recoarctation and paradoxical postoperative hypertension. Residual permanent hypertension requiring continued medical therapy is related to age at repair; therefore, surgical intervention is recommended at the time of diagnosis. Operative mortality for infants is less than 5%, and for children older than 1 year, it is less than 1%. Balloon dilation angioplasty in newborns has been successfully performed. However, aortic aneurysm formation and restenosis have been noted; therefore, surgical repair remains the correction of choice for the newborn.[13-16]

Aortic Stenosis

Aortic stenosis (AS) is a narrowing of the aortic outflow tract (Figure 33-14). The lesion accounts for 5% of all congenital heart defects.[2] Valvular stenosis is caused by malformation or fusion of the cusps. It is the most common type of AS, tends to be progressive, and, in rare cases, can lead to sudden death as a result of low cardiac output or myocardial ischemia. For children with mild AS, no exercise restrictions may be needed. For those with moderate AS, some exercise limitations may be advised. Severe AS is an indication for limiting exercise until the repair is accomplished. Less common forms of AS are subvalvular stenosis caused by a constricting fibrous ring below the valve and supravalvular stenosis that occurs above the valve.[7]

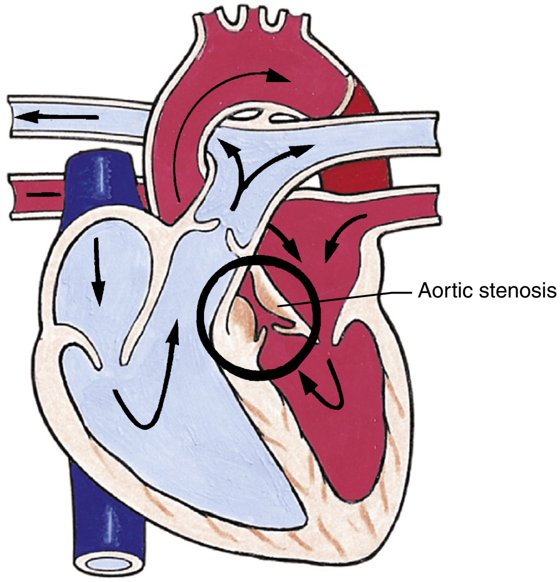

FIGURE 33-14 Aortic Stenosis. Narrowing of the aortic valve causing resistance to blood flow in the left ventricle, decreased cardiac output, left ventricular hypertrophy, and pulmonary congestion. (From Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby.)

PATHOPHYSIOLOGY. Obstruction to blood flowing out of the aorta causes an increased workload on the LV, resulting in left ventricle hypertrophy (LVH). LV failure may develop, leading to an increase in LA pressure and a backup in the system, eventually resulting in pulmonary vascular congestion and pulmonary arterial hypertension. LVH can decrease coronary artery perfusion, resulting in myocardial ischemia, and it can alter the LV papillary muscle, causing mitral insufficiency.

CLINICAL MANIFESTATIONS. Most children with mild to moderate AS are asymptomatic. Signs of exercise intolerance may not appear until preadolescence. Syncopal episodes, epigastric pain, and exertional chest pain may occur in more severe forms of AS. A systolic ejection murmur at the right upper sternal border that transmits to the neck and left lower sternal border is produced by blood flow through the stenotic area. An ejection click may be heard with valvular AS. Severe forms of AS, especially critical AS in the newborn, result in shock and require immediate intervention.

EVALUATION AND TREATMENT. Diagnosis may be made based on previous medical history and physical findings. Chest radiographic examination may reveal a dilated ascending aorta or LV enlargement. Increased pulmonary vascular markings may be seen in severe forms. In mild cases the ECG is normal. LVH with strain pattern (features of LVH with inverted T waves in the lateral precordial leads) may be seen in severe forms. An

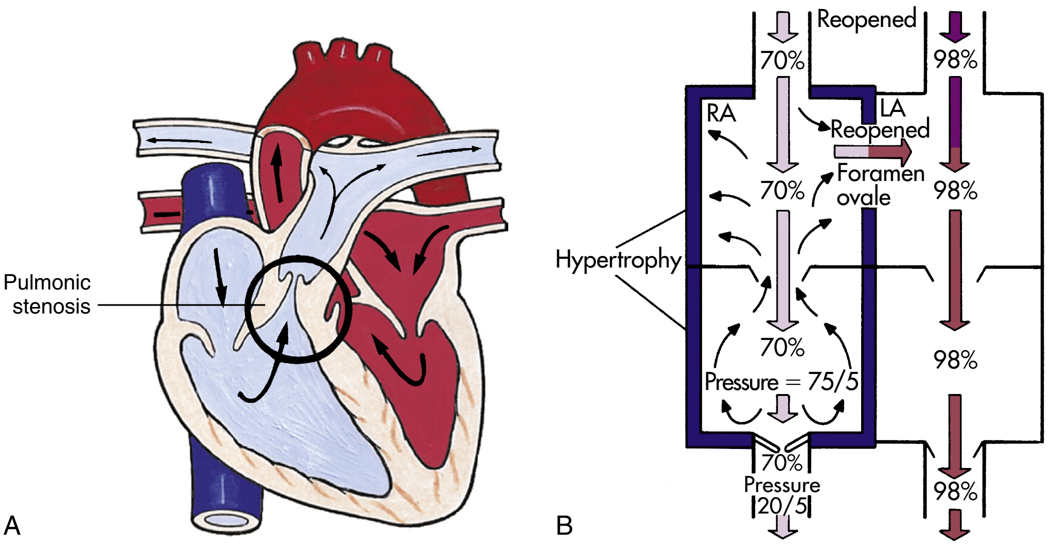

FIGURE 33-15 Pulmonary Stenosis. **A,** Obstruction of right ventricular outflow caused by pulmonary stenosis. Pressure on the ventricular side of the pulmonic semilunar valve (pulmonary valve) is much greater than that on the pulmonary arterial side. This difference disrupts the normal pressure gradient across the valve. Pulmonary stenosis increases ventricular afterload by decreasing blood flow through the valve, which causes ventricular hypertrophy. **B,** The backup of ventricular afterload into the right atrium reopens the foramen ovale. Venous blood then flows from the area of higher pressure (the right atrium) to the area of lower pressure (the left atrium), causing a right-to-left shunt. Cyanosis occurs if enough venous blood shunts from right to left to reduce oxygen saturation in the systemic circulation by 3% to 5%. *LA,* left atrium; *RA,* right atrium. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby.)

echocardiogram may reveal a thickened and poorly functioning LV with abnormal structure, opening and closure of the aortic valve. Cardiac catheterization may be performed to augment echocardiographic data or perform intervention.

The presence of ST-segment changes on ECG, manifestation of severe CHF, and evidence of discrete severe stenosis at the aortic outflow tract are indications for intervention. Balloon aortic valvuloplasty is a palliative procedure performed for valvular AS; however, it is associated with complications, including aortic insufficiency and dysrhythmia.[17] Aortic valvotomy, under inflow occlusion or cardiopulmonary bypass, is performed for valvular AS. Operative mortality remains high in infants (up to 20%), although older children have a mortality close to 0%.[13] As many as 25% of individuals require a second surgery within 10 years for restenosis, at which time valve replacement may be the procedure of choice.

Subvalvular AS and supravalvular AS require surgical repair involving excision of the area causing the constriction. For subvalvular AS involving a small LV outflow tract and aortic annulus, a Konno procedure may be done to enlarge the LV outflow tract and aortic annulus with a patch.[13,18]

Pulmonary Stenosis

Pulmonary stenosis (PS) is the narrowing of the pulmonary outflow tract. This may be in the form of abnormal thickening of the valve leaflets or narrowing of the arterial (supravalvular) or ventricular (subvalvular) side of the valve (Figure 33-15, *A*). **Pulmonary atresia** is the severe form of PS and involves complete fusion of the commissures, allowing no blood flow out of the RV to the PA. PS accounts for 5% to 8% of all congenital heart defects.[2]

PATHOPHYSIOLOGY. PS creates resistance to blood flow from the RV to the PA. The narrowed orifice (valve) produces increased resistance (afterload) to ejection. In order for the RV to maintain adequate cardiac output, the myocardium hypertrophies. If the RV outflow tract obstruction is severe, blood may back up into the RA, causing dilation. This may result in reopening of the foramen ovale with resultant unoxygenated blood shunting to the LA, causing cyanosis (see Figure 33-15, *B*).

CLINICAL MANIFESTATIONS. Clinical manifestations depend on the severity of PS. A systolic ejection murmur at the left upper sternal border reflects obstruction to flow through the narrowed pulmonary valve. In some children a variable systolic ejection click is present with valvular stenosis at the upper left sternal border. A thrill also may be palpated at the upper left sternal border. Children with moderate PS may have exertional dyspnea and fatigability because of the inability of the body to increase pulmonary blood flow to meet demands for increased cardiac output. Severe PS will produce cyanosis and HF.

EVALUATION AND TREATMENT. A chest radiograph shows a normal-size heart with a prominent main PA caused by poststenotic dilation. An ECG is usually normal but may reveal right-axis deviation and RV hypertrophy with moderate PS. Echocardiography confirms the diagnosis and detects associated defects. Cardiac catheterization, if performed for interventional purposes, further demonstrates PA anatomy.

Mild to moderate PS will not likely require intervention but should be observed closely. Most mild PS is not progressive. Treatment is indicated when a significant pressure gradient is detected across the RV outflow tract.

Critical (severe) PS must be addressed immediately. The treatment of choice is balloon angioplasty. This procedure is

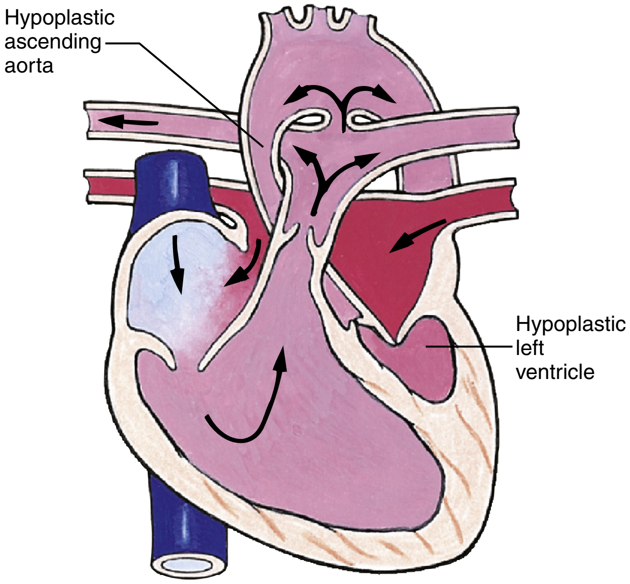

FIGURE 33-16 Hypoplastic Left Heart Syndrome. (From Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing*, ed 9, St Louis, 2013, Mosby.)

considered highly effective in decreasing the pressure gradient across the pulmonic valve and is noted to have few associated complications.[19] Surgical correction involves a pulmonary valvotomy incising the fused commissures. Operative mortality is less than 1%.[2] Both valvotomy and balloon angioplasty may result in some pulmonary valve incompetence, and long-term follow-up may reveal the need for further intervention.

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome (HLHS) refers to the abnormal development of the left-sided cardiac structures, resulting in obstruction to blood flow from the LV outflow tract. HLHS involves underdevelopment of the LV, aorta, and aortic arch, as well as mitral atresia or stenosis (Figure 33-16). Therefore, infants with HLHS must have a well-functioning RV and the presence of a PDA and atrial septal communication for survival. HLHS accounts for 1% of all congenital heart defects and is considered the most complex congenital defect.[7]

PATHOPHYSIOLOGY. Because of the high pressures caused by LV outflow tract obstruction, saturated blood enters the LA and mixes with desaturated blood in the RA through an atrial septal communication. Blood flow follows the normal pathways through the right side of the heart. Exiting the PA, the mixed-saturation blood flows through the ductus and to the descending aorta. The amount of blood flow that travels to the pulmonary and systemic circulations depends on vascular resistance in the respective systems. Retrograde blood flow through the hypoplastic ascending aorta provides coronary and cerebral blood flow if there is complete aortic atresia.

CLINICAL MANIFESTATIONS. Newborns with HLHS generally are born full-term and initially appear healthy. As the ductus closes, systemic perfusion is decreased, resulting in hypoxemia, acidosis, and shock. Usually no heart murmur is detected. The second heart sound is loud and single because of aortic atresia.

EVALUATION AND TREATMENT. A chest radiograph shows cardiomegaly and increased pulmonary venous congestion. ECG shows RV hypertrophy and diminished left-sided forces. Echocardiography reveals the components of the defect with a diminutive LV cavity, hypoplastic aortic valve and arch, and hypoplastic or absent mitral valve with an enlarged RV cavity. Interventional cardiac catheterization with balloon septostomy may be necessary if the atrial communication is inadequate. This procedure is very high risk.[7]

Prostaglandin infusion to maintain patency of the ductus arteriosus is essential for newborn infant survival. Immediate correction of acidosis, inotropic support for adequate cardiac output, and ventilatory manipulation to balance systemic and pulmonary blood flow prevent further deterioration and achieve stabilization.

Surgical intervention includes a three-stage approach that classically begins with a Norwood procedure. The Norwood procedure consists of an atrial septectomy, placement of a pulmonary-to-systemic artery shunt to maintain adequate pulmonary blood flow, creation of a permanent communication between the RV and aorta, and patch augmentation of the hypoplastic aorta. The Sano modification utilizes a graft between the RV and the PA to provide stable pulmonary blood flow rather than a pulmonary to systemic arterial shunt.[20] Postoperative complications include imbalance of systemic and pulmonary blood flow, leading to inadequate cardiac output and persistent HF. In most centers, survival after the initial procedure is now averaging greater than 70%.

The second stage is the bidirectional Glenn procedure, which is performed between 2 and 9 months of age, depending on the child's clinical status, pulmonary vascular resistance, and ventricular function. This involves joining the superior vena cava to the PA and take-down of the shunt to the lungs. Complications include superior vena cava obstruction, pleural effusion, and low cardiac output.

The third stage is the Fontan procedure, described earlier, which separates the systemic from the pulmonary circulation. Timing for surgical repair depends on the child's ventricular function, presence of AV valve regurgitation, and pulmonary vascular resistance. Most surgeons perform the Fontan procedure when the child is approximately 2 to 4 years of age.[7,13]

Cardiac transplant also may be an option for these newborns. Most surgical centers offer the three-staged palliative surgeries as an initial approach, with an option for cardiac transplantation later in life.[7,21]

Mixing Defects

Many complex defects are classified as mixing defects because of their dependence on the mixing of pulmonary and systemic circulations for survival during the postnatal period. This mixing results in desaturated systemic blood flow and cyanosis. Pulmonary congestion occurs because of preferential pulmonary blood flow. Clinically each defect has varying degrees of cyanosis and HF depending on the various components of the lesion.

Transposition of the Great Arteries

Transposition of the great arteries (TGA) refers to a condition in which the aorta arises from the RV and the PA from the LV

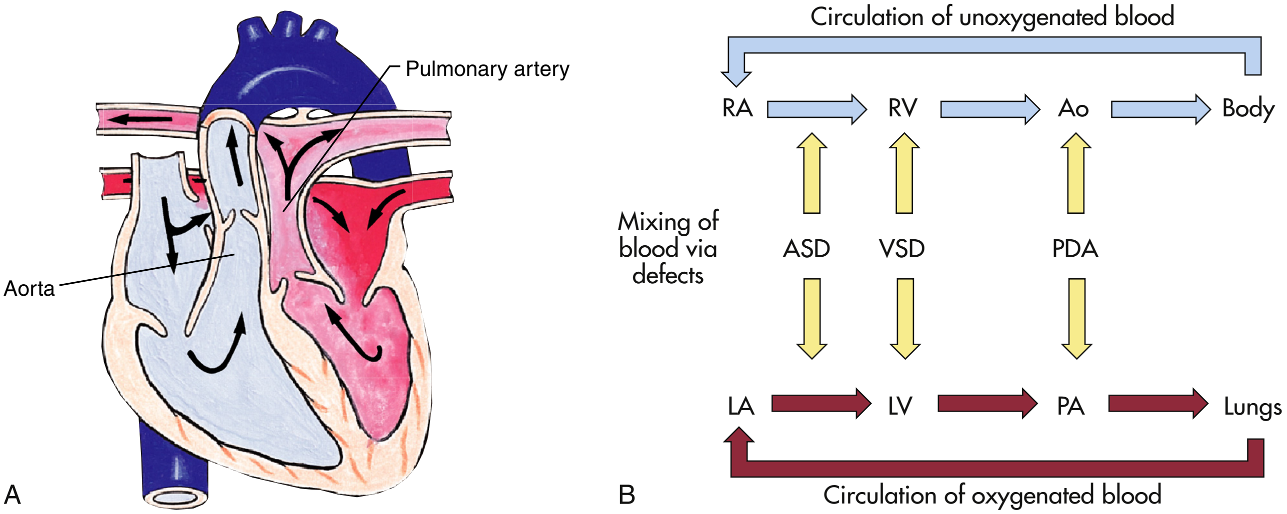

FIGURE 33-17 Hemodynamics in Transposition of the Great Arteries (TGA). **A,** Complete transposition of the great vessels with an intact interventricular septum. The aorta arises from the right ventricle and the pulmonary artery from the left. **B,** Oxygen saturation in the two parallel circuits. *Ao,* Aorta; *ASD,* atrial septal defect; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *PDA,* patent ductus arteriosus; *RA,* right atrium; *RV,* right ventricle; *VSD,* ventricular septal defect. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby.)

(Figure 33-17, *A*). The result is two separate, parallel circuits in which unoxygenated blood circulates continuously through the systemic circulation and oxygenated blood circulates repeatedly through the pulmonary circulation. This condition is incompatible with extrauterine life unless a communication exists between the two circuits to provide the necessary oxygen to the body. Communication is accomplished by mixing of pulmonary and systemic circulations through a PDA, ASD, or VSD (see Figure 33-17, *B*). Dextro-transposition of the great arteries (D-TGA) is the most common cyanotic congenital heart defect and accounts for 10% of all congenital heart defects; "dextro" refers to the aorta remaining to the right of the PA.[2,7]

Two factors allow newborns with complete transposition to survive long enough to be treated. First, blood from the two closed systems can mix through the ductus arteriosus for a short time after birth if pulmonary vascular resistance remains high. Some mixing also may occur through the foramen ovale. If the child has a VSD, mixing occurs through that opening as well.

PATHOPHYSIOLOGY. It is not known precisely which embryologic events lead to transposition, but researchers have proposed that the fault lies in the development of conal tissue in the fibrous skeleton of the heart.[1] The **conus** is a segment of muscle that separates the AV (tricuspid and mitral) valves from the semilunar (aortic and pulmonic) valves. (The fibrous skeleton and heart valves are described and illustrated in Chapter 31; see Figure 31-4.) The interventricular septum is intact in about 60% of cases of transposition; a VSD is present in the remaining 40%. PS is associated with the transposition in about 4% to 6% of children with intact septa and in 28% to 31% of children with VSDs.[2,7]

The discussion that follows is limited to the pathophysiology of complete transposition with an intact interventricular septum.

CLINICAL MANIFESTATIONS. The degree of mixing permitted by fetal structures determines the type and severity of clinical manifestations. Cyanosis may be mild shortly after birth and worsen during the first day because of functional closure of the ductus arteriosus. Low oxygen levels in the blood (hypoxemia) cause metabolic acidosis, tachycardia, and tachypnea. The presence of a PDA or large ASD allows for more mixing and results in only mild cyanosis, but the infant may develop CHF.

The first heart sound is normal, and the second sound may be heard as a single sound even though both the aortic and pulmonic valves are functioning. The loud single S_2 may occur because transposition places the aortic valve closer to the chest wall than the pulmonic valve. No murmur is noted with transposition of the great arteries with an intact ventricular septum.

EVALUATION AND TREATMENT. On chest radiograph the heart has a characteristic shape—like an egg on its side—and pulmonary vascular markings are increased. The heart may be enlarged if the infant is a few weeks old and has a VSD. ECG findings reveal a right-axis deviation and some RV hypertrophy. Echocardiography confirms the diagnosis of transposition of the great arteries. Cardiac catheterization may be necessary to define the coronary anatomy; measure ventricular ratios; and, if necessary, perform a balloon septostomy. Balloon septostomy is done only if the situation is critical because there are risks involved.[22]

Surgical repair during the newborn period involves the arterial switch operation that moves the great arteries. The coronary arteries are removed from the aorta before the arterial switch is performed and reimplanted without torsion or kinking into the aorta. This establishes normal blood flow with the LV as the systemic pump. Results are approaching 100% survival. Complications include narrowing at the sites of the great artery anastomoses and, rarely, coronary insufficiency.[7,22]

Mustard and Senning operations (the creation of an intraatrial tunnel to baffle the systemic venous blood flow to the

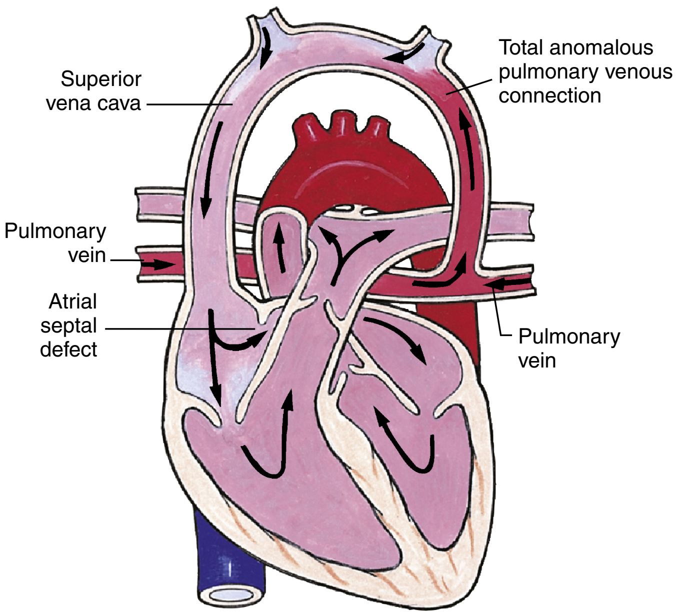

FIGURE 33-18 Hemodynamics of Total Anomalous Pulmonary Venous Connection (TAPVC). In the form of TAPVC represented here, the pulmonary veins enter the left anomalous vertical vein instead of the left atrium. From the left anomalous vertical vein, the mixed blood from the lungs flows into the superior vena cava through an innominate vein (literally, a "vein without a name"). Oxygen saturation within the four heart chambers, the pulmonary artery, and the aorta is the same. Blood pressure in the right heart exceeds that in the left heart because the right heart is receiving blood from both the pulmonary and systemic circulatory systems. (Abnormal vessels are shaded.) (From Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby.)

mitral valve and the pulmonary venous blood flow to the tricuspid valve) are no longer the procedures of choice because the RV must perform as the systemic pump. Long-term follow-up of children with Mustard and Senning operations revealed significant rates of RV failure and dysrhythmias.[7]

The Rastelli procedure is used in children with transposition, VSD, and severe PS. This procedure involves closing the VSD with a baffle by rerouting LV blood through the VSD to the aorta. The pulmonary valve is closed, and an RV-to-PA prosthetic or homograft valve conduit is placed. This procedure requires prosthetic conduit replacement as the child grows and is associated with ventricular failure and dysrhythmias in the postoperative period.[7]

Total Anomalous Pulmonary Venous Connection

Total anomalous pulmonary venous connection (TAPVC), or total anomalous pulmonary venous return, occurs when the pulmonary veins abnormally connect to the right side of the heart either directly or through one or more systemic veins that drain into the RA (Figure 33-18). An ASD generally is present also. This defect is extremely rare, accounting for only 1% of all congenital heart defects. The four types of TAPVC are based on the site of drainage. Supracardiac TAPVCs are the most common form (50%) and drain to the superior vena cava through the vertical or innominate vein. Cardiac TAPVCs (20%) drain directly into the RA or through the coronary sinus. Infracardiac TAPVCs (20%) traverse the diaphragm and drain into the portal or hepatic vein or the inferior vena cava. Mixed TAPVCs (10%) are a combination of the various types. Partial anomalous venous connection is a condition in which only one or two of the pulmonary veins, usually the right-sided veins, drains into the RA or one of its tributaries.[2]

PATHOPHYSIOLOGY. Physiologically TAPVC can be differentiated into two groups: nonobstructive and obstructive, depending on the absence or presence of obstruction to pulmonary venous drainage. The hemodynamics of the nonobstructive group involve the RA receiving the oxygenated blood that would normally flow into the LA. The amount of blood shunted into the LA vs. the volume entering the RV depends on the size of the ASD and compliance of the RV. Therefore, if the ASD is restrictive and RV compliance approaches normal, more blood will enter the RV than the LA, resulting in RA and RV enlargement, as well as increased pulmonary blood flow. This causes increased pulmonary venous blood return and larger amounts of saturated blood. If the ASD is unrestrictive and the RV does not become thinner to increase compliance, the majority of mixed saturated blood is shunted from the higher-pressure RA to the LA.

The hemodynamics of obstructed TAPVC cause pulmonary venous hypertension because of resistance caused by the obstruction resulting in an elevation in pulmonary vascular and RV pressures. Pulmonary edema occurs from hydrostatic capillary pressure exceeding the osmotic pressure of the blood and eventually contributing to the development of HF. This group has a strong association with the infracardiac type of TAPVC and is a surgical emergency.

CLINICAL MANIFESTATIONS. The predominant clinical manifestation in infants with TAPVC is cyanosis caused by mixture of oxygenated and deoxygenated blood entering the systemic circulation. The degree of cyanosis is inversely related to the amount of pulmonary blood flow. Children with unobstructed TAPVC may be asymptomatic until pulmonary vascular resistance drops, at which time pulmonary blood flow will increase, resulting in signs of pulmonary overcirculation, particularly growth retardation and frequent pulmonary infections, in addition to mild cyanosis. Obstructed TAPVC results in cyanosis and rapid deterioration necessitating immediate surgical correction, or death will occur.

Physical examination may reveal a systolic murmur at the left upper sternal border and a mid-diastolic murmur at the left lower sternal border. A murmur may be absent in obstructed TAPVC. A characteristic quadruple rhythm, consisting of S_1, widely split S_2, and S_3 or S_4, or a gallop rhythm also is present.

EVALUATION AND TREATMENT. The ECG shows a right-axis deviation, RV hypertrophy, and occasionally RA hypertrophy. The chest radiograph of unobstructed TAPVC reveals cardiomegaly, increased pulmonary vascular markings, and a snowman or figure-eight appearance in the supracardiac type. A chest roentgenogram of obstructed TAPVC shows a normal-size heart and a ground-glass appearance of the lung fields, reflecting pulmonary venous congestion or edema. The echocardiogram reveals the abnormal pulmonary venous connections.

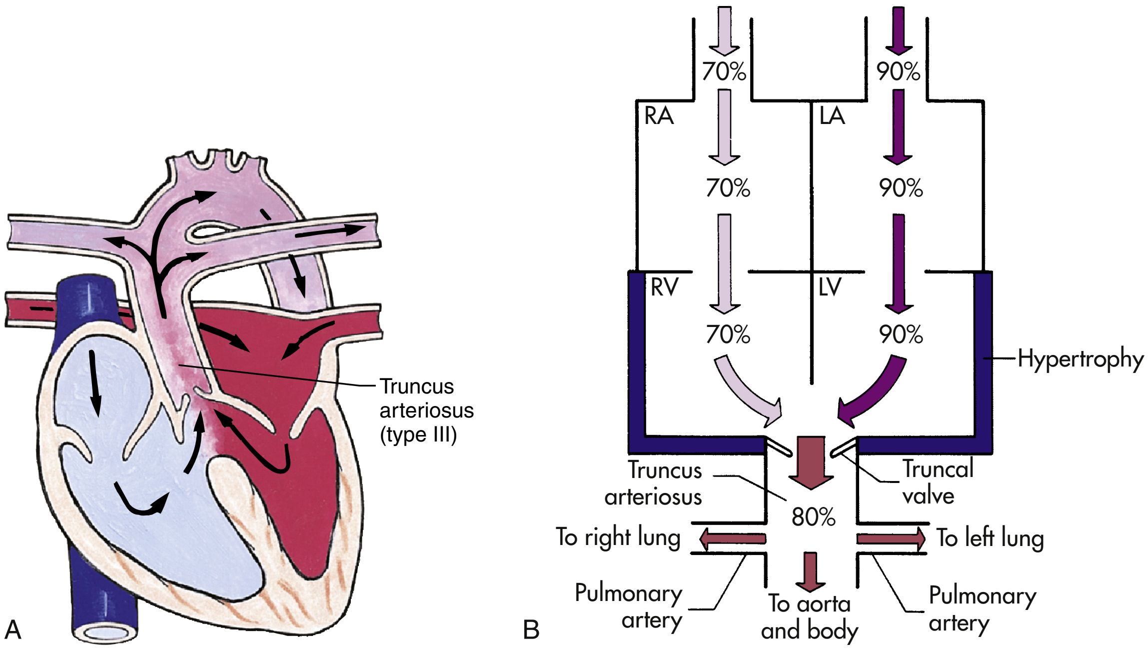

FIGURE 33-19 Truncus Arteriosus. **A,** Persistent truncus arteriosus. The truncus arteriosus fails to divide into the pulmonary artery and aorta, and the interventricular septum fails to close at the top. Blood from both ventricles mixes in the truncus arteriosus and then enters the pulmonary and systemic circuits. **B,** Alterations of hemodynamics and oxygen saturation by persistent truncus arteriosus. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (**A** from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing,* ed 9, St Louis, 2013, Mosby.)

Surgical repair varies with the type of TAPVC and whether the defect is obstructed or unobstructed. Obstructed lesions are repaired at the time of diagnosis, whereas the unobstructed type generally is repaired during infancy. The procedure is performed while the patient is on cardiopulmonary bypass and involves anastomosis of the common pulmonary vein to the LA and closing the ASD, as in the supracardiac and infracardiac types. Repair of the supracardiac type involves baffling the pulmonary venous drainage to the LA. This repair has the highest success rate because of the low technical difficulty, whereas infracardiac repair is associated with a high mortality (up to 25%) and morbidity. Potential complications include reobstruction; atrial dysrhythmias, including sick sinus syndrome; PA hypertension; and LV dysfunction.[13]

Truncus Arteriosus

Truncus arteriosus is the failure of the large embryonic artery, the truncus arteriosus, to divide into the PA and the aorta. This results in a single vessel arising from both ventricles, providing blood flow to the pulmonary and systemic circulations (Figure 33-19, *A*). This common trunk straddles the VSD (always present) and has a single valve with three or four leaflets, which may result in stenosis, regurgitation, or both. The incidence is 2% of all congenital heart defects, and a right aortic arch is present 50% of the time. There are four types of truncus arteriosus. Type I is the most common (60%) and involves the main PA arising from the truncus and then dividing into the right and left PAs. Type II is less common (20%) and involves the PAs arising from the posterior aspect of the truncus. Type III is the least common (10%) and involves the PAs arising from the lateral aspect of the truncus. Type IV, also known as pseudotruncus, is now considered a severe form of TOF with the bronchial arteries arising from the descending aorta to supply the lungs.[2]

PATHOPHYSIOLOGY. Blood flow from the RV and LV is pumped into the main truncus, resulting in mixing of the pulmonary and systemic circulations (see Figure 33-19, *B*). The differential flow out to either the pulmonary bed or the systemic circulation depends on the pulmonary and systemic vascular resistances. Generally the pulmonary vascular resistance is less than the systemic vascular resistance, resulting in the majority of blood flow traveling to the lungs. This may be altered, however, because of PS, small pulmonary arteries, or increased pulmonary vascular resistance. Pulmonary vascular disease develops early with this defect because of increased pulmonary blood flow.

CLINICAL MANIFESTATIONS. Physical findings depend on the amount of pulmonary blood flow and the presence of other cardiac anomalies. If PS is present, a newborn will present with cyanosis, caused by already elevated pulmonary vascular resistance, but no HF. Conversely, if PS is not present, the newborn initially will have mild to moderate cyanosis that worsens with activity. Once pulmonary vascular resistance drops, the pulmonary bed will receive preferential flow and the infant will have signs of HF. A harsh systolic regurgitant murmur is usually present along the left sternal border as a result of the VSD, and a systolic click at the apex and left upper sternal border may be present, reflecting opening of the truncal valve. An apical rumble with or without a gallop rhythm also may be present because of increased pulmonary blood flow. If truncal valve insufficiency exists, an early diastolic, high-pitched decrescendo murmur may be present.

EVALUATION AND TREATMENT. An ECG generally reveals biventricular hypertrophy and occasionally LA enlargement. A chest radiograph reveals cardiomegaly with biventricular and LA

enlargement, as well as increased pulmonary vascular markings. When PS is present, the heart size is normal and the pulmonary vascular markings are decreased. Echocardiography and cardiac catheterization, if performed, determine the type of truncal defect, competency of the truncal valve, and differential blood flow.

Surgical repair in early infancy is recommended to prevent the sequelae of severe HF and pulmonary vascular disease. The definitive repair consists of a modified Rastelli procedure involving VSD patch closure to divert the blood flow from the LV outflow tract into the truncus. The pulmonary arteries are excised from the aorta and connected to the RV through a tissue homograft—namely, aortic and PA segments or cadaver tissue that is specially preserved. Synthetic conduits may be used but tend to calcify and develop narrowing within the lumen, leading to obstruction and the need for early replacement. Mortality varies depending on the type of truncal anomaly (20% to 50%). Postoperative complications include HF, residual VSD, truncal valve (now the aorta) stenosis or insufficiency, dysrhythmias, and pulmonary hypertension. The RV to PA homograft requires replacement because it becomes inadequate for somatic growth.[13]

ACQUIRED CARDIOVASCULAR DISORDERS

Acquired heart diseases are those disease processes or abnormalities that occur after birth. They result from various causes, such as infection, genetic disorders, autoimmune processes in response to infection, environmental factors, or autoimmune diseases. Examples of acquired heart diseases include Kawasaki disease, myocarditis, rheumatic heart disease, cardiomyopathy, and systemic hypertension. This chapter discusses Kawasaki disease and systemic hypertension. Myocarditis, rheumatic heart disease, and cardiomyopathy are discussed in Chapter 32.

Kawasaki Disease

Kawasaki disease, formerly known as mucocutaneous lymph node syndrome, is an acute, self-limiting systemic vasculitis that may result in cardiac sequelae. Although Kawasaki disease occurs throughout the world, the greatest number of cases are reported in Japan.

Kawasaki disease is primarily a condition of young children: 80% of cases are seen in children younger than 5 years of age, with the incidence peaking in the toddler age group. Males are affected slightly more than females. Its peak incidence is in winter and spring.

The etiology of Kawasaki disease remains unknown. Theories center on an immunologic response to an infectious, toxic, or antigenic substance (including superantigen).[2,7,23]

PATHOPHYSIOLOGY. Kawasaki disease progresses pathologically and clinically in the following stages:

Stage I (days 1 to 12): Small capillaries, arterioles, and venules become inflamed, as does the heart itself.

Stage II (days 13 to 25): Inflammation spreads to larger vessels, and aneurysms of the coronary arteries develop.

Stage III (days 26 to 40): Medium-size arteries begin the granulation process, causing coronary artery thickening; inflammation resolves in the microcirculation; and there is risk of thrombus formation.

Stage IV (day 41 and beyond): Vessels develop scarring, intimal thickening, calcification, and stenosis of coronary arteries.

BOX 33-3 DIAGNOSTIC CRITERIA FOR KAWASAKI DISEASE

The child must exhibit five of the following six criteria, including fever:

1. Fever for 5 or more days (often diagnosed with shorter duration of fever if other symptoms are present)
2. Bilateral conjunctival infection without exudation
3. Changes in the oral mucous membranes, such as erythema, dryness, and fissuring of the lips; oropharyngeal reddening; or "strawberry tongue"
4. Changes in the extremities, such as peripheral edema, peripheral erythema, and desquamation of palms and soles, particularly periungual peeling
5. Polymorphous rash, often accentuated in the perineal area
6. Cervical lymphadenopathy

Modified from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children,* ed 9, St Louis, 2011, Mosby.

CLINICAL MANIFESTATIONS. The clinical course of the disease progresses in three stages: acute, subacute, and convalescent. In the acute phase the child has fever, conjunctivitis, oral changes ("strawberry" tongue), rash, and lymphadenopathy and is often irritable. During this phase myocarditis in addition to the vasculitis may develop. The subacute phase begins when the fever ends and continues until the clinical signs have resolved. It is at this time that the child is most at risk for coronary artery aneurysm development. Desquamation of the palms and soles occurs at this time, as well as marked thrombocytosis. The convalescent phase is marked by the continued elevation of the erythrocyte sedimentation rate and platelet count. Arthritis still may be present. This phase continues until all laboratory values return to normal—usually about 6 to 8 weeks after onset.

EVALUATION AND TREATMENT. The diagnosis is based on the diagnostic criteria for Kawasaki disease, which state that the child must exhibit five of six criteria, including fever (Box 33-3). These children usually have leukocytosis, increased erythrocyte sedimentation rates, marked thrombocytosis, and elevated levels of liver enzymes. An echocardiogram is obtained at the time of diagnosis as a baseline to assess for coronary aneurysms or inflammation. Serial echocardiograms are obtained after treatment to assess for future development of coronary aneurysms.

The use of aspirin and intravenous immunoglobulin during the acute phase has decreased the mortality of Kawasaki disease and has reduced the incidence of coronary abnormalities from approximately 20% to less than 2% at 6 to 8 weeks after initiation of therapy. Most children recover completely from Kawasaki disease, including the regression of aneurysms. The most common, although rare, cardiovascular sequela is coronary thrombosis. Studies are investigating long-term results of the disease.[5,23]

Systemic Hypertension

Hypertension (HTN) in children differs from adult HTN in etiology and presentation. Children diagnosed with HTN are often found to have some underlying disease, such as renal disease or COA (Box 33-4). In recent years an increased prevalence

BOX 33-4 CONDITIONS ASSOCIATED WITH SECONDARY HYPERTENSION IN CHILDREN

Renal Disorders

Congenital defects
- Polycystic kidney, ectopic kidney, horseshoe kidney, etc.
- Obstructive anomalies
- Hydronephrosis

Renal tumor
- Wilms tumor
- Retrovascular tumor

Abnormalities of renal arteries

Renal vein thrombosis

Acquired disorders
- Glomerulonephritis—acute or chronic
- Pyelonephritis
- Nephritis associated with collagen disease

Cardiovascular Disease

Coarctation of the aorta

Arteriovenous fistulae

Patent ductus arteriosus

Aortic or mitral insufficiency

Metabolic and Endocrine Diseases

Adrenal tumors
- Adenoma
- Pheochromocytoma
- Neuroblastoma
- Cushing syndrome
- Adrenogenital syndrome
- Hyperthyroidism
- Aldosteronism
- Hypercalcemia
- Diabetes mellitus

Neurologic Disorders

Space-occupying lesions of cranium (increased intracranial pressure)
- Tumors, cysts, hematoma
- Cerebral edema
- Encephalitis (including Guillain-Barré and Reye syndromes)

Miscellaneous Causes

Drugs (corticosteroids, oral contraceptives, pressor agents, amphetamines)

Burns

Genitourinary surgery

Trauma (e.g., stretching of femoral nerve with leg traction)

Insect bites (e.g., scorpion)

Intravascular overload (blood, fluid)

Hypernatremia

Toxemia of pregnancy

Heavy metal poisoning

of primary HTN in older children has been noted. Researchers are now focusing on primary HTN in older children in relation to morbidity and mortality and the presence of early atherosclerotic disease.[2,7,24,25]

Systemic hypertension in children is defined as systolic and diastolic blood pressure levels greater than the 95th percentile for age and gender on at least three occasions. The Fourth Task Force on Blood Pressure Control in Children uses height as an additional criterion to the blood pressure guide.[26]

PATHOPHYSIOLOGY. Hypertension is classified as (1) primary (or essential) hypertension, in which a specific cause cannot be identified; or (2) secondary hypertension, in which a cause is secondary to another alteration (see Box 33-4). In infants and children a cause of HTN is almost always found. In general, the younger the child with significant hypertension, the more likely that a correctable cause can be found. Therefore, a thorough evaluation needs to be done.[27]

The pathophysiology of primary HTN in children is not clearly understood but may result from a complex interaction of a strong disposing genetic component with disturbances in sympathetic vascular smooth muscle tone, humoral agents (angiotensin, catecholamines), renal sodium excretion, and cardiac output (Figure 33-20). Ultimately these factors impair the ability of the peripheral vascular bed to adjust its own resistance to meet tissue perfusion needs.[24]

CLINICAL MANIFESTATIONS. Most children with systemic HTN are asymptomatic. It is necessary that a thorough history (including family history of HTN and heart disease) and physical examination be obtained. The examination should include an accurate blood pressure measurement on three separate occasions using a cuff of appropriate size (Tables 33-6 and 33-7).

Certain factors influence blood pressure in children. Smoking is also associated with an increased risk for HTN. Obesity is emerging as one of the most important factors in the increasing prevalence of HTN in children.

EVALUATION AND TREATMENT. In children the history and physical examination should be directed at determining the etiology of HTN, such as COA or renal disease (Table 33-8). If COA is found, surgical or interventional correction is initiated. A complete blood count, serum chemistry levels, urinalysis, urine culture, lipid profile, and renal ultrasound are part of the routine evaluation for renal disease (Table 33-9).

Although the criteria for the diagnosis of hypertension are based on the use of a standard blood pressure cuff, some children have what is termed "white coat hypertension." Elevated blood pressure readings in these children occur only when measured in the clinic and may be caused by fear and anxiety. The use of ambulatory blood pressure monitoring (ABPM) records the blood pressure over a 24-hour period. In addition to identifying children with white coat hypertension, ABPM has been

TABLE 33-9 ROUTINE AND SPECIAL LABORATORY TESTS FOR HYPERTENSION

LABORATORY TEST	SIGNIFICANCE OF ABNORMAL RESULTS
Urinalysis, urine culture, blood urea nitrogen, creatinine, uric acid	Renal parenchymal disease
Serum electrolyte levels (hypokalemia)	Hyperaldosteronism (primary or secondary) Adrenogenital syndrome Renin-producing tumors
ECG, chest x-ray studies, and possibly echocardiography	Cardiac cause of hypertension, also baseline function
Intravenous pyelogram (or ultrasonography, radionuclide studies, computed tomography, or magnetic resonance imaging of the kidneys)	Renal parenchymal disease Renovascular hypertension Tumors (neuroblastoma, Wilms tumor)
Plasma renin activity (peripheral)	High-renin hypertension (renovascular hypertension, renin-producing tumors, some Cushing syndrome, some essential hypertension) Low-renin hypertension (adrenogenital syndrome, primary hyperaldosteronism)
24-hour urine collection for 17-ketosteroids and 17-hydroxycorticosteroids	Cushing syndrome Adrenogenital syndrome
24-hour urine collection for catecholamine levels and vanillylmandelic acid	Pheochromocytoma Neuroblastoma
Aldosterone	Hyperaldosteronism (primary or secondary) Renovascular hypertension Renin-producing tumors
Renal vein plasma renin activity	Unilateral renal parenchymal disease Renovascular hypertension
Abdominal aortogram	Renovascular hypertension Abdominal coarctation of the aorta Unilateral renal parenchymal diseases Pheochromocytoma

ECG, Electrocardiogram.

found to be useful in children with hypertension that is resistant to treatment (see What's New? Ambulatory Blood Pressure Monitoring in Children).[26]

If HTN is found to be essential, or primary, in nature, nonpharmacologic therapy is used initially. Moderate weight loss can decrease systolic and diastolic pressures in many children. Appropriate diet, regular physical activity, and avoidance of smoking have been shown to be effective in reducing blood pressure.[28]

WHAT'S NEW?

Ambulatory Blood Pressure Monitoring in Children

Ambulatory blood pressure monitoring (ABPM) records blood pressure over a 24-hour period. Its use in children was endorsed by the Fourth Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children primarily to help identify those children with "white coat hypertension." Paradoxically, some children have normal blood pressure readings in the clinic but are hypertensive during other parts of the day. This is called "masked hypertension" and also can be identified by ABPM. ABPM is useful in documenting what is called the "BP load," which is the total amount of time the blood pressure (BP) is elevated above normal limits during a 24-hour period. By measuring BP load, ABPM may be able to identify those children who are at greatest risk for target organ damage. It can also help with management of children who suffer hypotensive episodes in response to pharmacologic therapy for their hypertension. Finally, ABPM facilitates medication changes in those with hypertension resistant to medication.

Data from Flynn JT, Urbina EM: *J Clin Hypertens* 14(6):372–382, 2012; National High Blood Pressure Education Program Working Group on High Blood Pressure in Children: *Pediatrics* 114:555–576, 2004.

Drug therapy is controversial in children with primary hypertension; however, when nonpharmacologic therapy fails, a staged approach with the use of diuretics and/or beta-blockers and afterload reduction is indicated. The emphasis on preventive cardiology, especially for children, is significant because many investigators believe signs of atherosclerosis and other cardiovascular risk factors are present from childhood.[29-32]

Childhood Obesity

Childhood obesity is considered an epidemic not only in the United States but also in other countries such as Australia.[33-35] Despite attention from U.S. federal and state initiatives, the prevalence of obesity in children and young adults has steadily increased over the past four decades, with estimates as high as 25% of children considered obese.[33] Although not without controversy, percentile of body mass index (BMI) expressed as weight/height^2 (BMI-kg/m^2) is used to identify overweight and obesity in children and adolescents. The Centers for Disease Control and Prevention (CDC), the supplier of national growth charts and prevalence data, avoids characterizing children and adolescents as "obese"; instead, the CDC suggests two levels of overweight: (1) the 85th percentile, an "at risk" level; and (2) the 95th percentile, the more severe level.[36]

Causes of obesity in young children and adolescents are multivariable and multidimensional. Risk factors associated with developing childhood obesity include race, socioeconomic status, and lack of health insurance. Children of black and Hispanic race are at higher risk, as well as children with no insurance.[34] The presence of parental obesity also is associated with childhood obesity.[37] In addition, early childhood nutrition, level of physical activity, and engagement of sedentary activities, such as watching television and computer use, is associated with the development of overweight and obese children.[38-40]

Similar to obese adults, overweight and obese children are at risk for acquiring numerous other serious and potentially life-threatening illnesses, such as asthma, sleep apnea, hypertension, type 2 diabetes, dyslipidemia, and cardiovascular disease.[7] Researchers also have reported a multitude of social and economic consequences in adolescents as a result of being overweight. Overweight adolescents are more likely to complete fewer years of education, are less likely to marry, and have a lower household income in adulthood, independent of familial socioeconomic status.[41]

As in other acquired diseases, efforts should be focused on prevention. The initial approach is a combined program of physical activity with nutritional improvements. Healthcare professionals play a vital role in recognizing the need for intervention, immediate referral, and support. Successful outcomes for most overweight and obese children require support, change in lifestyle at home, and involvement of family members. Researchers are involving school-based programs in promoting and preventing obesity in the young.[42]

SUMMARY REVIEW

Development of the Cardiovascular System

1. The heart arises from the mesenchyme and begins as an enlarged blood vessel with a large lumen and a muscular wall. By approximately the eighth week of gestation, all structures of the fetal heart and vascular system are present.
2. The endocardial cushions are instrumental in closing the atrial septum, dividing the AV canals into the right and left AV orifices, and closing the septum.
3. In the fetus the pulmonary and systemic circulatory systems are connected by the foramen ovale, an opening between the atria; by the ductus arteriosus, a fetal vessel that joins the PA to the aorta; and by the ductus venosus, a fetal vessel that connects the inferior vena cava to the umbilical vein.
4. Fetal circulation is different from postnatal circulation because of the presence of fetal shunts and altered metabolic needs of the various organs.
5. Fetal blood flow depends on resistance for its distribution through the body. Resistance in the pulmonary circulation is higher than resistance in the systemic circulation, so myocardial thickness is about the same in the right heart and the left heart.
6. After birth, systemic resistance increases and pulmonary resistance decreases.
7. Pulmonary vascular resistance drops suddenly at birth because the lungs expand and the pulmonary vessels dilate. It continues to decrease gradually during the first 6 to 8 weeks after birth. Decreased resistance causes the right myocardium to become thinner.
8. Systemic vascular resistance increases markedly at birth because severance of the umbilical cord removes the low-resistance placenta from the systemic circulation. Increased systemic resistance causes the left myocardium to become dominant and thicken over time.
9. Changes in resistance cause disappearance of the fetal connections between the pulmonary and systemic circulatory systems. The foramen ovale closes functionally at birth and anatomically several months later; the ductus arteriosus closes functionally 15 to 18 hours after birth and anatomically within 10 to 21 days; and the ductus venosus closes within 1 week after birth.
10. At birth a series of circulatory changes occur that affect blood flow, vascular resistance, and oxygen tension. The most important change is the shift of gas exchange from the placenta to the lungs.
11. After birth, significant postnatal changes occur, including thinning of the right ventricular myocardium as the pulmonary vascular resistance drops. As the systemic vascular resistance increases, the left ventricular myocardium becomes thicker and more dominant as it is in the adult heart.

Congenital Heart Defects

1. Most congenital cardiovascular defects have begun to develop by the eighth week of gestation, and most have many causes, both environmental and genetic.
2. Environmental risk factors associated with the incidence of congenital heart defects typically are maternal conditions. Among these are viral infections, diabetes, drug intake, alcohol intake, metabolic disorders, and advanced maternal age.
3. Genetic factors associated with congenital heart defects include but are not limited to Down syndrome, trisomy 13, trisomy 18, cri du chat syndrome, and Turner syndrome. It now appears, however, that most genetic mechanisms of causation are multifactorial.
4. Classification of congenital heart defects is based on whether they: (a) cause blood flow to the lungs to increase or decrease, (b) obstruct ventricular blood flow patterns, or (c) cause mixing of unoxygenated and oxygenated blood.
5. Symptoms of HF are usually the result of congenital heart defects that increase blood volume and pressure in the pulmonary circulation. Clinical manifestations are almost the same as the manifestations of CHF in adults. A unique manifestation in children is FTT.
6. Cyanosis, a bluish discoloration of the skin, indicates that the tissues are not receiving fully adequate oxygenated blood. Cyanosis can be caused by defects that (a) reduce pulmonary blood flow; (b) overload the pulmonary

SUMMARY REVIEW—cont'd

circulation, causing pulmonary hypertension, pulmonary edema, and respiratory difficulty; and (c) cause large amounts of unoxygenated blood to shunt from the pulmonary to the systemic circulation.

7. Congenital defects that maintain or create direct communication between the pulmonary and systemic circulatory systems cause blood to shunt from one system to another, mixing oxygenated and unoxygenated blood and increasing blood volume and pressure on the receiving side of the shunt.
8. The direction of shunting through an abnormal communication depends on differences in pressure and resistance between the two systems. Flow is always from an area of high pressure to an area of low pressure. The resistance to flow determines the volume of the shunting.
9. Acyanotic congenital defects that increase pulmonary blood flow consist of abnormal openings (PDA, ASD, VSD, AVC defect, or truncus arteriosus) that permit blood to shunt from left (systemic circulation) to right (pulmonary circulation). Cyanosis does not occur because the left-to-right shunt does not interfere with the flow of oxygenated blood through the systemic circulation.
10. If the abnormal communication between the left and right circuits is large, volume and pressure overload in the pulmonary circulation leads to CHF.
11. In truncus arteriosus the main trunk fails to divide longitudinally into the aorta and PA. All blood from both ventricles enters the truncus, so that mixed blood is delivered by both circulatory systems, causing varying degrees of cyanosis and HF.
12. In heart defects that decrease pulmonary blood flow (TOF, tricuspid atresia), myocardial hypertrophy cannot compensate for restricted right ventricular outflow. Flow to the lungs decreases, and cyanosis is caused by mixing of systemic and pulmonary venous return.
13. Obstruction of ventricular outflow commonly is caused by PS, AS, COA, interrupted aortic arch, or hypoplastic left heart syndrome.
14. Despite obstruction, ventricular output remains normal for a long time because of compensatory ventricular hypertrophy stimulated by increased afterload and, in postductal COA, development of collateral circulation around the coarctation.
15. Signs of HF can occur with pulmonary overcirculation or myocardial failure.
16. Complex congenital defects that depend on mixing of the pulmonary and systemic circulations for survival during the postnatal period include complete transposition of the great arteries and total anomalous pulmonary venous connection. This mixing results in desaturated systemic blood flow and cyanosis.
17. In complete transposition of the great vessels, the circulatory systems are not connected serially or through a shunt, so that oxygenated blood remains permanently in the pulmonary circulation and unoxygenated blood remains in the systemic circulation. Survival depends on patency of the ductus arteriosus; in the absence of patency, surgical intervention is mandatory.
18. Total anomalous pulmonary venous connection is caused by abnormal pulmonary vein development and the lack of direct pulmonary venous return to the LA. All blood from the pulmonary and systemic circulations enters the RA. Mixed blood enters the LA through an ASD; it then flows into the systemic circulation and causes cyanosis.
19. Treatment for all hemodyamically severe congenital defects is surgical or interventional correction of the anomaly and management of cyanosis and HF.

Acquired Cardiovascular Disorders

1. The most common acquired cardiovascular disorders of childhood are Kawasaki disease, rheumatic heart disease, and hypertension.
2. Kawasaki disease is an acute systemic vasculitis that also may result in the development of coronary artery aneurysms and thrombosis.
3. Essential or primary hypertension in children is the same as that in adults, except that it is more likely to be diagnosed in an early, asymptomatic stage. Most cases of hypertension in young children are secondary to an underlying cause.
4. Obesity in childhood is epidemic in the United States and other countries.
5. Obese children are at risk for acquiring numerous other serious and potentially life-threatening illnesses, such as asthma, sleep apnea, hypertension, type 2 diabetes mellitus, and cardiovascular disease.

- Review Questions and Answers

CHAPTER OUTLINE

The pulmonary system consists of upper and lower airways, the chest wall, and pulmonary circulation. The primary function of the pulmonary system is the exchange of gases between the environmental air and the blood. There are three steps in this process: (1) ventilation, the movement of air into and out of the lungs; (2) diffusion, the movement of gases between air spaces in the lungs and the bloodstream; and (3) perfusion, the movement of blood into and out of the capillary beds of the lungs to body organs and tissues. The first two functions are carried out by the pulmonary system and the third by the cardiovascular system (see Chapter 31). Normally the pulmonary system functions efficiently under a variety of conditions and with little energy expenditure.

STRUCTURES OF THE PULMONARY SYSTEM

The pulmonary system is made up of the upper airways, two lungs, the lower airways, and the blood vessels that serve them (Figure 34-1); the chest wall, or thoracic cage; and the diaphragm. The lungs are divided into lobes: three in the right lung (upper, middle, lower) and two in the left lung (upper, lower). Each lobe is further divided into segments and lobules. The space between the lungs, which contains the heart, great vessels, and esophagus, is called the *mediastinum.* A set of conducting airways, called bronchi, deliver air to each section of the lung. The lung tissue that surrounds the airways supports them, preventing their distortion or collapse as gas moves in and out during ventilation. The diaphragm is a dome-shaped muscle that separates the thoracic and abdominal cavities and is involved in ventilation.

The lungs are protected from a variety of exogenous contaminants by a series of mechanical and cellular defenses (Table 34-1). These defense mechanisms are so effective that in the healthy individual, contamination of the lung tissue itself is unusual. (Other defense mechanisms are discussed in Chapters 7 and 8.)

Conducting Airways

The conducting airways are the portion of the pulmonary system that provides a passage for the movement of air into and out of the gas-exchange portions of the lung. They consist of upper and lower airways. The **nasopharynx, oropharynx,** and related structures often are called the *upper airway* (Figure 34-2). These structures are lined

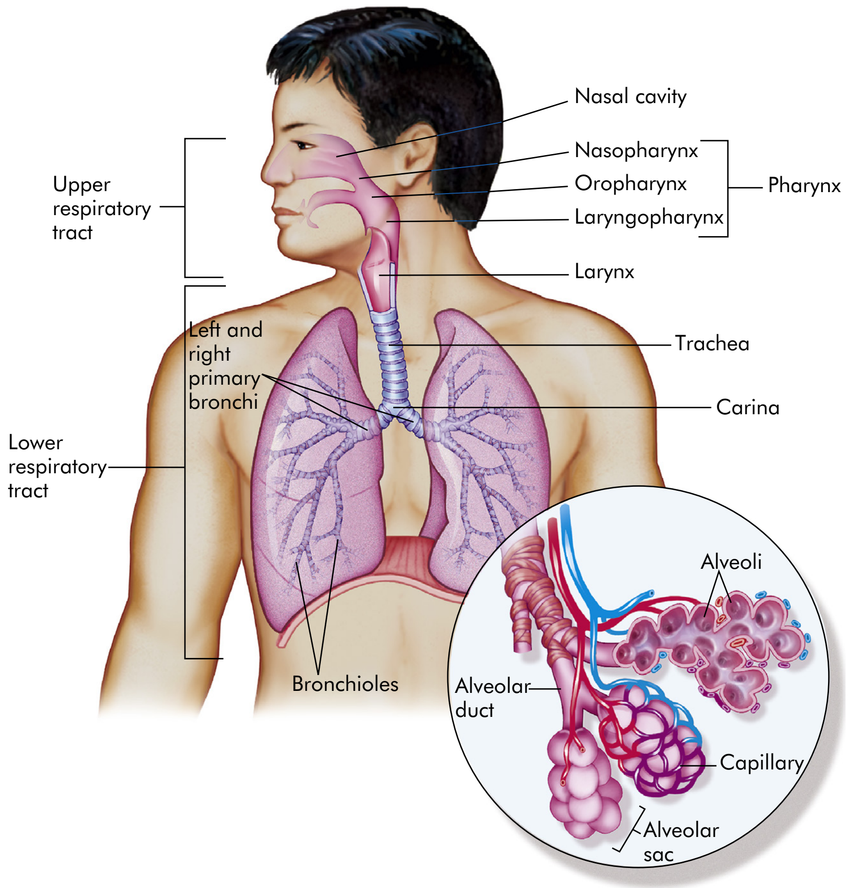

FIGURE 34-1 Structural Plan of the Respiratory System. *Inset* shows alveolar sacs where the interchange of oxygen and carbon dioxide takes place through the walls of the grapelike alveoli. Capillaries surround the alveoli. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

TABLE 34-1 PULMONARY DEFENSE MECHANISMS

STRUCTURE OR SUBSTANCE	MECHANISM OF DEFENSE
Upper respiratory tract mucosa	Maintains constant temperature and humidification of gas entering the lungs; traps and removes foreign particles, some bacteria, and noxious gases from inspired air
Nasal hairs and turbinates	Trap and remove foreign particles, some bacteria, and noxious gases from inspired air
Mucous blanket	Protects trachea and bronchi from injury; traps most foreign particles and bacteria that reach the lower airways
Cilia	Propel mucous blanket and entrapped particles toward the oropharynx, where they can be swallowed or expectorated
Alveolar macrophages	Ingest and remove bacteria and other foreign material from alveoli by phagocytosis (see Chapter 7)
Surfactant	Enhance phagocytosis of pathogens and allergens in alveoli; down-regulate inflammatory responses
Irritant receptors in nares (nostrils)	Stimulation by chemical or mechanical irritants triggers sneeze reflex, which results in rapid removal of irritants from nasal passages
Irritant receptors in trachea and large airways	Stimulation by chemical or mechanical irritants triggers cough reflex, which results in removal of irritants from the trachea and large airways

with a ciliated mucosa with a very rich vascular supply. The mucosal lining warms and humidifies inspired air to 100% and removes foreign particles from it as it passes into the lungs. During quiet breathing, gas usually flows through the nose, nasopharynx, and oropharynx to the lower airways. The mouth and oropharynx provide for ventilation when the nose is obstructed or when increased flow is required, such as during exercise. Filtering and humidifying are not as efficient with mouth breathing.

The **larynx** connects the upper and lower airways. The structure of the larynx consists of the endolarynx and its surrounding triangular-shaped bony and cartilaginous structures. The endolarynx is formed by two pairs of folds that form the false vocal cords (supraglottis) and the true vocal cords. The slit-shaped space between the true cords forms the glottis (see Figure 34-2). The vestibule is the space above the false vocal cords. The laryngeal box is formed by three large cartilages—the epiglottis, thyroid, and cricoid—and three smaller

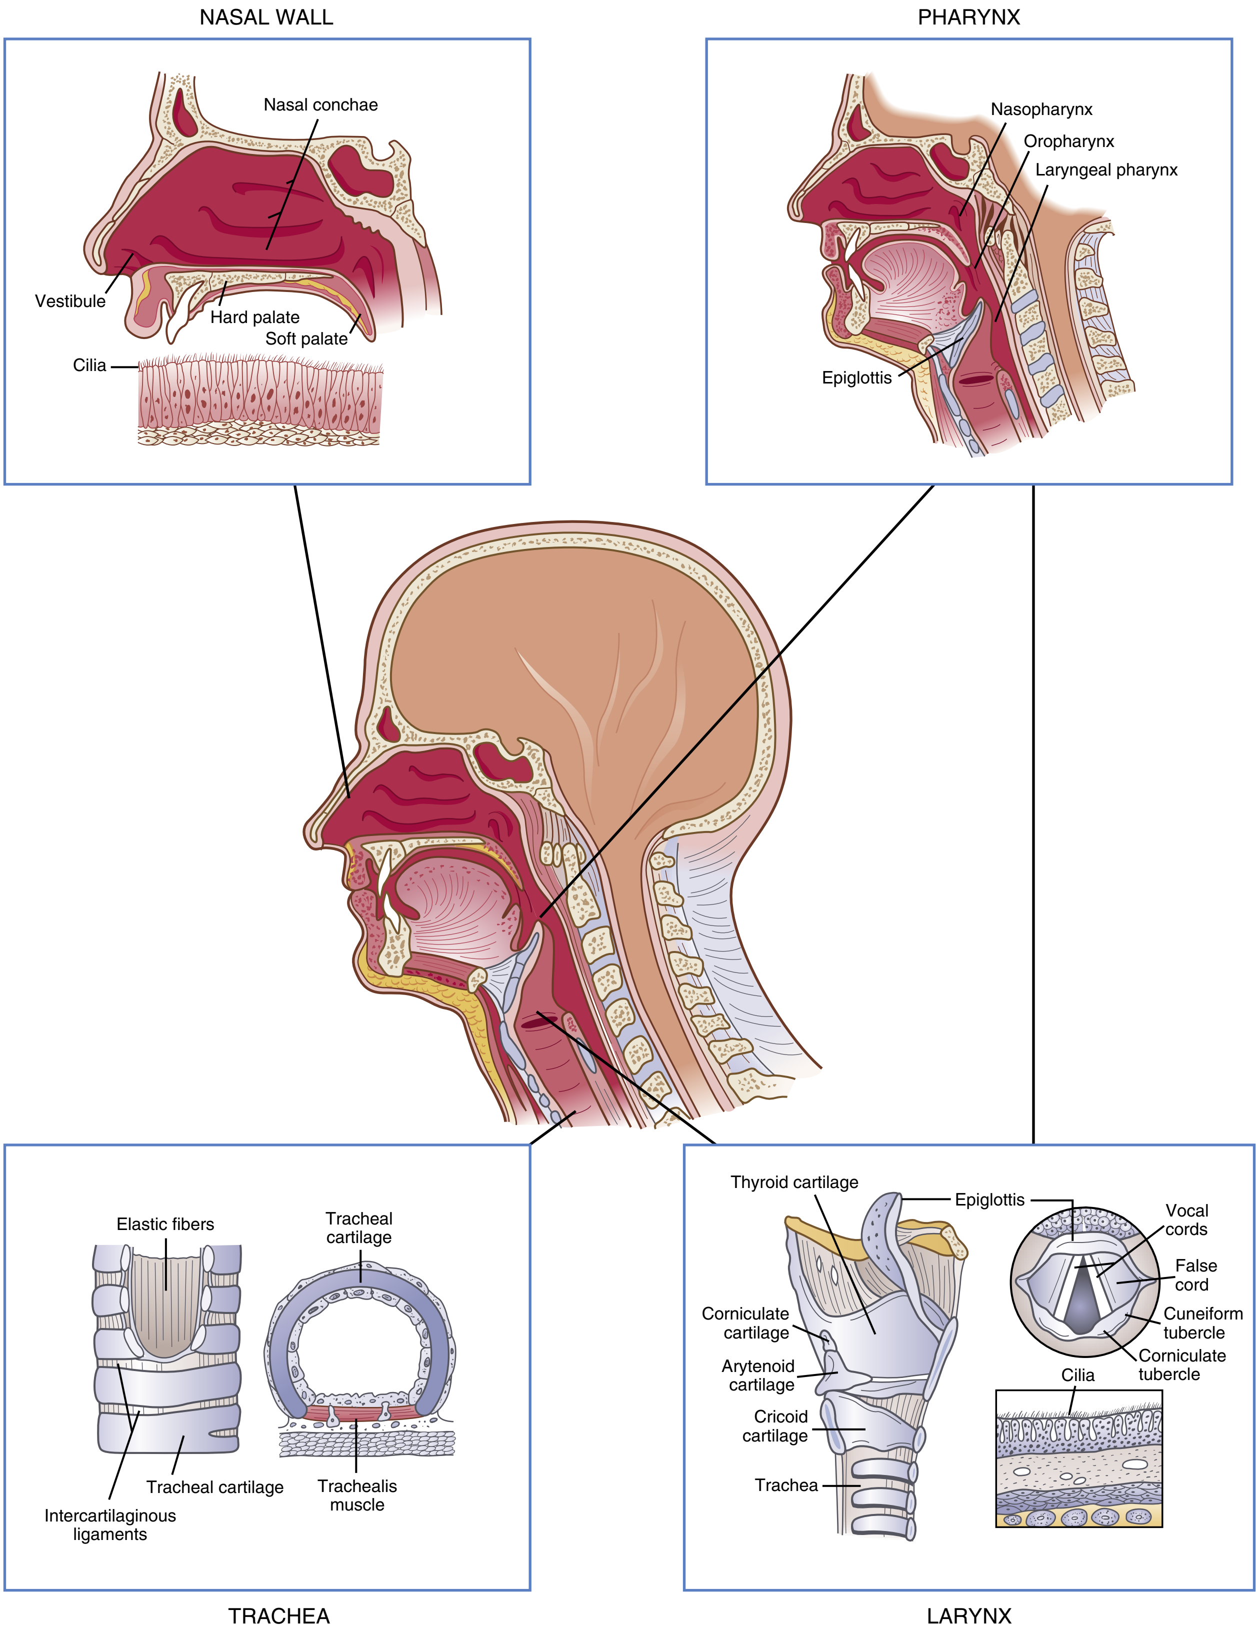

FIGURE 34-2 Structures of the Upper Airway. (Redrawn from Thompson JM et al: *Mosby's clinical nursing,* ed 5, St Louis, 2002, Mosby.)

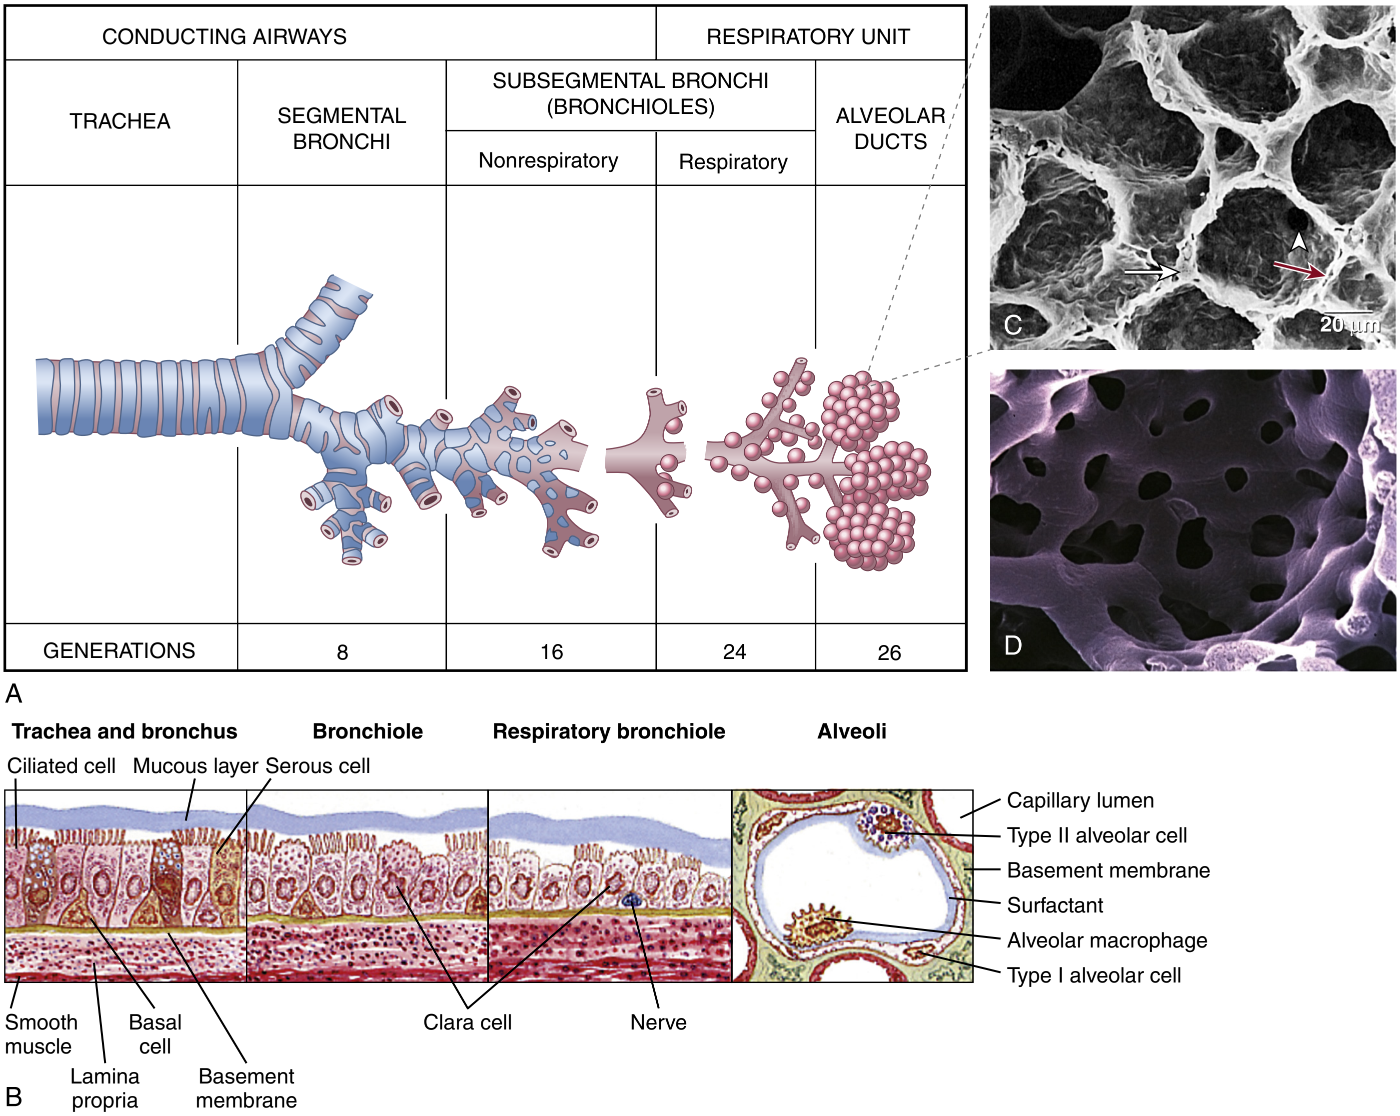

FIGURE 34-3 Conducting Airways and Respiratory Unit. **A,** Structures of respiratory airways. **B,** Changes in bronchial wall with progressive branching. **C,** Electron micrograph of alveoli: long white arrow identifies type II pneumonocyte (secretes surfactant); short white arrow identifies pores of Kohn; red arrow identifies alveolar capillary. **D,** Plastic cast of pulmonary capillaries at high magnification. Churg, MD, and J. Wright, MD, Vancouver, Canada. From Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach,* ed 2, Philadelphia, 2011, Saunders.)

cartilages—the arytenoid, corniculate, and cuneiform—that are connected by ligaments. The supporting cartilages prevent collapse of the larynx during inspiration and swallowing. The internal laryngeal muscles control vocal cord length and tension, and the external laryngeal muscles move the larynx as a whole. Both sets of muscles are important to swallowing, respiration, and vocalization.[1] The internal muscles contract during swallowing to prevent aspiration into the trachea and contribute to voice pitch.

The **trachea,** which is supported by U-shaped cartilage, connects the larynx to the **bronchi,** the conducting airways of the lungs. The trachea divides into the two main airways, or bronchi, at the **carina** (see Figure 34-1). This area is very sensitive and when stimulated can cause coughing and airway narrowing. The left mainstem bronchus branches from the trachea at about a 45° angle. The right mainstem bronchus is slightly larger and more vertical than the left (branches at about a 20° to 30° angle from the trachea). Aspirated fluids or foreign particles thus tend to enter the right lung rather than the left. The right and left main bronchi enter the lungs at the **hila,** or "roots" of the lungs, along with the pulmonary blood and lymphatic vessels. From the hila the main bronchi branch into lobar bronchi, then to segmental and subsegmental bronchi, and finally end at the sixteenth division in the smallest of the conducting airways, the terminal **bronchioles** (Figure 34-3). With these multiple divisions, the cross-sectional area of the airways increases to 20 times that of the trachea. This results in decreased velocity of airflow into the gas-exchange portion of the lung and allows for optimal gas diffusion.[2]

The bronchial walls have three layers: an epithelial lining, a smooth muscle layer, and a connective tissue layer. In the large bronchi (to approximately the tenth division), the connective tissue layer contains cartilage. The epithelial lining of the bronchi contains single-celled exocrine glands—the mucus-secreting **goblet cells**—and ciliated cells. High columnar pseudostratified epithelium lines the larger airways, changing to columnar cuboidal epithelium in the bronchioles (types of epithelia are illustrated in Chapter 1). The submucosal glands of the bronchial lining also produce mucus, contributing to the mucous blanket that covers the bronchial epithelium. The ciliated epithelial cells rhythmically beat this mucous blanket toward the trachea and pharynx, where it can be swallowed or expectorated by coughing. Foreign particles and microorganisms that are not expelled by mucociliary clearance and coughing are attacked by cellular components of the inflammatory response and antibodies of the secretory immune system (see Chapter 8).[3] The biochemical mediators released early in inflammation also play a part in antibody-mediated hypersensitivity reactions, such as asthma, because they stimulate bronchial smooth muscles to constrict. With branching, the layers of epithelium that line the bronchi become thinner (see Figure 34-3). Ciliated cells and goblet cells become more sparse, and smooth muscle and connective tissue layers thin toward the terminal bronchioles.[4]

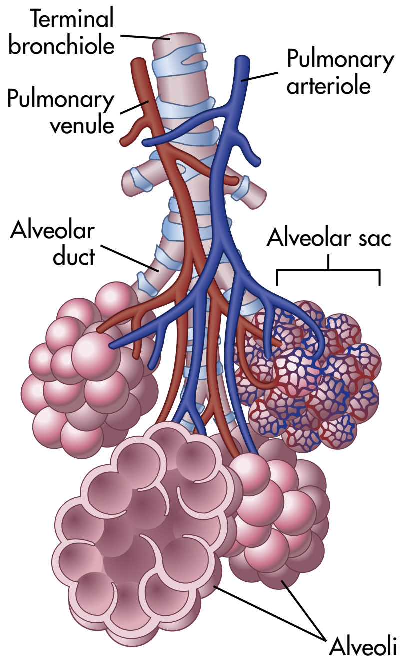

FIGURE 34-4 **Alveoli.** Bronchioles subdivide to form tiny tubes called *alveolar ducts* that end in clusters of alveoli called *alveolar sacs.* (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Gas-Exchange Airways

The bronchioles terminate in gas-exchange airways, where oxygen (O_2) enters the blood and carbon dioxide (CO_2) is removed from it. The gas-exchange airways consist of **respiratory bronchioles, alveolar ducts,** and **alveoli** (see Figure 34-3). These structures together are sometimes called the **acinus,** and all of them participate in gas exchange.[5]

The bronchioles from the sixteenth through the twenty-third divisions contain increasing numbers of alveoli and are called *respiratory bronchioles.* The walls of the respiratory bronchioles are very thin, consisting of an epithelial layer devoid of cilia and goblet cells, very little smooth muscle fiber, and a very thin and elastic connective tissue layer. These bronchioles end in alveolar ducts, which lead to alveolar sacs made up of numerous alveoli.

The alveoli are the primary gas-exchange units of the lung, where oxygen enters the blood and CO_2 is removed (Figure 34-4). Tiny passages called *pores of Kohn* permit some air to pass through the septa from alveolus to alveolus, promoting collateral ventilation and even distribution of air among the alveoli. The lungs contain approximately 50 million alveoli at birth and about 480 million by adulthood.[4,6]

The alveolar septa consist of an epithelial layer and a thin, elastic basement membrane but no muscle layer (see Figure 34-3). Two major types of epithelial cells appear in the alveolus. Type I alveolar cells provide structure, and type II alveolar cells secrete **surfactant,** a lipoprotein that coats the inner surface of the alveolus and facilitates its expansion during inspiration, lowers alveolar surface tension at end-expiration, and, thereby, prevents lung collapse.[7] Surfactant also contributes to control of lung inflammation and innate and adaptive immunity.[7a]

Like the bronchi, alveoli contain cellular components of inflammation and immunity, particularly the mononuclear phagocytes. The mononuclear phagocytes of the lungs are called *alveolar macrophages.* These cells ingest foreign material that reaches the alveolus and prepare it for removal through the lymphatics.[8] (Phagocytosis and the mononuclear phagocyte system are described in Chapters 7 and 8.)

Pulmonary and Bronchial Circulation

The pulmonary circulation facilitates gas exchange, delivers nutrients to lung tissues, acts as a blood reservoir for the left ventricle, and serves as a filtering system that removes clots, air, and other debris from the circulation (Figure 34-5).

Although the entire cardiac output from the right ventricle goes into the lungs, the pulmonary circulation has a lower pressure and resistance than the systemic circulation. Pulmonary arteries are exposed to about one fifth the pressure of the systemic circulation and have a much thinner muscle layer. (Systemic vessels are described in Chapter 31.) Mean pulmonary artery pressure is 18 mmHg; mean aortic pressure is 90 mmHg. About one third of the pulmonary vessels are filled with blood (perfused) at any given time.[9] More vessels become perfused when right ventricular cardiac output increases. Therefore, increased delivery of blood to the lungs does not normally increase mean pulmonary artery pressure.

The **pulmonary artery** divides and enters the lung at the hilus, travels with each main bronchus, and branches with the bronchus at every division so that every bronchus and bronchiole has an accompanying artery or arteriole. The arterioles, less than 1 mm in diameter, regulate blood flow through their respective capillary beds.[9]

The arterioles divide at the terminal bronchiole to form a network of **pulmonary capillaries** around the acinus. The capillaries are an integral part of the alveolar septa. Capillary walls

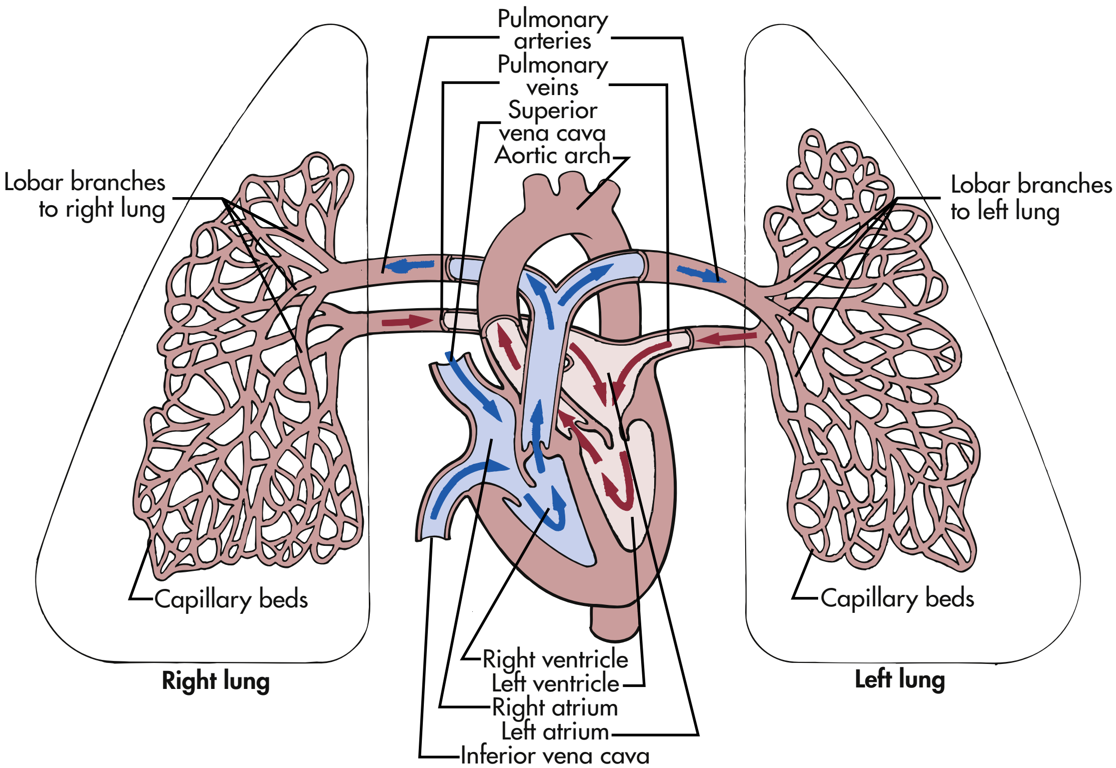

FIGURE 34-5 **The Pulmonary Circulation.** The right and left pulmonary veins and arteries and the branching capillaries are illustrated. Note the pulmonary artery carries venous blood, and the pulmonary vein carries arterial blood.

consist of an endothelial layer and a thin basement membrane, which often fuses with the basement membrane of the alveolar septum (see Figure 34-3). This results in very little separation between blood in the capillary and gas in the alveolus.

The shared alveolar and capillary walls compose the **alveolocapillary membrane,** a very thin membrane made up of the alveolar epithelium, the alveolar basement membrane, an interstitial space, the capillary basement membrane, and the capillary endothelium (Figure 34-6). These extremely thin alveolar walls are easily damaged and can leak plasma and blood into the alveolar space. Gas exchange occurs across the alveolocapillary membrane. With normal perfusion approximately 100 ml of blood in the pulmonary capillary bed is spread very thinly over about 140 m^2 of alveolar surface area.[9] The alveolocapillary membrane efficiently exposes large quantities of blood to gas in the alveoli. Any disorder that thickens the membrane impairs gas exchange.

Each **pulmonary vein** drains several pulmonary capillaries. Unlike the pulmonary arteries, which follow the branching bronchi, pulmonary veins are dispersed randomly throughout the lung and then leave the lung at the hila and enter the left atrium. They are similar to veins in the systemic circulation, but they have no valves.

The bronchial circulation is part of the systemic circulation. It supplies nutrients to the conducting airways, nerves, lymph nodes, large pulmonary vessels, and membranes (pleurae) that surround the lungs and moistens inspired air.[10] The bronchial circulation is unique in that not all of its capillaries drain into its own venous system. Some of the bronchial capillaries empty into the pulmonary vein and contribute to the normal venous admixture (mixing of oxygenated and deoxygenated blood) or right-to-left shunt (right-to-left shunts [ventilation-perfusion abnormalities] are described in Chapter 35). The bronchial circulation does not participate in gas exchange.

Lung vasculature also includes deep and superficial **pulmonary lymphatic capillaries.** The deep lymphatic capillaries begin at the level of the terminal bronchioles; there are no lymphatic structures in the acinus. Fluid and alveolar macrophages migrate from the alveoli to the terminal bronchioles, where they enter the lymphatic system. The superficial lymphatic capillaries drain the membrane that surrounds the lungs. Both deep and superficial lymphatic vessels leave the lung at the hilus through a series of mediastinal lymph nodes. The lymphatic system plays an important role in keeping the lung free of fluid and providing immune defense. (The lymphatic system is described in Chapter 31.)

Control of the Pulmonary Circulation

The caliber of pulmonary artery lumina decreases as smooth muscle in arterial walls contracts. Contraction increases pulmonary artery pressure. Caliber increases as these muscles relax, decreasing blood pressure. Contraction (vasoconstriction) and relaxation (vasodilation) occur in response to local humoral conditions, even though the pulmonary circulation is innervated by the autonomic nervous system (ANS) in the same manner as the systemic circulation.

The most important cause of pulmonary artery constriction is a low alveolar partial pressure of oxygen (P_{AO_2}).

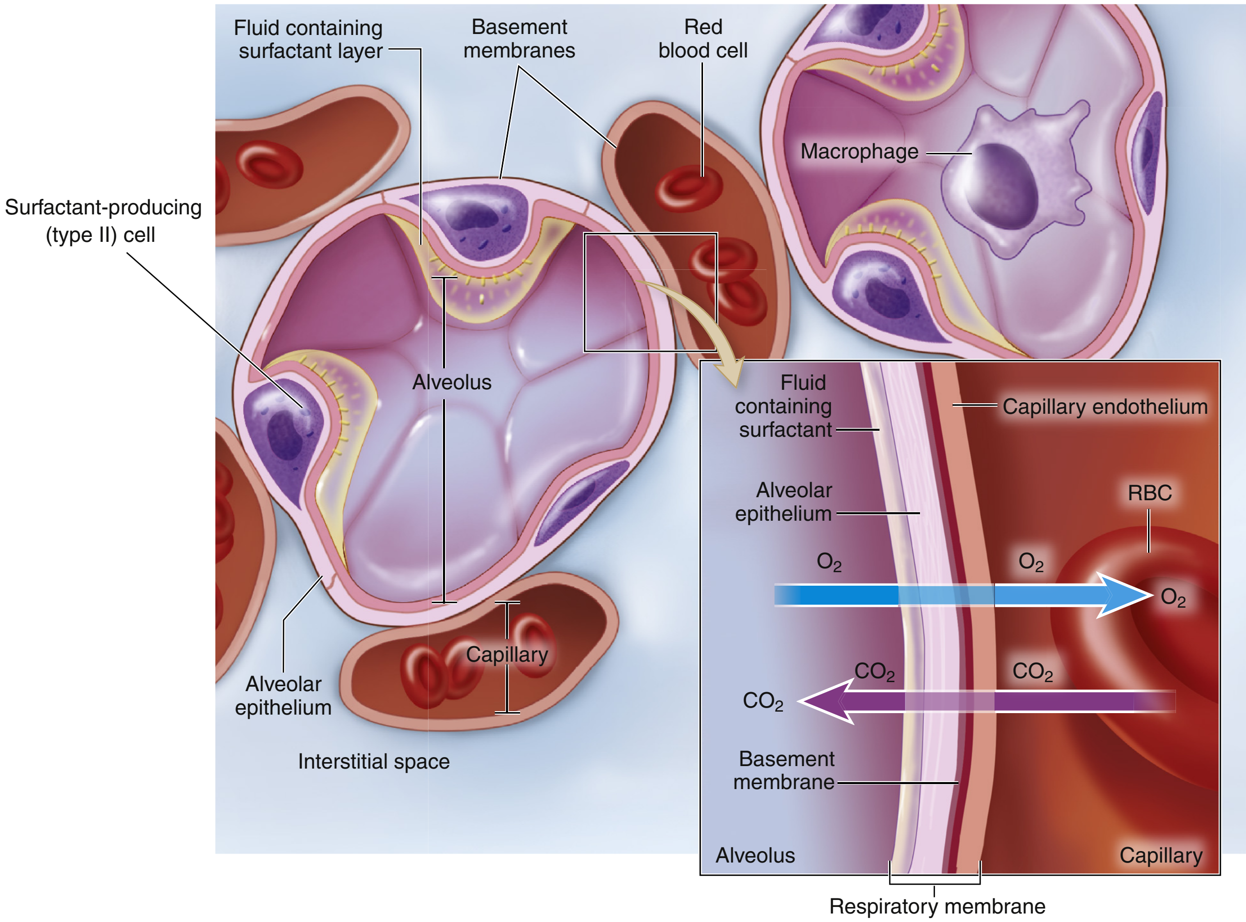

FIGURE 34-6 Section Through the Alveolar Septum (Gas-Exchange Membrane). *Inset* shows a magnified view of the respiratory membrane composed of the alveolar wall (fluid containing surfactant, epithelial cells, basement membrane), interstitial space, and wall of a pulmonary capillary (basement membrane, endothelial cells). The gases—carbon dioxide *(CO_2)* and oxygen *(O_2)*—diffuse across the respiratory membrane. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Vasoconstriction caused by alveolar and pulmonary venous hypoxia, often termed **hypoxic pulmonary vasoconstriction,** can affect only one portion of the lung or the entire lung. If only one segment of the lung is involved, the arterioles to that segment constrict, shunting blood to other, well-ventilated portions of the lung. This reflex improves the lung's efficiency by better matching ventilation and perfusion. If alveolar hypoxia affects all segments of the lung, however, vasoconstriction occurs throughout the pulmonary vasculature, and pulmonary hypertension (elevated pulmonary artery pressure) can result. The pulmonary vasoconstriction caused by low P_{AO_2} is reversible if the P_{AO_2} is corrected. Chronic alveolar hypoxia can result in permanent pulmonary artery hypertension, which eventually leads to cor pulmonale and heart failure (see What's New? Update on Hypoxic Pulmonary Vasoconstriction).[11]

Acidemia also causes pulmonary artery constriction. If the acidemia is corrected, the vasoconstriction is reversed. (Respiratory acidosis and metabolic acidosis are described in Chapter 3.) It is important to note that an elevated P_{aCO_2} without a drop in pH does not cause pulmonary artery constriction. Other biochemical factors that affect the caliber of vessels in pulmonary circulation are histamine, prostaglandins, endothelin, serotonin, nitric oxide, and bradykinin.

Chest Wall and Pleura

The chest wall (skin, ribs, intercostal muscles) protects the lungs from injury, and its muscles, in conjunction with the **diaphragm,** perform the muscular work of breathing. The **thoracic cavity** is contained by the chest wall and encases the lungs (Figure 34-7). A serous membrane called the **pleura** adheres firmly to the lungs. It then folds over itself and attaches firmly to the chest wall. The membrane covering the lungs is the visceral pleura; that lining the thoracic cavity is the parietal pleura. The area between the two pleurae is called the **pleural space,** or **pleural cavity.** Normally only a thin layer of fluid secreted by the pleura (pleural fluid) fills the pleural space. About 18 ml of fluid is in the pleural space with a pH of about 7.6, a few cells, about 1 g/dl protein, and glucose and electrolyte concentrations that approximate those of the plasma.[9] This lubricates the pleural surfaces, allowing the two layers to slide over each other without separating. Pressure in the pleural space is usually negative or subatmospheric (−4 to −10 mmHg).

WHAT'S NEW?

Update on Hypoxic Pulmonary Vasoconstriction

Hypoxic pulmonary vasoconstriction is a physiologic response to changes in the environment and pulmonary pathologic conditions that affect alveolar oxygen content (P_{AO_2}). Decreases in P_{AO_2} to less than 12% of normal induce a locally controlled constriction of preacinar arteriolar smooth muscle and endothelial cells and therefore decrease blood flow through those vessels. When a pulmonary disorder is characterized by localized areas of acutely decreased alveolar oxygen content, vasoconstriction of the arterioles perfusing those areas is a positive compensatory mechanism that reduces shunt (wasted perfusion). However, in diffuse and chronic lung disorders (e.g., chronic obstructive pulmonary disease [COPD] or cystic fibrosis), widespread and persistent hypoxic pulmonary vasoconstriction creates resistance to pulmonary blood flow and raises the pressure in the pulmonary artery, causing a condition known as *secondary pulmonary artery hypertension*. Pulmonary hypertension can become severe enough to impede right ventricular ejection and eventually cause right heart failure known as *cor pulmonale*. In addition, lung hypoxia activates many hypoxia-dependent genes in pulmonary vascular endothelial cells to produce a variety of chemicals and growth factors. Recent studies have shown that alveolar hypoxia causes the production of reactive oxygen species (toxic oxygen radicals), vasoconstrictors (such as endothelin), and vascular endothelial growth factor that in conjunction with vascular fibroblasts cause deleterious changes in the pulmonary arteriolar walls called *remodeling*. Remodeling is a process by which the vascular wall becomes scarred and thickened, thus resulting in permanent decreases in luminal diameter, increased resistance to blood flow, and permanent pulmonary artery hypertension. Research is in progress to inhibit and potentially reverse this remodeling.

FUNCTIONS OF THE PULMONARY SYSTEM

The pulmonary system functions to (1) ventilate the alveoli, (2) diffuse gases into and out of the blood, and (3) perfuse the lungs so that the organs and tissues of the body receive blood that is rich in oxygen and low in CO_2. Each component of the pulmonary system contributes to one or more of these functions (Figure 34-8).

Ventilation

Ventilation is the mechanical movement of gas or air into and out of the lungs. Ventilation often is misnamed **respiration,** which is actually the exchange of O_2 and CO_2 during cellular metabolism. "Respiratory rate" is actually the ventilatory rate, or the number of times gas is inspired and expired per minute. The amount of effective ventilation is calculated by multiplying the ventilatory rate (breaths per minute) by the volume of air per breath (liters per breath, tidal volume). This is called the **minute volume** (or **minute ventilation**) and is expressed in liters per minute.

CO_2, the gaseous form of carbonic acid (H_2CO_3), is a product of cellular metabolism. The lung eliminates about 10,000 milliequivalents (mEq) of carbonic acid per day in the form of CO_2, which is produced at the rate of approximately 200 ml/minute. CO_2 elimination is necessary to maintain a normal partial pressure of arterial CO_2 (Pa_{CO_2}) of 40 mmHg and normal acid-base balance (see Chapter 3 for a discussion of acid-base regulation).[9]

The adequacy of **alveolar ventilation** *cannot* be accurately determined by observation of ventilatory rate, pattern, or effort. If a healthcare professional needs to determine the adequacy of ventilation, an arterial blood gas analysis must be performed to measure Pa_{CO_2}.

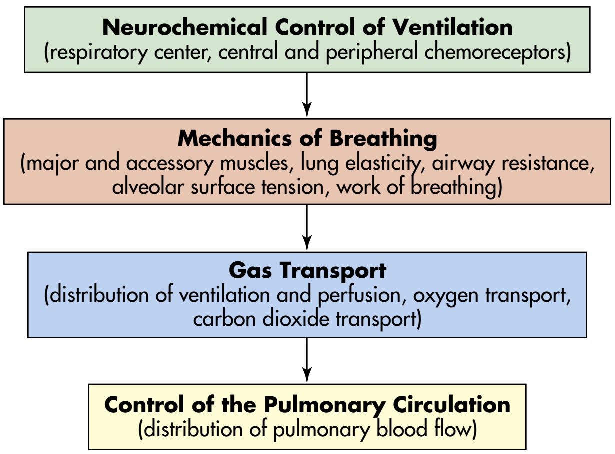

FIGURE 34-8 Functional Components of the Respiratory System. The central nervous system responds to neurochemical stimulation of ventilation and sends signals to the chest wall musculature. The response of the respiratory system to these impulses is influenced by several factors that affect the mechanisms of breathing and therefore affect the adequacy of ventilation. Gas transport between the alveoli and pulmonary capillary blood depends on a variety of physical and chemical activities. The control of the pulmonary circulation plays a role in the appropriate distribution of blood flow.

Neurochemical Control of Ventilation

The mechanisms that control respiration are very complex.[12-14] Breathing is usually involuntary because homeostatic changes in the ventilatory rate and volume are adjusted automatically by the nervous system to maintain normal gas exchange. Voluntary breathing is necessary for talking, singing, laughing, and holding one's breath.

The **respiratory center** in the brainstem controls respiration by transmitting impulses to the respiratory muscles, causing them to contract and relax (Figure 34-9). The respiratory center is composed of several groups of neurons located bilaterally in the brainstem: the dorsal respiratory group (DRG), the ventral respiratory group (VRG), the pneumotaxic center, and the apneustic center.[15] The basic automatic rhythm of respiration is set by the DRG, a cluster of inspiratory nerve cells located in the medulla that sends efferent impulses to the diaphragm and inspiratory intercostal muscles. The DRG also receives afferent impulses from **peripheral chemoreceptors** in the carotid and aortic bodies, which detect the $Paco_2$ and the amount of oxygen in the arterial blood (Pao_2). In addition, several different types of receptors in the lungs stimulate the VRG through afferent nerves. The VRG, also located in the medulla, contains inspiratory and expiratory neurons. It is almost inactive during normal, quiet respiration, becoming active when increased ventilatory effort is required. The pneumotaxic center and apneustic center, situated in the pons, do not generate primary rhythm, but rather act as modifiers of the inspiratory depth and rate established by the medullary centers.[16] Breathing can be modified by input from the cortex, the limbic system, and the hypothalamus, and the pattern of breathing can be influenced by emotion and by disease.

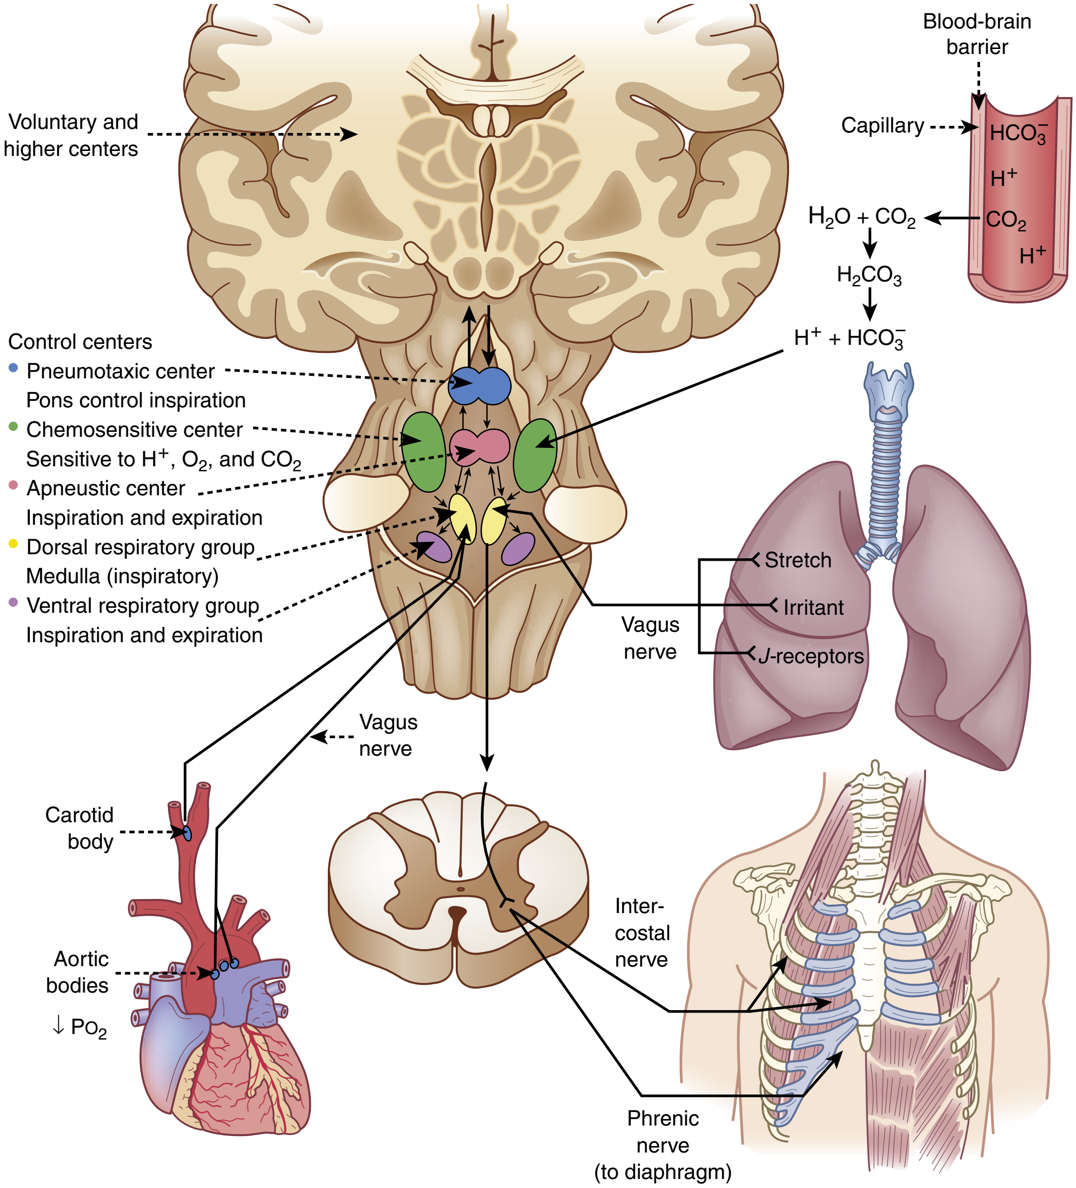

FIGURE 34-9 Neurochemical Respiratory Control System.

Lung Receptors. Three types of lung receptors send impulses from the lungs to the dorsal respiratory group:

1. **Irritant receptors** (rapidly adapting receptors) are found in the epithelium of the conducting airways. They are sensitive to noxious aerosols (vapors), gases, and particulate matter (e.g., inhaled dusts), which cause them to initiate the cough reflex. When stimulated, irritant receptors also cause bronchoconstriction and increased ventilatory rate. These receptors are located primarily in the proximal larger airways and are nearly absent in the distal airways; thus it is possible for secretions to accumulate in the distal respiratory tree without initiating cough.
2. **Stretch receptors** (slowly adapting receptors) are located in the smooth muscles of airways and are sensitive to increases in the size or volume of the lungs. They decrease ventilatory rate and volume when stimulated, an occurrence sometimes referred to as the *Hering-Breuer expiratory reflex.* This reflex is active in newborns and assists with ventilation.[17] In adults, this reflex is active only at high tidal volumes (such as with exercise and mechanical ventilation) and may play a role in protecting against excess lung inflation. Stretch receptors called **rapidly adapting receptors (RARs)** have been found to be an important mediator of cough.[18]
3. ***J*-receptors** (juxta-pulmonary capillary or pulmonary C fiber receptors) are located near the capillaries in the alveolar septa. They are sensitive to increased pulmonary capillary pressure, which stimulates them to initiate rapid, shallow breathing; laryngeal constriction on expiration and mucus secretion; hypotension; and bradycardia.[19]

The lung is innervated by the autonomic nervous system (ANS). Fibers of the sympathetic division of the ANS in the lung branch from the upper thoracic and cervical ganglia of the spinal cord. Fibers of the parasympathetic division of the ANS travel in the vagus nerve to the lung. (Structures and function of the ANS are discussed in detail in Chapter 15.) The parasympathetic and sympathetic divisions of the ANS control airway caliber (interior diameter of the airway lumen) by stimulating bronchial smooth muscle to contract or relax. The parasympathetic receptors cause smooth muscle to contract, whereas sympathetic receptors cause it to relax. Bronchial smooth muscle tone depends on equilibrium, that is, equal stimulation of contraction and relaxation. The parasympathetic division of the ANS is the main controller of airway caliber under normal conditions.[20] Constriction occurs if the irritant receptors in the airway epithelium are stimulated by irritants in inspired air, by inflammatory mediators (e.g., histamine, serotonin, prostaglandins), by many drugs, and by humoral substances.

Chemoreceptors. Chemoreceptors monitor pH, $Paco_2$, and Pao_2. **Central chemoreceptors** monitor arterial blood indirectly by sensing changes in the pH of cerebrospinal fluid (CSF). They are located near the respiratory center and are sensitive to hydrogen ion concentration in the CSF. (Chapter 3 describes the relationship between ions and the pH, or acid-base status, of body fluids.) The pH, or concentration of hydrogen ions in the CSF, reflects $Paco_2$ because, unlike H^+ ions, CO_2 in arterial blood diffuses across the blood-brain barrier (the capillary wall separating blood from cells of the central nervous system) into the CSF until the partial pressure of CO_2 (Pco_2) is equal on both sides. CO_2 that has entered the CSF combines with H_2O to form carbonic acid, which subsequently dissociates into hydrogen ions that are capable of stimulating the central chemoreceptors. In this way $Paco_2$ regulates ventilation through its effect on the pH (hydrogen ion content) of the CSF.[12,13,21]

If alveolar ventilation is inadequate, $Paco_2$ increases. CO_2 diffuses across the blood-brain barrier until Pco_2 in the blood and CSF reaches equilibrium. As the central chemoreceptors sense the resulting decrease in pH (increase in hydrogen ion concentration), they stimulate the respiratory center to increase the depth and rate of ventilation. Increased ventilation causes the $Paco_2$ to decrease below that of the CSF, and CO_2 diffuses back out of the CSF, returning its pH to normal.

The central chemoreceptors are sensitive to very small changes in the pH of CSF (equivalent to a 1 to 2 mmHg change in Pco_2) and are able to maintain a normal $Paco_2$ under many different conditions, including strenuous exercise. If inadequate ventilation, or hypoventilation, is long term (e.g., in chronic obstructive pulmonary disease), these receptors become insensitive to small changes in $Paco_2$ and regulate ventilation poorly. In addition, prolonged increases in $Paco_2$ result in renal compensation through bicarbonate retention. This bicarbonate gradually diffuses into the CSF, where it normalizes the pH and negates the effect on ventilatory drive.[22]

The **peripheral chemoreceptors** are located in aortic bodies, the aortic arch, and carotid bodies at the bifurcation of the carotids, near the baroreceptors (see Chapter 31). Although the peripheral chemoreceptors are sensitive to changes in $Paco_2$ and pH, they are primarily sensitive to oxygen levels in arterial blood (Pao_2) and are responsible for all of the increase in ventilation that occurs in response to arterial hypoxemia.[23] As Pao_2 and pH decrease, peripheral chemoreceptors, particularly in the carotid bodies, send signals to the respiratory center to increase ventilation. The peripheral chemoreceptors are not as sensitive as the central chemoreceptors. The Pao_2 must drop well below normal (to approximately 60 mmHg) before the peripheral chemoreceptors have much influence on ventilation.[9] If $Paco_2$ is elevated as well, however, ventilation increases much more than it would in response to either abnormality alone. The peripheral chemoreceptors become the major stimulus to ventilation when the central chemoreceptors are "reset" by chronic hypoventilation.

Mechanics of Breathing

The mechanical aspects of inspiration and expiration are known collectively as the *mechanics of breathing* and involve: (1) major and accessory muscles of inspiration and expiration, (2) elastic properties of the lungs and chest wall, and (3) resistance to airflow through the conducting airways. Alterations in any of these properties increase the work of breathing, or the metabolic energy that must be exerted to achieve adequate ventilation and oxygenation of the blood.

Major and Accessory Muscles. The major muscles of inspiration are the diaphragm and the external intercostal muscles (muscles between the ribs) (Figure 34-10). The

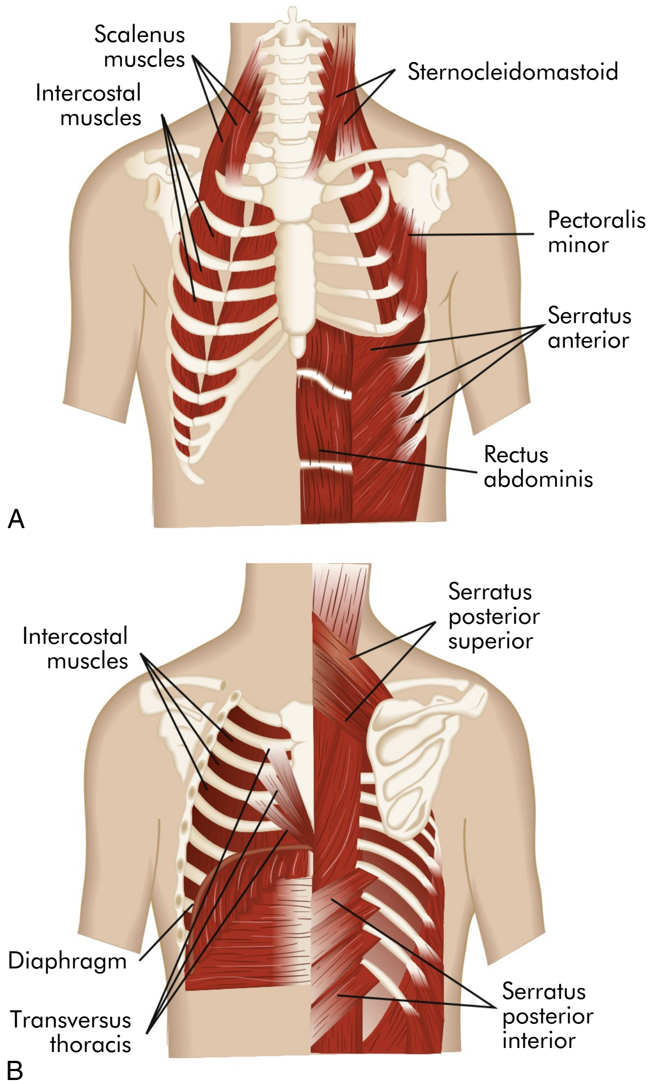

FIGURE 34-10 Muscles of Ventilation. **A,** Anterior view. **B,** Posterior view. (Modified from Thompson JM et al: *Mosby's clinical nursing,* ed 5, St Louis, 2002, Mosby.)

diaphragm is a dome-shaped muscle that separates the abdominal and thoracic cavities. When the diaphragm contracts, it flattens downward, increasing the volume of the thoracic cavity, and creates a negative pressure that draws gas into the lungs through the upper airways and trachea. Contraction of external intercostal muscles elevates the anterior portion of the ribs. This increases the volume of the thoracic cavity by increasing its front-to-back (anteroposterior [AP]) diameter. Although the external intercostal muscles may contract during quiet breathing, inspiration at rest usually is assisted by the diaphragm only.

The accessory muscles of inspiration are the sternocleidomastoid and scalene muscles. Like the external intercostal muscles, these muscles enlarge the thorax by increasing its AP diameter. The accessory muscles of inspiration assist inspiration when the minute volume (volume of air inspired and expired per minute) is very high, such as during strenuous exercise or when the work of breathing is increased because of disease. The accessory muscles do not increase the volume of the thorax as efficiently as the diaphragm does.

There are no major muscles of expiration because normal, relaxed expiration is passive and requires no muscular effort. The accessory muscles of expiration, the abdominal and internal intercostal muscles, assist expiration when minute volume is high, during coughing, or when airway obstruction is present. When the abdominal muscles contract, intra-abdominal pressure increases, pushing up the diaphragm and decreasing the volume of the thorax. The internal intercostal muscles pull down the anterior ribs, decreasing the AP diameter of the thorax.

Alveolar Surface Tension. **Surface tension** occurs at any gas-liquid interface and refers to the tendency for liquid molecules that are exposed to air to adhere to one another. This phenomenon can be seen, for example, in a glass of liquid that is about to overflow or in the way liquids "bead" when splashed on a waterproof surface. In both examples this phenomenon decreases the surface area exposed to the air.

Within a sphere, such as an alveolus, surface tension tends to make expansion difficult. According to the law of Laplace, the pressure *(P)* required to inflate a sphere is equal to two times the surface tension *(2T)* divided by the radius *(r)* of the sphere, or $P = 2T/r$.[9] As the radius of the sphere (or alveolus) becomes smaller, more and more pressure is required to inflate it. If the alveoli were lined with a water-like fluid, taking breaths would be extremely difficult.

Alveolar ventilation, or distention, is made possible by surfactant, which lowers the surface tension by coating the air-liquid interface in the alveoli (see Figure 34-3). Surfactant, a lipoprotein (90% lipids and 10% protein) produced by type II alveolar cells, includes two groups of surfactant proteins. One group (SP-B and SP-C) consists of small hydrophobic molecules that have a detergent-like effect that separates the liquid molecules, thereby decreasing alveolar surface tension. The second group (SP-A and SP-D) consists of large hydrophilic molecules called **collectins** (pattern recognition molecules) that are capable of inhibiting foreign pathogens[7a] (see Chapter 7).

Surfactant lines the alveolar side of the alveolocapillary membrane and, in effect, reverses Laplace's law. As the radius of a surfactant-lined sphere (alveolus) grows smaller, the surface tension *decreases,* and as the radius grows larger, the surface tension *increases.* This occurs because the surfactant molecules have much weaker intermolecular attraction compared with the liquid molecules. The surfactant molecules occupy most of the air-fluid interface and disrupt the intermolecular forces that tend to collapse the alveoli. Therefore, the alveoli are much easier to inflate at low lung volumes (i.e., after expiration) than at high volumes (i.e., after inspiration). The decrease in surface tension caused by surfactant also is responsible for keeping the alveoli free of fluid. If surfactant production is disrupted or surfactant is not produced in adequate quantities, alveolar surface tension increases, causing alveolar collapse, decreased lung expansion, increased work of breathing, and severe gas-exchange abnormalities (see What's New? Update on Surfactant and Immunity).

WHAT'S NEW?

Update on Surfactant and Immunity

Surfactant is produced from alveolar type II cells and is a complex molecule made up of glycophospholipid, cholesterol, and protein. Surfactant's primary role is to form a lipid monolayer between the surface of the alveoli and the inspired air and therefore reduce surface tension, preventing expiratory alveolar collapse. More recent investigations have found multiple roles for surfactant in immune function, preventing infection and acting as an antioxidant both in the alveoli and in extrapulmonary mucosal tissues. The protein component of surfactant includes surfactant proteins A, B, C, and D (SP-A, SP-B, SP-C, SP-D). SP-A and SP-D are *collectins,* which are involved in initiating the immune response and clearing pathogens and allergens. SP-A and SP-D appear to decrease the growth of certain bacteria and viruses. SP-A is also called an *opsonin,* which means it makes microorganisms more vulnerable to phagocytosis, including viruses, bacteria, and fungi. SP-D is postulated to activate macrophages and enhance their recognition of pathogens by increasing their cell surface receptors. Both SP-A and SP-D regulate the inflammatory response in the lung, have antioxidant properties, and down-regulate allergic reactions. These findings are leading to exciting developments in the synthesis of therapeutic forms of surfactant that may be useful in treating a broad range of pulmonary disorders.

Data from Glasser JR, Mallampalli RK: *Microbes Infect* 14(1):17–25, 2012; Nayak A et al: *Front Immunol* 3:131, 2012; Silveyra P, Floros J: *Front Biosci* 17:407–429, 2012.

The decrease in surface tension caused by surfactant is also responsible for keeping the alveoli free of fluid. In the absence of surfactant, the surface tension tends to attract fluid into the alveoli. In addition, surfactant participates in host defense against respiratory pathogens.[25]

Elastic Properties of the Lung and Chest Wall. The lung and chest wall have elastic properties that permit expansion during inspiration and return to resting volume during expiration. The elasticity of the lungs is caused both by elastin fibers in the alveolar walls and surrounding the small airways and pulmonary capillaries and by surface tension at the alveolar air-liquid interface.[9] The elasticity of the chest wall is the result of the configuration of its bones and musculature.

Elastic recoil is the tendency of the lungs to return to the resting state after inspiration. Normal elastic recoil permits passive expiration, eliminating the need for major muscles of expiration. Passive elastic recoil may be insufficient during labored breathing (high minute volume), in which case the accessory muscles of expiration may be needed. The accessory muscles also are used if disease comprises elastic recoil (e.g., in emphysema) or blocks the conducting airways.

Normal elastic recoil depends on an equilibrium between opposing forces of recoil in the lungs and chest wall. Under normal conditions the chest wall tends to recoil by expanding outward. This can be observed readily during open heart surgery. When the sternum is split to open the thoracic cavity, the chest wall moves outward laterally. The tendency of the chest wall to recoil by expanding is balanced by the tendency of the lungs to recoil or collapse around the hila. This reaction is caused by elastic recoil and surface tension in the alveoli. The tendency of the lungs to collapse can be demonstrated if the chest is opened without mechanically ventilating the lungs (e.g., at postmortem examination). As the thorax is opened, the lungs immediately collapse, like inflated balloons that have been released. The opposing forces of the chest wall and lungs create, in part, the small negative intrapleural pressure.

Balance between the outward recoil of the chest wall and the inward recoil of the lungs occurs at the resting level, at the end of expiration. During inspiration the diaphragm and intercostal muscles contract, air flows into the lungs, and the chest wall expands. Muscular effort is needed to overcome the resistance of the lungs to expansion. During expiration the muscles relax and the elastic recoil of the lungs causes the thorax to decrease in volume until, once again, balance between the chest wall and lung recoil forces is reached[26] (Figure 34-11).

Compliance is the measure of lung and chest wall distensibility. It represents the relative ease with which these structures can be stretched. Compliance is therefore the reciprocal of elasticity. Compliance is determined by the alveolar surface tension and the elastic recoil of the lung and chest wall. It can be measured with the following formula:

$$C = \frac{\Delta V}{\Delta P}$$

where C = compliance in liters per centimeter of water, ΔV = volume change (usually tidal volume), and ΔP = pressure change (airway or pleural pressure) in centimeters of water.[9]

Increased compliance indicates that the lungs or chest wall is abnormally easy to inflate and has lost some elastic recoil. A decrease indicates that the lungs or chest wall is abnormally stiff or difficult to inflate. Compliance is increased in emphysema and decreased in acute respiratory distress syndrome, pneumonia, pulmonary edema, and fibrosis. (These disorders are described in Chapter 35.)

Airway Resistance. **Airway resistance,** which is similar to resistance to blood flow (described in Chapter 31), is determined by the length, radius, and cross-sectional area of the airways and by the density, viscosity, and velocity of the gas (Poiseuille's law). Resistance is computed by dividing change in pressure *(P)* by rate of flow *(F)*, or $R = P/F$ (Ohm's law), and can easily be measured in the pulmonary function laboratory.[9]

Airway resistance is normally very low. One half to two thirds of total airway resistance occurs in the nose. The next highest resistance is in the oropharynx and larynx. There is very little resistance in the conducting airways of the lungs because of their large cross-sectional area. Resistance increases as the diameter of the airways (total cross-sectional area) decreases; airway resistance increases when the diameter of the airways decreases. **Bronchoconstriction,** which increases airway resistance, can be caused by stimulation of parasympathetic receptors in the bronchial smooth muscle and by numerous irritants and inflammatory mediators.[27]

Bronchodilation, which decreases resistance to airflow, is caused by β_2-adrenergic receptor stimulation. Airway resistance also can be increased by edema of the bronchial mucosa and by airway obstructions such as mucus, tumors, or foreign bodies.

Work of Breathing. The **work of breathing** is determined by the muscular effort (and therefore oxygen and energy) required for ventilation. The work of breathing is normally very low,

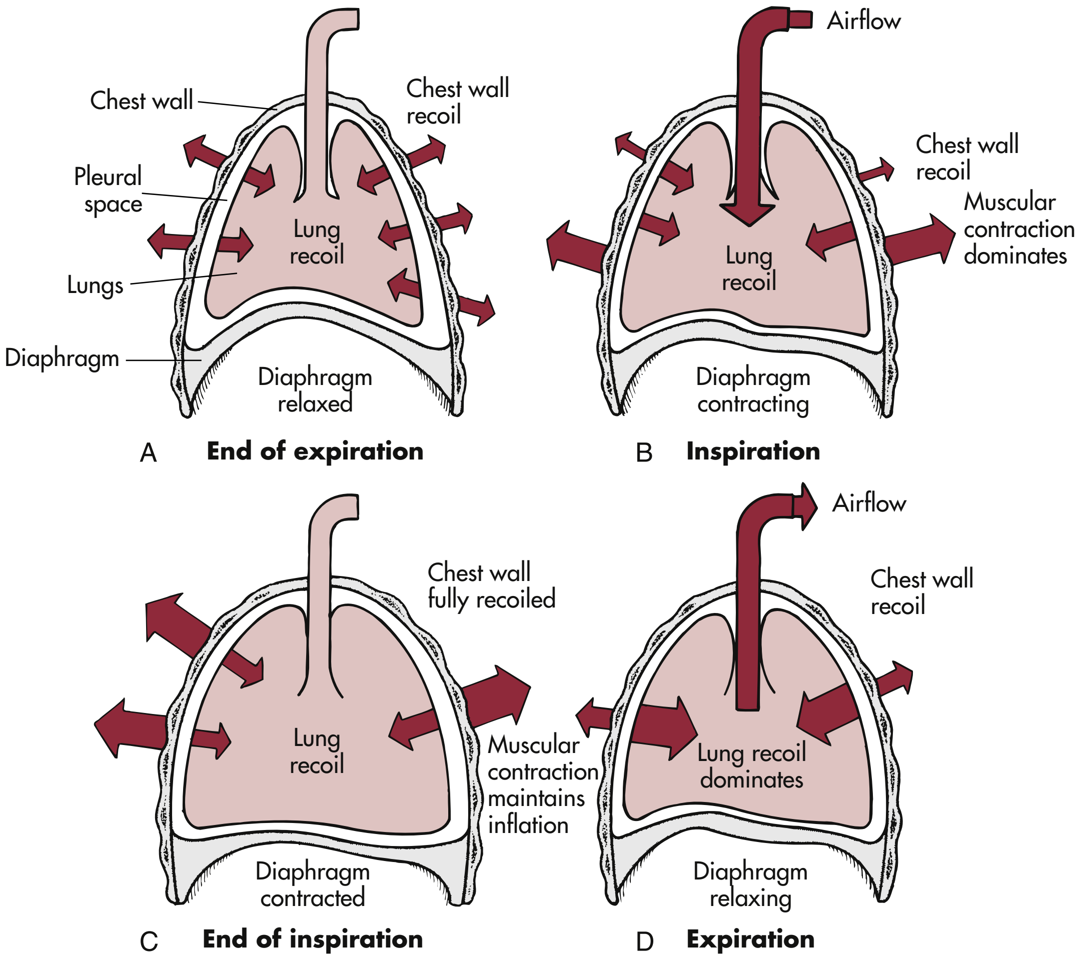

FIGURE 34-11 Interaction of Forces During Inspiration and Expiration. **A,** Outward recoil of the chest wall equals inward recoil of the lungs at the end of expiration. **B,** During inspiration, contraction of respiratory muscles, assisted by chest wall recoil, overcomes tendency of lungs to recoil. **C,** At the end of inspiration, respiratory muscle contraction maintains lung expansion. **D,** During expiration, respiratory muscles relax, allowing elastic recoil of the lungs to deflate the lungs.

but may increase considerably in disease states that disrupt the equilibrium between forces exerted by the lung and chest wall. More muscular effort is required when lung compliance is decreased (e.g., in pulmonary edema), chest wall compliance is decreased (e.g., in spinal deformity or obesity), or airways are obstructed by bronchospasm or mucous plugging (e.g., in asthma or bronchitis).[28] An increase in the work of breathing can result in a marked increase in oxygen consumption and metabolic demand, which can cause significant morbidity in individuals with severe lung disease.

Measurement of Gas Pressure

A gas is made up of millions of molecules moving randomly. As they move, they collide with each other and the wall of the space in which they are contained. These collisions exert pressure. If more molecules are present in the space, the pressure, or number of collisions, increases (Figure 34-12). If the same number of gas molecules is contained in a small and a large container, the pressure is greater in the small container because more collisions occur in the smaller space. Heat increases the speed of the molecules, which increases the number of collisions. Therefore, pressure also increases at higher temperatures.

Barometric pressure (P_B) (atmospheric pressure) is the pressure exerted by gas molecules in air at specific altitudes. At sea level, barometric pressure is 760 mmHg. This number is the sum of the pressure exerted by each gas in the air at sea level. The portion of the total pressure exerted by any individual gas is its **partial pressure** (see Figure 34-12). At sea level the air is made up of oxygen (20.9%), nitrogen (78.1%), and a few other trace gases. The partial pressure of oxygen is equal to the percentage of oxygen in the air (20.9%) times the total pressure (760 mmHg), or 159 mmHg ($760 \times 0.209 = 158.84$). (Symbols used in the measurement of gas pressures and pulmonary ventilation are defined in Table 34-2.)

The amount of water vapor contained in a gas mixture is determined by the temperature of the gas and is unrelated to barometric pressure. Gas that enters the lungs becomes saturated with water vapor (humidified) as it passes through the upper airway. At body temperature (37° C, 98.6° F), water vapor exerts a pressure of 47 mmHg. Because this is true regardless of total (barometric) pressure, the partial pressure of water vapor (always 47 mmHg) must be subtracted from the barometric pressure before the partial pressure of other gases in the mixture can be determined. In saturated

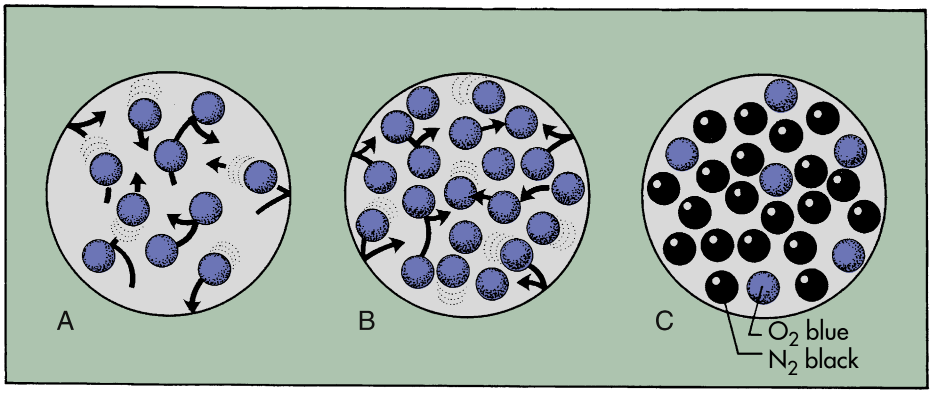

FIGURE 34-12 Relationship Between Number of Gas Molecules and Pressure Exerted by the Gas in an Enclosed Space. **A,** Theoretically 10 molecules of the same gas exert a total pressure of 10 within the space. **B,** If the number of molecules is increased to 20, total pressure is 20. **C,** If there are different gases in the space, each gas exerts a partial pressure: here the partial pressure of nitrogen *(N_2)* is 18, that of oxygen *(O_2)* is 6, and total pressure is 24.

TABLE 34-2 COMMON PULMONARY ABBREVIATIONS

SYMBOL*	DEFINITION
V	Volume or amount of gas
Q	Perfusion or blood flow
P	Pressure (usually partial pressure) of a gas
Pa_{O_2}	Partial pressure of oxygen in arterial blood
P_{AO_2}	Partial pressure of oxygen in alveolar blood
Pa_{CO_2}	Partial pressure of carbon dioxide in arterial blood
P_{H_2O}	Partial pressure water vapor
P_{N_2}	Partial pressure of nitrogen
$P\bar{v}_{O_2}$	Partial pressure of oxygen in mixed venous or pulmonary artery blood
$P(A–a)_{O_2}$	Difference between alveolar and arterial partial pressure of oxygen (A–a gradient)
P_B	Barometric or atmospheric pressure
Sa_{O_2}	Saturation of hemoglobin (in arterial blood) with oxygen
$S\bar{v}_{O_2}$	Saturation of hemoglobin (in mixed venous blood)
V_A	Alveolar ventilation—effective total lung capacity
V_D	Dead-space ventilation
V_E	Minute capacity
V_T	Tidal volume or average breath
$\dot{V}/\dot{Q}$	Ratio of ventilation to perfusion
Fi_{O_2}	Fraction of inspired oxygen
FRC	Functional residual capacity
FVC	Forced vital capacity
FEV_1	Forced expiratory volume in 1 second
ERV	Expiratory reserve volume
IRC	Inspiratory reserve volume
IC	Inspiratory capacity

From Kacmarek RM, Stoller JK, Jeuer AJ: *Egan's fundamentals of respiratory care,* ed 10, St Louis, 2013, Mosby.
*Subscripts identify the particular gas, volume, or pressure being discussed. A dot, such as above $\dot{V}/\dot{Q}$, means measurement over time, usually 1 minute.

air at sea level, the partial pressure of oxygen is therefore $(760 - 47) \times 0.209 = 149$ mmHg.[9] All pressure and volume measurements made in pulmonary function laboratories specify the temperature and humidity of a gas at the time of measurement.

Many pressure measurements are stated as variations from barometric pressure, rather than percentages of it. On such scales, barometric pressure is considered zero, and pressure varies up or down from zero. Physiologic pressure measurements that involve fluids, rather than gases, are measured as variations from barometric pressure. For example, a systolic blood pressure of 120 mmHg indicates that systolic pressure is 120 mmHg above barometric pressure.

Gas Transport

Gas transport, the delivery of oxygen to the cells of the body and the removal of CO_2, has four steps:

1. Ventilation of the lungs
2. Diffusion of oxygen from the alveoli into the capillary blood
3. Perfusion of systemic capillaries with oxygenated blood
4. Diffusion of oxygen from systemic capillaries into the cells

Steps in the transport of CO_2 occur in reverse order:

1. Diffusion of CO_2 from the cells into the systemic capillaries
2. Perfusion of the pulmonary capillary bed by venous blood
3. Diffusion of CO_2 into the alveoli
4. Removal of CO_2 from the lung by ventilation

If any step in gas transport is impaired by a respiratory or cardiovascular disorder, gas exchange at the cellular level is compromised.

Distribution of Ventilation and Perfusion

Effective gas exchange depends on an approximately even distribution of gas (ventilation) and blood (perfusion) in all portions of the lungs. The lungs are suspended from the hila in the thoracic cavity. When the individual is in an upright position (sitting or standing), gravity pulls the lungs down toward the diaphragm and compresses their lower portions or bases. The alveoli in the upper portions, or apexes, of the lungs contain a greater residual volume of gas and are larger and less numerous than those in the lower portions. Because surface tension increases as the alveoli become larger, the larger alveoli in the upper portions of the lung are more difficult to inflate (less

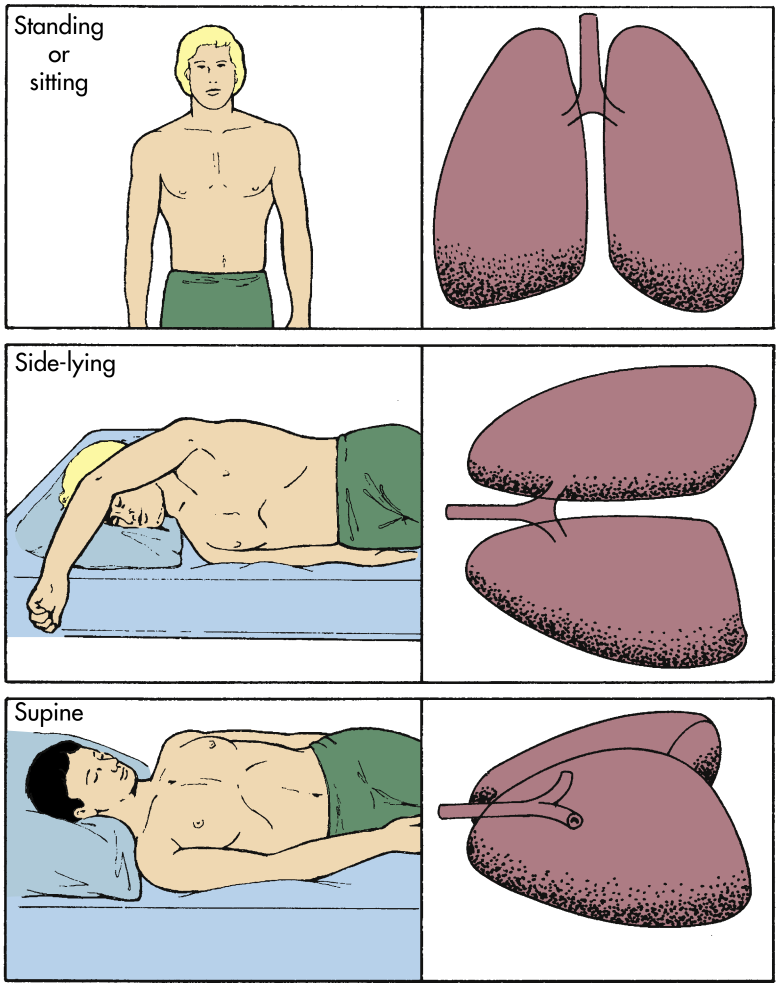

FIGURE 34-13 **Pulmonary Blood Flow and Gravity.** The greatest volume of pulmonary blood flow will normally occur in the gravity-dependent areas of the lungs. Body position has a significant effect on the distribution of pulmonary blood flow.

compliant) than the smaller alveoli in the lower portions of the lung. Therefore, during ventilation most of the tidal volume is distributed to the bases of the lungs, where compliance is greater.

The heart pumps against gravity to perfuse the pulmonary circulation. As blood is pumped into the lung apexes of a sitting or standing individual, some blood pressure is dissipated in overcoming gravity. As a result, blood pressure at the apexes is lower than that at the bases. Because greater pressure causes greater perfusion, the bases of the lungs are better perfused than the apexes (Figure 34-13). Thus ventilation and perfusion are greatest in the same lung portions: the lower lobes. Ventilation and perfusion depend on body position. If a standing individual assumes a supine or side-lying position, the areas of the lungs that are then most dependent become the best ventilated and perfused.

Distribution of perfusion in the pulmonary circulation also is affected by alveolar pressure (gas pressure in the alveoli). The pulmonary capillary bed differs from the systemic capillary bed in that it is surrounded by gas-containing alveoli. If the gas pressure in the alveoli exceeds the blood pressure in the capillary, the capillary collapses and flow ceases. This is most likely to occur in portions of the lung where blood pressure is lowest and alveolar gas pressure is greatest, that is, the apex of the lung.

The lungs are divided into three zones on the basis of the relationships among all the factors affecting pulmonary blood flow. Alveolar pressure plus the forces of gravity, arterial blood pressure, and venous blood pressure affect the distribution of perfusion (Figure 34-14).

Zone I is where alveolar pressure exceeds pulmonary arterial and venous pressures. The capillary bed collapses, and normal blood flow ceases. Normally zone I is a very small part of the lung at the apex. Zone II is the portion where alveolar pressure is greater than venous pressure, but not greater than arterial pressure. Blood flows through zone II, but it is impeded to a certain extent by alveolar pressure. Zone II is normally above the level of the left atrium. In zone III arterial and venous pressures are greater than alveolar pressure and blood flow is not affected by alveolar pressure. Zone III is in the base of the lung. Blood flow through the pulmonary capillary bed increases in regular increments from the apex to the base.

Although blood flow and ventilation are greater at the base of the lungs than at the apexes, they are not perfectly matched in any of the zones. Perfusion exceeds ventilation in the bases

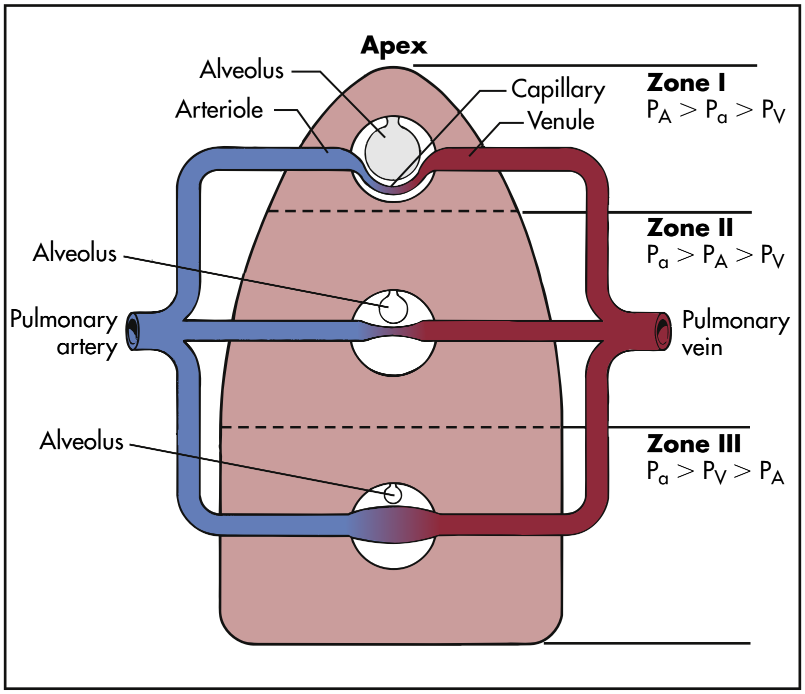

FIGURE 34-14 **Gravity and Alveolar Pressure.** Effects of gravity and alveolar pressure on pulmonary blood flow in the three lung zones. In zone I, alveolar pressure *(P_A)* is greater than arterial and venous pressure, and no blood flow occurs. In zone II, arterial pressure *(P_a)* exceeds alveolar pressure, but alveolar pressure exceeds venous pressure *(P_V)*. Blood flow occurs in this zone, but alveolar pressure compresses the venules (venous ends of the capillaries). In zone III, both arterial and venous pressures are greater than alveolar pressure and blood flow fluctuates, depending on the difference between arterial and venous pressures.

of the lungs, and ventilation exceeds perfusion in the apexes of the lung. The relationship between ventilation and perfusion is expressed as a ratio called the **ventilation-perfusion ratio,** or $\dot{V}/\dot{Q}$.[9] The normal $\dot{V}/\dot{Q}$ ratio is 0.8. This is the amount by which perfusion exceeds ventilation under normal conditions.

Oxygen Transport

Approximately 1000 ml (1 L) of oxygen is transported to the cells each minute. Oxygen is transported in the blood in two forms. A small amount dissolves in plasma, and the remainder binds to hemoglobin molecules. Without hemoglobin, oxygen would not reach the cells in amounts sufficient to maintain normal metabolic function. (Hemoglobin is discussed in detail in Chapter 27; cellular metabolism is discussed in Chapter 1.)

Diffusion Across the Alveolocapillary Membrane. The alveolocapillary membrane is the ideal medium for oxygen diffusion, because it has a large total surface area (70 to 100 m^2) and is very thin (0.5 μm). In addition, the partial pressure of oxygen molecules (Po_2) is much greater in alveolar gas than in capillary blood, a condition that promotes rapid diffusion down the concentration gradient from the alveolus into the capillary.[9]

The amount of oxygen in the alveoli ($P\text{AO}_2$) depends on the amount of oxygen in the inspired air and on the amount of air that remains in the alveoli and tracheobronchial tree between breaths (**physiologic dead space**).[9] The $P\text{AO}_2$ can be estimated by using the alveolar gas equation:

$$P\text{AO}_2 = F\text{iO}_2 - P\text{aCO}_2/0.8 \text{ (the respiratory quotient)}$$

This value is approximately 104 mmHg at sea level with relaxed breathing; therefore a pressure gradient of approximately 60 mmHg facilitates the diffusion of oxygen from the alveolus into the capillary (Figure 34-15). Different values for $P\text{AO}_2$ can be calculated if there are changes in the inspired oxygen content or the $Paco_2$, which are common occurrences in clinical settings.

Blood remains in the pulmonary capillary for about 0.75 second, but only 0.25 second is required for oxygen concentration to equilibrate (equalize) across the alveolocapillary membrane.[9] Therefore, oxygen has ample time to diffuse into the blood, even during increased cardiac output, which speeds blood flow, shortening the time the blood remains in the capillary.

Determinants of Arterial Oxygenation. As oxygen diffuses across the alveolocapillary membrane, it dissolves in the plasma, where it exerts pressure (the partial pressure of oxygen in arterial blood, or Pao_2). As the Pao_2 increases, oxygen moves from the plasma into the red blood cells (erythrocytes) and binds with hemoglobin molecules. Oxygen continues to bind with hemoglobin until the hemoglobin binding sites are filled or saturated. Oxygen then continues to diffuse across the alveolocapillary membrane until the Pao_2 and $P\text{AO}_2$ equilibrate, eliminating the pressure gradient across the alveolocapillary membrane. At this point diffusion ceases (see Figure 34-15).

Normally approximately 20 ml of oxygen is transported per 100 ml of blood. Because oxygen is not very soluble in plasma, most of the oxygen molecules bind with hemoglobin. Plasma carries only about 0.3 ml of oxygen per 100 ml of blood (at sea

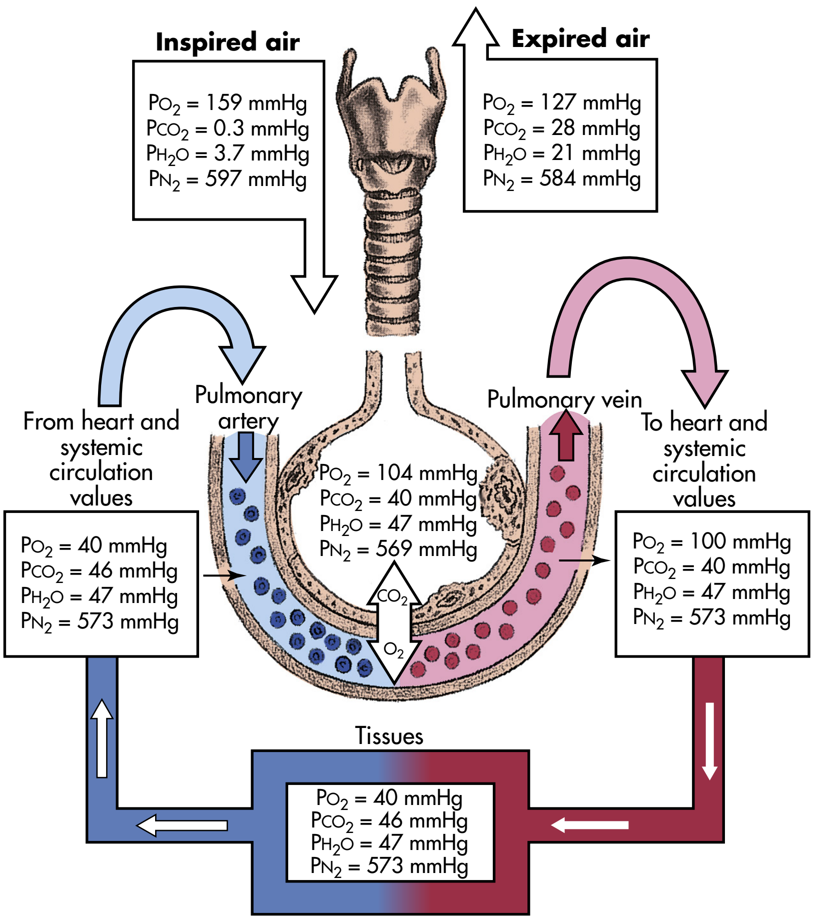

FIGURE 34-15 **Partial Pressure of Respiratory Gases in Normal Respiration.** These are average values. The values of Po_2, Pco_2, and PN_2 fluctuate from breath to breath. *CO_2,* Carbon dioxide; *O_2,* oxygen; *Pco_2,* partial pressure of carbon dioxide; *PH_2O,* partial *pressure* of water; *PN_2,* partial pressure of nitrogen; *Po_2,* partial pressure of oxygen.

level). Although the remaining 19.7 ml is carried by hemoglobin, it is the small amount of oxygen dissolved in plasma that is responsible for oxygen's partial pressure (Pao_2) in the blood.

Although Pao_2 is important in that it provides the driving pressure that loads the hemoglobin with oxygen, it gives little information about the *amount* of oxygen carried in the blood. This amount, which is measured in milliliters per deciliter (1 dl = 100 ml) of blood, is the **oxygen content** of the blood. The total oxygen content of the blood depends on the amount of oxygen chemically combined with hemoglobin, as well as that dissolved in the blood. To calculate the total arterial oxygen content, we must know (1) hemoglobin concentration, or the amount of hemoglobin that is available to bind with oxygen (hemoglobin [Hb] in grams per deciliter); (2) the oxygen saturation or percentage of available hemoglobin that is bound to oxygen (Sao_2); and (3) the partial pressure of oxygen (Pao_2). The maximum amount of oxygen that can be transported by hemoglobin is 1.34 ml/g. The amount of oxygen that can be physically dissolved in blood is 0.003 ml/dl per mmHg. If these specific values are known, the oxygen content of arterial blood can be calculated.[9] To calculate the oxygen content of venous blood, the partial pressure of mixed venous blood (Pvo_2) and venous oxygen saturation (Svo_2) are substituted for the arterial values in the basic formula. Normal venous oxygen content is 15 to 16 ml/dl.

Because hemoglobin transports all but a small fraction of the oxygen carried in arterial blood, increases in hemoglobin concentration affect the oxygen content of the blood. Decreases in hemoglobin concentration below the normal value of 15 ml/dl of blood reduce oxygen content, and increases in hemoglobin concentration may minimize the effect of impaired gas exchange. In fact, an increase in hemoglobin concentration is a major compensatory mechanism in pulmonary diseases that impair gas exchange. For this reason, measurement of hemoglobin concentration is important in assessing individuals with pulmonary disease. If cardiovascular function is normal, the body's initial response to low oxygen content is to accelerate cardiac output. In individuals who also have cardiovascular disease, this compensatory mechanism does not work, making increased hemoglobin concentration an even more important compensatory mechanism. (Hemoglobin structure and function are described in Chapter 27.)

Oxyhemoglobin Association and Dissociation. When hemoglobin molecules bind with oxygen, **oxyhemoglobin (HbO_2)** is formed. Binding occurs in the lungs and is called *oxyhemoglobin association* or *hemoglobin saturation with oxygen*

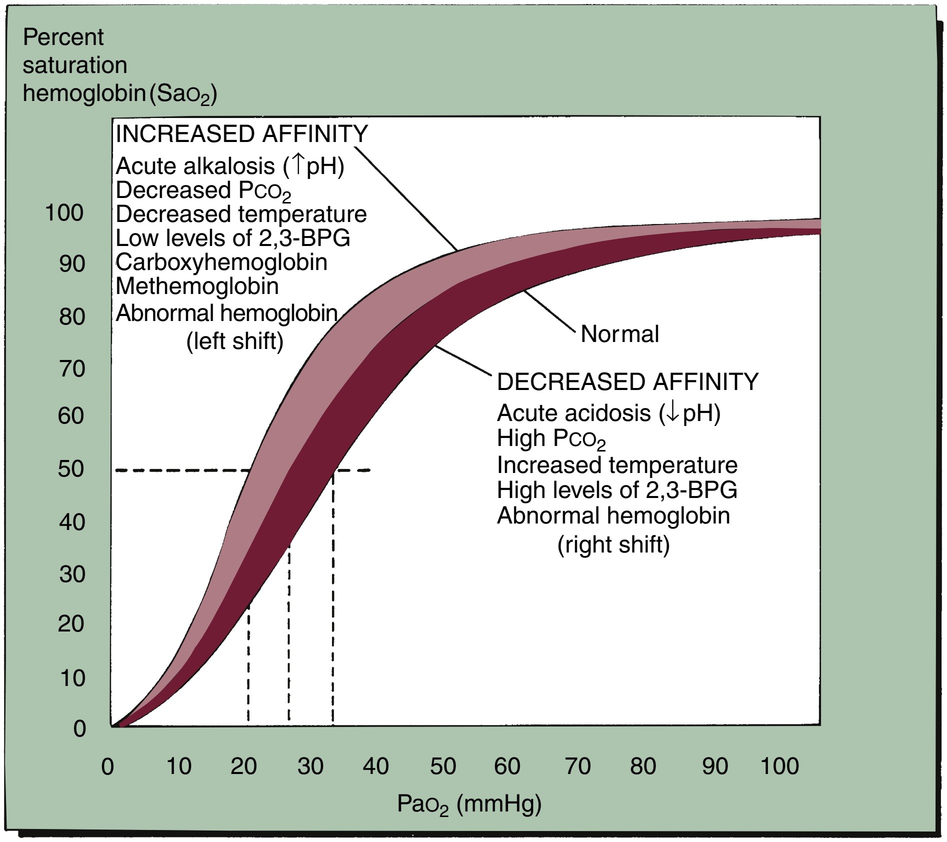

FIGURE 34-16 **Oxyhemoglobin Dissociation Curve.** The horizontal or flat segment of the curve at the top of the graph is sometimes called the *arterial portion,* or that part of the curve where oxygen is bound to hemoglobin. This portion of the curve is flat because partial pressure changes of oxygen between 60 and 100 mmHg do not significantly alter the percent saturation of hemoglobin with oxygen. The wide range of partial pressures of oxygen (Pa_{O_2} of 60 to 100 mmHg), represented by the flat part of the curve, allows adequate hemoglobin saturation at a variety of *altitudes.* For example, a Pa_{O_2} of 100 mmHg at sea level results in a hemoglobin saturation with oxygen of 98%. At an altitude of 5000 feet the Pa_{O_2} is about 70 mmHg and hemoglobin saturation is 94%, only 4% less than at sea level. If the relationship between Sa_{O_2} and Pa_{O_2} were linear (in a downward-sloping straight line) instead of flat between 60 and 100 mmHg, there would be inadequate saturation of hemoglobin with oxygen. For example, with a Pa_{O_2} of 70 mmHg the saturation would be only 70%, which is equivalent to normal venous oxygen saturation, and life could not be sustained at altitudes much higher than sea level. The steep part of the oxyhemoglobin dissociation curve occurs after the Pa_{O_2} drops below 60 mmHg and represents the rapid dissociation of oxygen from hemoglobin. During this phase oxygen diffuses rapidly from the blood into tissue cells. Conditions associated with altered affinity of hemoglobin for O_2 are listed. P_{50} is the Pa_{O_2} at which hemoglobin is 50% saturated, normally 26.6 mmHg. A lower than normal P_{50} represents increased affinity of hemoglobin for O_2; a high P_{50} is seen with decreased affinity. Note that variation from the normal is associated with decreased (low P_{50}) or increased (high P_{50}) availability of O_2 to tissues *(dashed lines).* The *shaded area* shows the entire oxyhemoglobin dissociation curve under the same circumstances. *2,3-BPG,* 2,3-Biphosphoglycerate. (From Lane EE, Walker JF: *Clinical arterial blood gas analysis,* St Louis, 1987, Mosby.)

(Sa_{O_2}). The reverse process, in which oxygen is released from hemoglobin, occurs in the body tissues at the cellular level and is called *hemoglobin desaturation.* When hemoglobin saturation and desaturation are plotted on a graph, the result is a distinctive S-shaped curve known as the **oxyhemoglobin dissociation curve** (Figure 34-16).

Several factors can change the relationship between Pa_{O_2} and Sa_{O_2}, causing the oxyhemoglobin dissociation curve to shift to the right or left (see Figure 34-16). A shift to the right depicts hemoglobin's decreased affinity for oxygen or an increase in the ease with which oxyhemoglobin dissociates and oxygen moves into the cells. A shift to the left depicts hemoglobin's increased affinity for oxygen, which promotes association in the lungs and inhibits dissociation in the tissues.

The oxyhemoglobin dissociation curve is shifted to the right by acidosis (low pH) and hypercapnia (increased Pa_{CO_2}). In the tissues the increased levels of CO_2 and hydrogen ions produced by metabolic activity decrease the affinity of hemoglobin for oxygen. The curve is shifted to the left by alkalosis (high pH) and hypocapnia (decreased Pa_{CO_2}). In the lungs, as CO_2 diffuses from the blood into the alveoli, the blood CO_2 level is reduced and the affinity of hemoglobin for oxygen is increased. The shift in the oxyhemoglobin dissociation curve caused by changes in CO_2 and hydrogen ion concentration in the blood is called the **Bohr effect.**[9]

The oxyhemoglobin curve is shifted also by changes in body temperature and increased or decreased levels of 2,3-biphosphoglycerate (2,3-BPG), a substance normally present in erythrocytes. Hyperthermia and increased 2,3-BPG levels shift

the curve to the right. Hypothermia and decreased 2,3-BPG levels shift the curve to the left.

Carbon Dioxide Transport

Approximately 200 ml of CO_2 is produced by the tissues per minute as a byproduct of cellular metabolism. This CO_2 equilibrates with carbonic acid ($H_2O + CO_2 \rightleftharpoons H_2CO_3 \rightleftharpoons H + HCO_3^-$) and must be eliminated continuously to prevent acidosis. The elimination of CO_2 by the lungs plays an important role in the regulation of acid-base balance (see Chapter 3).

CO_2 is carried in the blood in three ways: (1) dissolved in plasma, (2) as bicarbonate, and (3) as carbamino compounds. As CO_2 diffuses out of the cells into the blood, it dissolves in the plasma. Approximately 10% of the total CO_2 in venous blood and 5% of the CO_2 in arterial blood are carried dissolved in the plasma. As CO_2 moves into the blood, it diffuses into the red blood cells. Within the red blood cells, CO_2, with the help of the enzyme carbonic anhydrase, combines with water to form carbonic acid and then quickly dissociates into H^+ and HCO_3^-. As carbonic acid dissociates, the H^+ binds to hemoglobin, where it is buffered, and the HCO_3^- moves out of the red blood cell into the plasma. Approximately 60% of the CO_2 in venous blood and 90% of the CO_2 in arterial blood are carried in the form of bicarbonate. The remainder combines with blood proteins, hemoglobin in particular, to form carbamino compounds (see Figure 3-12). Approximately 30% of the CO_2 in venous blood and 5% of the CO_2 in arterial blood are carried as carbamino compounds.[9]

CO_2 is 20 times more soluble than O_2 and diffuses quickly from the tissue cells into the blood.[9] The amount of CO_2 that is able to enter the blood is enhanced by diffusion of oxygen out of the blood and into the cells. Reduced hemoglobin (hemoglobin that is dissociated from oxygen) is able to carry more CO_2 than hemoglobin that is saturated with O_2. Therefore, the drop in Sa_{O_2} at the tissue level increases the ability of hemoglobin to carry CO_2 back to the lung.

The diffusion gradient for CO_2 in the lung is only approximately 6 mmHg (venous Pv_{CO_2} = 46 mmHg; alveolar $P_{A_{CO_2}}$ = 40 mmHg), yet CO_2 is so soluble in the alveolocapillary membrane that the CO_2 in the blood quickly diffuses into the alveoli, where it is removed from the lung with each expiration.[9] Diffusion of CO_2 in the lung is so efficient that diffusion defects that cause hypoxemia (low oxygen content of the blood) do not cause hypercapnia (excessive CO_2 in the blood).

The diffusion of CO_2 out of the blood also is enhanced by oxygen binding with hemoglobin in the lung. As hemoglobin binds with O_2, the amount of CO_2 carried by the blood is decreased. Thus in the tissue capillaries, O_2 dissociation from hemoglobin facilitates the pickup of CO_2, and the binding of O_2 to hemoglobin in the lungs facilitates the release of CO_2 from the blood. This effect of oxygen on CO_2 transport is called the **Haldane effect** and can have significant clinical implications for the management of lung disease.[29,30]

TESTS OF PULMONARY FUNCTION

Several laboratory tests aid in the diagnosis and evaluation of pulmonary system abnormalities. Most of them are easy to perform at hospitals and clinics. They provide valuable information about the possible cause of a respiratory abnormality and evaluate the progression or resolution of disease.

Spirometry is used to measure forced expiration, which often is affected by diffuse pulmonary disease. Because the pulmonary system has remarkable reserves, disease may become well established before clinical manifestations appear. Spirometry enables clinicians to detect restrictive or obstructive deficits early in the course of disease. Restrictive lung diseases restrict the lungs' volume: the lungs are unable to expand normally, diminishing the amount of gas that can be inspired. Obstructive diseases affect gas flow: airflow into and out of the lungs is obstructed.

Spirometry measures both volume and flow. The test is performed with a spirometer, which is a water-filled cylinder into which an inverted cylinder or bell has been inserted. A length of tubing runs from the inverted bell to a mouthpiece through which a person breathes during testing. The bell is attached to a pen that writes on calibrated paper rotating at a constant speed. As a person performs various breathing maneuvers, the inverted bell moves up and down, causing the pen to move on the calibrated paper. This produces a spirogram, which is a record of the individual's ventilation in relation to time (Figure 34-17). Clinically the most important spirometric tests are the forced vital capacity (FVC) and the forced expiratory volume in 1 second (FEV_1).[31] (These tests and other important measures are described in Table 34-3.)

Lung capacities, such as vital capacity and total lung capacity, are always the sum of two or more volumes. Norms for volumes and capacities are based on age, gender, and height and are referred to as *predicted values.* Changes from predicted or baseline values are taken into account in diagnosing and assessing respiratory disorders.

Diffusing capacity is a measure of the rate of gas diffusion across the alveolocapillary membrane. Oxygen, or more commonly carbon monoxide, is used to measure diffusing capacity. The measurement is made by determining how much carbon monoxide is taken up by the blood and dividing this amount by the pressure gradient across the alveolocapillary membrane. Helium often is added to the gas mixture to obtain a simultaneous measurement of **residual volume (RV), functional reserve capacity (FRC),** and **total lung capacity (TLC).** Individuals are asked to perform ventilatory maneuvers similar to those of spirometry. A decreased diffusing capacity can be the result of an abnormal ventilation-perfusion ratio or an actual diffusion defect. Diffusing capacity is decreased in individuals with emphysema.

Arterial blood gas analysis commonly is performed for individuals with suggested or diagnosed pulmonary disease. Direct analysis of the pH and gas concentrations in arterial blood provides valuable information about an individual's gas exchange and acid-base status. Acidosis (low pH), alkalosis (high pH), ventilatory alterations, and decreased Pa_{O_2} can be diagnosed accurately only by arterial blood gas analysis. A blood gas report may be divided into an acid-base/ventilation portion and an oxygenation portion. (Normal values for arterial blood gases are given in Table 34-4; acid-base alterations are described in Chapter 3.) Oximetry can be used to monitor oxygen saturation

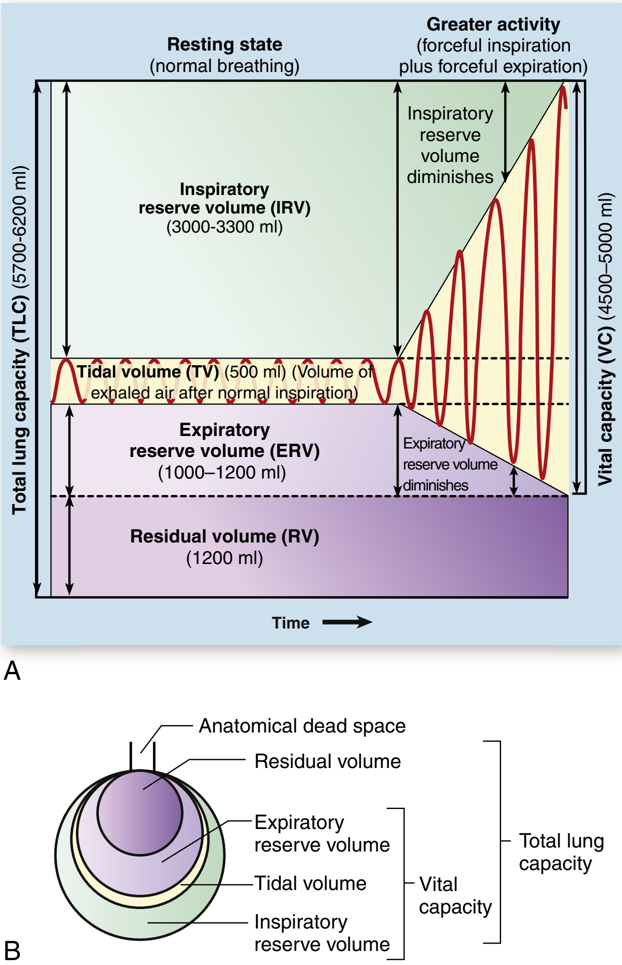

FIGURE 34-17 Pulmonary Ventilation and Lung Capacities. **A,** Spirogram. During normal, quiet respirations the atmosphere and lungs exchange about 500 ml of air (V_T). With a forcible inspiration, about 3300 ml more air can be inhaled *(IRV)*. After a normal inspiration and normal expiration, approximately 1000 ml more air can be forcibly expired *(ERV)*. Vital capacity is the amount of air that can be forcibly expired after a maximal inspiration and indicates, therefore, the largest amount of air that can enter and leave the lungs during respiration. Residual volume *(RV)* is the air that remains trapped in the alveoli. **B,** Lung capacities. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

once the arterial blood gas analysis has accurately measured the Pa_{O_2}, but it does not measure Pa_{CO_2} or pH.

Signs and symptoms of most respiratory abnormalities first appear when the system is stressed during exercise. Therefore, if pulmonary disease is suspected, the individual is evaluated at rest and during exercise. During exercise the usual procedures are spirometry and withdrawal of arterial blood for gas analysis. The exercise usually consists of riding a stationary bicycle or walking on a treadmill. Exercise testing enables clinicians to detect early changes in respiratory function and thus begin treatment. Exercise tests also are used in planning and evaluating exercise and rehabilitation programs.

Chest radiographs are among the most common examinations of the pulmonary system. A few of the abnormalities detected in chest radiographs are air trapping in the alveoli and airways (e.g., in asthma or emphysema), consolidation of lung tissue (e.g., in pneumonia or pulmonary edema), cavities (e.g., abscesses or tuberculosis), and nodules (e.g., lung cancer). Often pulmonary abnormalities are detected in routine chest radiographs of asymptomatic individuals. Various radiographic techniques are available for the diagnosis and evaluation of respiratory disorders.

TABLE 34-3 VALUES MEASURED BY SPIROMETRY

SYMBOL	VENTILATORY PROPERTY MEASURED
FVC	Forced vital capacity: maximum amount of gas that can be displaced from the lung during a forced expiration
FEV_1	Forced expiratory volume in 1 second: maximum amount of air that can be expired from the lung in 1 second
FEV_1/FVC	Percentage of maximum inspiration that is expired in 1 second, usually 80% of FVC
FEV_3	Forced expiratory volume in 3 seconds; maximum amount of gas that can be expired in 3 seconds
FEV_3/FVC	Percentage of FVC that is expired in 3 seconds; usually 95% of FVC
$FEF_{25\%-75\%}$	Forced expiratory flow rate during the middle 50% of expiration; sometimes reported as maximum midexpiratory flow rate (MMFR)

AGING AND THE PULMONARY SYSTEM

Most knowledge about pulmonary structure and function is based on norms for the middle years. Less is known about structure and function in the very young (see Chapter 36) and older adults, but a few normal physiologic (developmental and degenerative) changes are known to occur from birth to old age. An understanding of these changes is needed to provide appropriate care and to differentiate between normal alterations and disease. Normal alterations include: (1) loss of elastic recoil, (2) stiffening of the chest wall, (3) changes in gas exchange, and (4) increases in flow resistance (Figure 34-18). These changes are gradual and usually without adverse consequences in healthy individuals. They are influenced by environmental and sociocultural factors, nutritional status, respiratory disease, body size, gender, and race.[32-34]

During adulthood and as age advances, the alveoli tend to lose alveoli wall tissue and capillaries. This process diminishes alveolar surface area available for gas diffusion and decreases airway support provided by normal lung tissues. Mechanical changes involve elastic properties of the lungs and chest wall. Chest wall compliance decreases with age, because the ribs become ossified (less flexible) and joints become stiffer. As a result the chest wall loses some of its ability to expand. In addition, respiratory muscle strength and endurance decrease by up to 20% by age 70.[33] These mechanical changes in the lung and chest wall, along with structural changes in the alveoli, reduce ventilatory capacity in older adults.[35] Vital capacity decreases and residual volume increases; however, total lung capacity remains unchanged. These changes decrease ventilatory reserves and lead to decreased ventilation-perfusion ratios. With advancing

TABLE 34-4 NORMAL RANGES FOR ARTERIAL AND MIXED VENOUS BLOOD GASES

MEASUREMENT	ARTERIAL BLOOD	MIXED VENOUS BLOOD*	CLINICAL NOTES
Acid-base status (pH)	7.35-7.45	7.33-7.43	Most important acid-base value; detects acidosis or alkalosis
Partial pressure of carbon dioxide (P_{CO_2})	35-45 mmHg	41-57 mmHg	Measures adequacy of ventilation and respiratory contribution of acid-base abnormality (respiratory acidosis)
Bicarbonate (HCO^-_3)	22-26 mEq/L	24-28 mEq/L	Measures metabolic contribution to acid-base abnormality (metabolic acidosis); calculated from pH and P_{CO_2}
Base excess (BE)	−2 to +2	0 to +4	Reflects deviation of bicarbonate concentration from normal
Partial pressure of oxygen (P_{O_2}) (sea level)	80-100 mmHg	35-40 mmHg	Indicates driving pressure that causes oxyhemoglobin binding; varies with age and barometric pressure
Saturation of hemoglobin with oxygen (S_{O_2})	96-98%	70-75%	Indicates abnormalities of oxyhemoglobin association and dissociation; may be measured directly or calculated from P_{CO_2}, pH, and body temperature
Concentration of hemoglobin in the blood	15 g/dl	15 g/dl	Detects alterations of gas transport caused by anemia

*Mixed venous (pulmonary artery) blood is analyzed for critically ill individuals and those undergoing cardiac catheterization (it is not practical to withdraw samples except from a pulmonary artery catheter). Mixed venous blood gas analysis, in conjunction with arterial analysis, provides important information about the adequacy of cardiac output and tissue oxygenation.

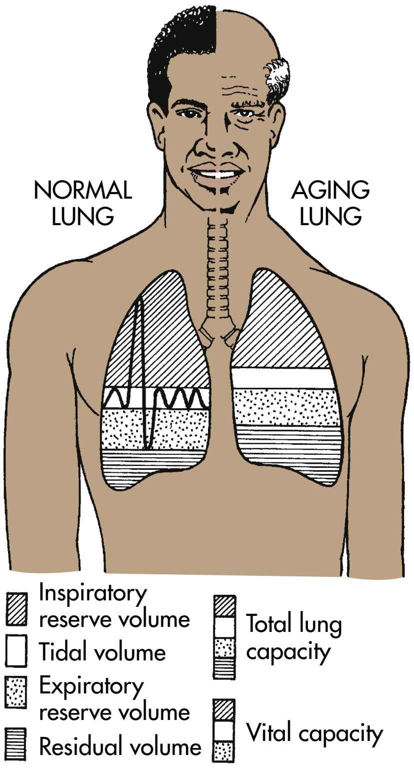

FIGURE 34-18 Changes in Lung Volumes with Aging. With aging, note particularly the decrease in vital capacity and the increase in residual volume.

age there is also increased immune dysregulation, asymptomatic low-grade inflammation, and increased risk of infection.[33,36-39]

Alterations in gas exchange are reflected by blood gas analysis. With advancing age, pH and Pa_{CO_2} do not change much, even though it has been documented that the chemoreceptors become less sensitive to gas partial pressures with age.[40] Older adults have a decreased compensatory response to hypercapnia and hypoxemia; however, the perception of dyspnea remains intact and is even enhanced. Pa_{O_2} declines with age as a result of structural and mechanical changes, such as loss of alveolar surface area and increased ventilation-perfusion mismatch. The maximum Pa_{O_2} in an older adult at sea level can be estimated by multiplying the person's age by 0.3 and subtracting the product from 100. For example, an 80-year-old individual would have an estimated maximum Pa_{O_2} of 76 mmHg ($0.3 \times 80 = 24$; $100 - 24 = 76$).[41] There is also a decrease in the capillary network.

The decrease in Pa_{O_2} and diminished ventilatory reserve in an older adult lead to a decrease in exercise tolerance. Respiratory muscle strength and endurance decrease with age.[39] Furthermore, older adults are at greater risk for respiratory depression caused by medications. Changes in respiratory structure and function can vary considerably from person to person, however. Changes also are affected by activity and fitness earlier in life. A very active, physically fit individual will, all else being equal, have fewer changes in function at any age than one who has been sedentary.

SUMMARY REVIEW

Structures of the Pulmonary System

1. The pulmonary system consists of the lungs, airways, chest wall, diaphragm, and pulmonary and bronchial circulation.
2. Air is inspired and expired through the conducting airways, which include the nasopharynx, oropharynx, trachea, bronchi, and bronchioles to the sixteenth division.
3. Gas exchange occurs in structures beyond the sixteenth division: the respiratory bronchioles, alveolar ducts, and alveoli. Together these structures comprise the acinus.
4. The chief gas-exchange units of the lungs are the alveoli. The membrane that surrounds each alveolus and contains the pulmonary capillaries is called the *alveolocapillary membrane.*

SUMMARY REVIEW—cont'd

5. The gas-exchange airways are served by the pulmonary circulation, a separate division of the circulatory system. The bronchi and other lung structures are served by a branch of the systemic circulation called the *bronchial circulation*.
6. The pulmonary circulation is innervated by the ANS, but vasodilation and vasoconstriction are controlled mainly by local and humoral factors, particularly arterial oxygenation and acid-base status.
7. Vasoconstriction of the pulmonary arterial system is caused by alveolar hypoxia, acidemia, and inflammatory mediators (histamine, serotonin, prostaglandins, and bradykinin).
8. The chest wall, which contains and protects the contents of the thoracic cavity, consists of the skin, ribs, and intercostal muscles, which lie between the ribs.
9. The chest wall is lined by a serous membrane called the *parietal pleura;* the lungs are encased in a separate membrane called the *visceral pleura.* The area where these two pleurae come into contact and slide over each another is called the *pleural space.*

Functions of the Pulmonary System

1. The pulmonary system enables oxygen to diffuse into the blood and CO_2 to diffuse out of the blood.
2. Ventilation is the process by which air flows into and out of the gas-exchange airways.
3. Ventilation is involuntary most of the time. It is controlled by the respiratory center in the brainstem and by the sympathetic and parasympathetic divisions of the ANS, which adjust airway caliber (by causing bronchial smooth muscle to contract or relax) and control the rate and depth of ventilation.
4. Neuroreceptors in the lungs (lung receptors) monitor the mechanical aspects of ventilation. Irritant receptors sense the need to expel unwanted substances, stretch receptors sense lung volume (lung expansion), and *J*-receptors sense alveolar size.
5. Chemoreceptors in the circulatory system and brainstem sense the effectiveness of ventilation by monitoring the pH status of cerebrospinal fluid and the oxygen content of arterial blood (Pao_2).
6. Successful ventilation involves the mechanics of breathing: the interaction of forces and counterforces involving the muscles of inspiration and expiration, alveolar surface tension, elastic properties of the lungs and chest wall, and resistance to airflow.
7. The major muscle of inspiration is the diaphragm. When the diaphragm contracts, it moves downward in the thoracic cavity, creating a vacuum that causes air to flow into the lungs.
8. The alveoli produce surfactant, produced by type II alveolar cells. It is a lipoprotein that lines the alveoli. Surfactant reduces alveolar surface tension and permits the alveoli to expand more easily with air intake.
9. Compliance is the ability of the lungs and chest wall to expand during inspiration. Lung compliance is ensured by adequate production of surfactant; chest wall expansion depends on flexibility.
10. Elastic recoil is the tendency of the lungs and chest wall to return to their resting state after inspiration. The elastic recoil forces of the lungs and chest wall are in opposition and pull on each other, creating the normally negative pressure of the pleural space.
11. Gas transport depends on ventilation of the alveoli, diffusion across the alveolocapillary membrane, perfusion of the pulmonary and systemic capillaries, and diffusion between systemic capillaries and tissue cells.
12. Efficient gas exchange depends on an even distribution of ventilation and perfusion within the lungs. Ventilation and perfusion are greatest in the bases of the lungs because the alveoli in the bases are more compliant (their resting volume is low), and perfusion is greater in the bases as a result of gravity.
13. Almost all of the oxygen that diffuses into pulmonary capillary blood is transported by hemoglobin, a protein contained within red blood cells. The remainder of the oxygen is transported dissolved in plasma.
14. Oxygen enters the body by diffusing down the concentration gradient, from high concentrations in the alveoli to lower concentrations in the capillaries. Diffusion ceases when alveolar and capillary oxygen pressures equilibrate.
15. Oxygen is loaded onto hemoglobin by the driving pressure exerted by Pao_2 in the plasma. As pressure decreases at tissue level, oxygen dissociates from hemoglobin and enters tissue cells by diffusion, again down the concentration gradient.
16. CO_2 is more soluble in plasma than oxygen is and diffuses readily from tissue cells into plasma. CO_2 returns to the lungs dissolved in plasma, as bicarbonate, or in carbamino compounds (e.g., bound to hemoglobin).

Tests of Pulmonary Function

1. Spirometry measures volume and flow rate during forced expiration.
2. The alveolar-arterial oxygen gradient is used to evaluate the cause of hypoxia.
3. Diffusing capacity is a measure of the gas diffusion rate at the alveolocapillary membrane.
4. Arterial blood gas analysis can be used to determine pH and oxygen and CO_2 concentrations.
5. Radiographic examination of the chest evaluates air trapping, consolidation, cavity formation, or presence of tumors.

Aging and the Pulmonary System

1. Aging affects the mechanical aspects of ventilation by decreasing chest wall compliance and elastic recoil of the lungs. Changes in these elastic properties reduce ventilatory reserve.
2. Aging causes the Pao_2 to decrease but does not affect the $Paco_2$.

CHAPTER OUTLINE

Pulmonary disease is often classified as acute or chronic, obstructive or restrictive, and infectious or noninfectious. Because skillful and knowledgeable care plays a major role in decreasing respiratory morbidity and mortality, the clinician with a clear understanding of the pathophysiology of common respiratory problems can greatly affect the outcome for each individual.

CLINICAL MANIFESTATIONS OF PULMONARY ALTERATIONS

Signs and Symptoms of Pulmonary Disease

Pulmonary disease is associated with many signs and symptoms and their specific characteristics often help in identifying the underlying disorder. The most common are dyspnea and cough. Others include abnormal sputum, hemoptysis, altered breathing patterns, hypoventilation and hyperventilation, cyanosis, clubbing of the digits, and chest pain.

Dyspnea

Dyspnea is a subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiologic, psychologic, social, and environmental factors, and it may induce secondary physiologic and behavioral responses. It is often described as breathlessness, air hunger, shortness of breath, increased work of breathing, chest tightness, and preoccupation with breathing.[1] Dyspnea may be the result of pulmonary disease or many other conditions, such as pain, heart disease, trauma, and anxiety.

The severity of the experience of dyspnea may not directly correlate with the severity of underlying disease.[2,3] Either

diffuse or focal disturbances of ventilation, gas exchange, or ventilation-perfusion relationships can cause dyspnea, as can increased work of breathing or diseases that damage lung tissue (lung parenchyma). One proposed mechanism involves an impaired sense of effort where the perceived work of breathing is greater than the actual motor response generated. Stimulation of many receptors can contribute to the sensation of dyspnea including mechanoreceptors (the stretch receptors, irritant receptors, and *J*-receptors), upper airway receptors, and central and peripheral chemoreceptors that interact with the sensory and motor cortex.[4,5]

The more severe signs of dyspnea include flaring of the nostrils, use of accessory muscles of respiration, and retraction (pulling back) of the intercostal spaces. In dyspnea caused by parenchymal disease (e.g., pneumonia), retractions of tissue between the ribs (subcostal and intercostal retractions) are observed more often than supercostal retractions (retractions of tissues above the ribs), which predominate in upper airway obstruction. Retractions of any type are more commonly seen in children or in adults who are thin and have poorly developed thoracic musculature. Dyspnea can be quantified by the use of ordinal rating scales or visual analog scales.[3]

Dyspnea can occur transiently or can become chronic. The first episode commonly occurs with exercise and is called **dyspnea on exertion. Orthopnea** is dyspnea that occurs when an individual lies flat and is common in individuals with heart failure. The recumbent position redistributes body water, causes the abdominal contents to exert pressure on the diaphragm, and decreases the efficiency of the respiratory muscles. Sitting in a forward-leaning posture or supporting the upper body on several pillows generally relieves orthopnea. **Paroxysmal nocturnal dyspnea (PND)** occurs when individuals with heart failure or lung disease wake up at night gasping for air and must sit up or stand to relieve the dyspnea.

Cough

Cough is a protective reflex that helps clear the airways by an explosive expiration. Inhaled particles, accumulated mucus, inflammation, or the presence of a foreign body initiates the cough reflex by stimulating irritant receptors in the airway. There are few such receptors in the most distal bronchi and the alveoli; thus it is possible for significant amounts of secretions to accumulate in the distal respiratory tree without cough being initiated. The cough reflex consists of inspiration, closure of the glottis and vocal cords, contraction of the expiratory muscles, and reopening of the glottis, causing a sudden, forceful expiration that removes the offending matter. The effectiveness of the cough depends on the depth of the inspiration and the degree to which the airways narrow, increasing the velocity of expiratory gas flow. Stimulation of cough receptors is transmitted centrally through the vagus nerve, and central modulation of the cough reflex can be influenced by opiates and serotonergic agents.[6,7] Cough occurs frequently in healthy individuals; however, those with an inability to cough effectively are at greater risk for pneumonia.

Acute cough is cough that resolves within 2 to 3 weeks of the onset of illness or resolves with treatment of the underlying condition. It is most commonly the result of upper respiratory tract infections, allergic rhinitis, acute bronchitis, pneumonia, congestive heart failure, pulmonary embolus, or aspiration. **Chronic cough** is defined as cough that has persisted for more than 3 weeks, although some researchers have suggested that 7 or 8 weeks is a more appropriate timeframe because acute cough and bronchial hyperreactivity can be prolonged in some cases of viral infection. In nonsmokers, chronic cough is commonly caused by postnasal drainage syndrome, nonasthmatic eosinophilic bronchitis, asthma, gastroesophageal reflux disease, or heightened cough reflex sensitivity.[8] In smokers, chronic bronchitis is the most common cause of chronic cough, although lung cancer must always be considered. Individuals taking angiotensin-converting enzyme inhibitors for hypertension may develop chronic cough that resolves with discontinuation of the drug.

Abnormal Sputum

Changes in the amount, consistency, color, and odor of **sputum** provide information about progression of disease and effectiveness of therapy. The gross and microscopic appearances of sputum enable the clinician to identify cellular debris or microorganisms that aid in diagnosis and choice of therapy.

Hemoptysis is the coughing up of blood or bloody secretions. This is sometimes confused with hematemesis, which is the vomiting of blood. Blood that is coughed up is usually bright red, has an alkaline pH, and is mixed with frothy sputum. Blood that is vomited is dark, has an acidic pH, and is mixed with food particles.

Hemoptysis usually indicates infection or inflammation that damages the bronchi (bronchitis, bronchiectasis) or the lung parenchyma (pneumonia, tuberculosis, lung abscess). Other causes include cancer and pulmonary infarction. The amount and duration of bleeding provide important clues about its source. Bronchoscopy, combined with chest computed tomography (CT), is used to confirm the site of bleeding.[9]

Abnormal Breathing Patterns

Normal breathing (eupnea) is rhythmic and effortless. Ventilatory rate is 8 to 16 breaths per minute, and tidal volume ranges from 400 to 800 ml. A short expiratory pause occurs with each breath, and the individual takes an occasional deeper breath or sigh. Sigh breaths, which help maintain normal lung function, are usually 1.5 to 2 times the normal tidal volume and occur approximately 10 to 12 times per hour.

The rate, depth, regularity, and effort of breathing undergo characteristic alterations in response to physiologic and pathophysiologic conditions. Patterns of breathing automatically adjust to minimize the work of respiratory muscles. Strenuous exercise or metabolic acidosis induces **Kussmaul respirations (hyperpnea).** Kussmaul respirations are characterized by a slightly increased ventilatory rate, very large tidal volume, and no expiratory pause.

Labored breathing occurs whenever there is an increased work of breathing, especially if the airways are obstructed, as in chronic obstructive pulmonary disease (COPD). If the large airways are obstructed, a slow ventilatory rate, increased

effort, prolonged inspiration or expiration, and stridor (high-pitched sounds made during inspiration) or audible wheezing (whistling sounds on expiration) are typical. In small airway obstruction, like that seen in asthma and chronic obstructive pulmonary disease, a rapid ventilatory rate, small tidal volume, increased effort, prolonged expiration, and wheezing are often present.

Restricted breathing is commonly caused by disorders such as pulmonary fibrosis that stiffen the lungs or chest wall and decrease compliance. Restricted breathing is characterized by small tidal volumes and rapid ventilatory rate (tachypnea).

Shock and severe cerebral hypoxia (insufficient oxygen in the brain) contribute to gasping respirations that consist of irregular, quick inspirations with an expiratory pause. Anxiety can cause sighing respirations that consist of irregular breathing characterized by frequent, deep sighing inspirations.

Cheyne-Stokes respirations are characterized by alternating periods of deep and shallow breathing. Apnea lasting 15 to 60 seconds is followed by ventilations that increase in volume until a peak is reached, after which ventilation (tidal volume) decreases again to apnea. Cheyne-Stokes respirations result from any condition that slows the blood flow to the brainstem, which in turn slows impulses sending information to the respiratory centers of the brainstem. Neurologic impairment above the brainstem is also a contributing factor (see Table 17-4 and Figure 17-1).

Hypoventilation and Hyperventilation

Hypoventilation is inadequate alveolar ventilation in relation to metabolic demands. It is caused by alterations in pulmonary mechanics or in the neurologic control of breathing such that minute volume (tidal volume × respiratory rate) is reduced. When alveolar ventilation is normal, carbon dioxide (CO_2) is removed from the lungs at the same rate at which it is produced by cellular metabolism. This maintains arterial CO_2 pressure ($Paco_2$) at normal levels (40 mmHg). With hypoventilation, CO_2 removal does not keep up with CO_2 production and $Paco_2$ increases, causing hypercapnia ($Paco_2$ greater than 44 mmHg). (Table 34-2 contains the definition of gas partial pressure and other pulmonary abbreviations.) This results in an increase in hydrogen ion in the blood, termed respiratory acidosis, which can affect the function of many tissues throughout the body.

Hypoventilation is often overlooked until it is severe because breathing pattern and ventilatory rate may appear normal. Blood gas analysis (i.e., measurement of the $Paco_2$ of arterial blood) reveals the hypercapnia. Pronounced hypoventilation can cause somnolence or disorientation. In addition, alveolar hypoventilation with hypercapnia results in secondary hypoxemia because the accumulation of alveolar CO_2 displaces oxygen (see Hypercapnia, p. 1251).

Hyperventilation is alveolar ventilation that exceeds metabolic demands. The lungs remove CO_2 at a faster rate than it is produced by cellular metabolism, resulting in decreased $Paco_2$ or **hypocapnia** ($Paco_2$ less than 36 mmHg). Hypocapnia results in a respiratory alkalosis that also can interfere with tissue function. Like hypoventilation, hyperventilation can be determined only by arterial blood gas analysis. Hyperventilation commonly occurs with severe anxiety, acute head injury, and conditions that cause insufficient oxygenation of the blood.

Cyanosis

Cyanosis is a bluish discoloration of the skin and mucous membranes caused by increasing amounts of desaturated or reduced hemoglobin (which is bluish) in the blood. It generally develops when 5 g of hemoglobin is desaturated, regardless of hemoglobin concentration. For example, if total hemoglobin concentration is 15 g/dl of blood, 5 g/dl must be desaturated to cause cyanosis. If total hemoglobin level is 11 g/dl, 5 g/dl must still be desaturated for cyanosis to occur.

Peripheral cyanosis (slow blood circulation in fingers and toes) is most often caused by poor circulation resulting from intense peripheral vasoconstriction, like that seen in Raynaud's disease, cold environments, or severe stress. Peripheral cyanosis is best seen in the nail beds. *Central cyanosis* is caused by decreased arterial oxygenation (low Pao_2) from pulmonary diseases or pulmonary or cardiac right-to-left shunts. Central cyanosis is best seen in buccal mucous membranes and lips.

Lack of cyanosis does not necessarily indicate that oxygenation is normal. In adults, cyanosis is not evident until severe hypoxemia is present and, therefore, is an insensitive indication of respiratory failure. For example, severe anemia (inadequate hemoglobin concentration) and carbon monoxide poisoning (in which hemoglobin binds to carbon monoxide instead of binding to oxygen) can result in inadequate oxygenation of tissues without causing cyanosis. Individuals with polycythemia (an abnormal increase in numbers of red blood cells), however, may have cyanosis when tissue oxygenation is adequate. Because polycythemia causes hemoglobin concentration to be greater than normal, 5 g/dl can be desaturated, causing cyanosis, without having much effect on oxygenation. Therefore, the significance of cyanosis as a clinical finding must be interpreted in relation to the underlying pathophysiology. If cyanosis is suggested, the Pao_2 should be measured.

Clubbing

Clubbing is the selective bulbous enlargement of the end (distal segment) of a digit (finger or toe) (Figure 35-1) whose severity can be graded from 1 to 5 based on the extent of nail bed hypertrophy and the amount of changes in the nails themselves. It is usually painless. Clubbing is commonly associated with diseases that interfere with oxygenation, such as bronchiectasis, cystic fibrosis, pulmonary fibrosis, lung abscess, and congenital heart disease. It is rarely reversible with treatment of the underlying pulmonary condition. It can sometimes be seen in individuals with lung cancer even without hypoxemia, because of the effects of inflammatory cytokines and growth factors *(hypertrophic osteoarthropathy)*.[10]

Pain

Pain caused by pulmonary disorders originates in the pleurae, airways, or chest wall.[11] Pleural pain is the most common pain caused by pulmonary disease and is usually sharp or stabbing in character. Infection and inflammation of the parietal pleura (pleuritis or pleurisy) cause pain when the pleurae stretch

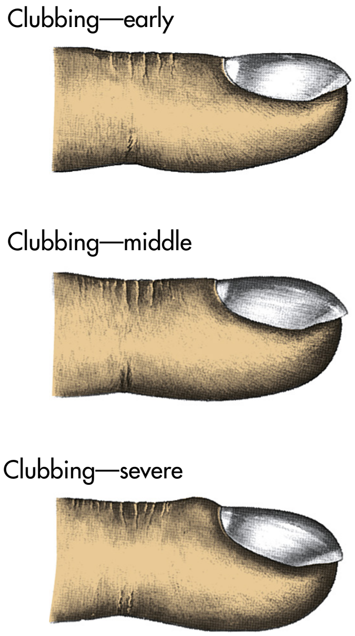

FIGURE 35-1 Clubbing of Fingers Caused by Chronic Hypoxemia. (From Seidel HM et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.)

during inspiration. The pain is usually localized to a portion of the chest wall, where a unique breath sound called a *pleural friction rub* may be heard over the painful area. Laughing or coughing makes pleural pain worse. Pleural pain is also common with pulmonary infarction (tissue death) caused by pulmonary embolism and emanates from the area around the infarction.

Pulmonary pain can be central chest pain that is pronounced after coughing and occurs in individuals with infection and inflammation of the trachea or bronchi (tracheitis or tracheobronchitis). Central chest pain can be difficult to differentiate from cardiac pain (see Chapter 32). High blood pressure in the pulmonary circulation (pulmonary hypertension) can cause pain during exercise that is often mistaken for cardiac pain (angina pectoris).

Pain in the chest wall is muscle pain or rib pain. The common causes of chest wall pain are rib fractures and excessive coughing, which make the muscles sore. Inflammation of the costochondral junction (costochondritis) also can cause chest wall pain. Chest wall pain can often be reproduced by pressing on the sternum or ribs.

Conditions Caused by Pulmonary Disease or Injury

Hypercapnia

Hypercapnia, or increased CO_2 concentration in the arterial blood (increased $Paco_2$), is caused by hypoventilation of the alveoli.[12] As discussed in Chapter 34, CO_2 is easily diffused from the blood into the alveolar space; thus minute volume (respiratory rate × tidal volume) determines not only alveolar ventilation, but also $Paco_2$. Hypoventilation is often overlooked because breathing pattern and ventilatory rate may appear normal; it is important to obtain blood gas analysis to determine the severity of hypercapnia and resultant respiratory acidosis (acid-base balance is described in Chapter 3).

There are many causes of hypercapnia.[13] Most are a result of a decreased drive to breathe or an inadequate ability to respond to ventilatory stimulation. Causes include: (1) depression of the respiratory center by drugs; (2) diseases of the medulla, including infections of the central nervous system or trauma; (3) abnormalities of the spinal conducting pathways, as in spinal cord disruption or poliomyelitis; (4) diseases of the neuromuscular junction or of the respiratory muscles themselves, as in myasthenia gravis or muscular dystrophy; (5) thoracic cage abnormalities, as in chest injury or congenital deformity; (6) large airway obstruction, as in tumors or sleep apnea; and (7) increased work of breathing or physiologic dead space, as in emphysema.

Hypercapnia and the associated respiratory acidosis can result in several important clinical manifestations. Of greatest concern are electrolyte abnormalities that occur in response to the low pH that may cause dysrhythmias. Individuals also may have somnolence and even be in a coma because of changes in intracranial pressure associated with high levels of arterial carbon dioxide, which causes cerebral vasodilation. Alveolar hypoventilation with increased alveolar carbon dioxide limits the amount of alveolar oxygen available for diffusion into the blood, leading to secondary hypoxemia.

Hypoxemia

Hypoxemia, or reduced oxygenation of arterial blood (reduced Pao_2), is caused by respiratory alterations, whereas **hypoxia,** or reduced oxygenation of cells in tissues, may be caused by alterations of other systems as well. Although hypoxemia can lead to tissue hypoxia, tissue hypoxia can result from other abnormalities, such as low cardiac output or cyanide poisoning.

Hypoxemia results from problems with one or more of the major mechanisms of oxygenation:

1. Oxygen delivery to the alveoli
   a. Oxygen content of the inspired air (Fio_2)
2. Ventilation of the alveoli
3. Diffusion of oxygen from the alveoli into the blood
   a. Balance between alveolar ventilation and perfusion ($\dot{V}/\dot{Q}$ mismatch)
   b. Diffusion of oxygen across the alveolocapillary membrane
4. Perfusion of pulmonary capillaries

Table 35-1 lists some of the common clinical causes of these problems.

The amount of oxygen in the alveoli is called the P_{AO_2} and is dependent on two factors. The first factor is the presence of adequate oxygen content of the inspired air. The amount of oxygen in inspired air is expressed as the percentage or fraction of air that is composed of oxygen, called the Fio_2. The Fio_2 of air at sea level is approximately 21% or 0.21. Anything that decreases the Fio_2 (such as high altitude) decreases the P_{AO_2}. The second factor is the amount of alveolar minute ventilation (tidal volume × respiratory rate). Hypoventilation results in an increase in P_{ACO_2} and a decrease in P_{AO_2} such that there is less oxygen available in the alveoli for diffusion into the blood. This type of hypoxemia can be completely corrected if alveolar ventilation is improved by increases in the rate and depth of breathing. Hypoventilation causes hypoxemia in unconscious persons; in

TABLE 35-1 CAUSES OF HYPOXEMIA

MECHANISM	COMMON CLINICAL CAUSES
Decrease in inspired oxygen (decreased F_{IO_2})	High altitude
	Low oxygen content of gas mixture
	Enclosed breathing spaces (suffocation)
Hypoventilation of the alveoli	Lack of neurologic stimulation of the respiratory center (oversedation, drug overdose, neurologic damage)
	Defects in chest wall mechanics (neuromuscular disease, trauma, chest deformity, air trapping)
	Large airway obstruction (laryngospasm, foreign body aspiration, neoplasm)
	Increased work of breathing (emphysema, severe asthma)
Ventilation-perfusion mismatch	Asthma
	Chronic bronchitis
	Pneumonia
	Acute respiratory distress syndrome
	Atelectasis
	Pulmonary embolism
Alveolocapillary diffusion abnormality	Edema
	Fibrosis
	Emphysema
Decreased pulmonary capillary perfusion	Intracardiac defects
	Intrapulmonary arteriovenous malformations

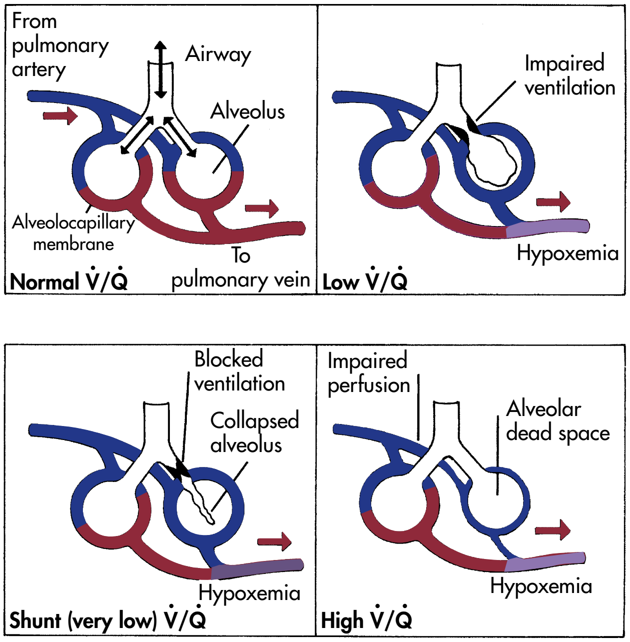

FIGURE 35-2 Ventilation-Perfusion Abnormalities. (Data from Glenny RW: *Adv Physiol Educ* 32[3]:192–195, 2008.)

people with neurologic, muscular, or bone diseases that restrict chest expansion; and in individuals who have COPD.

Diffusion of oxygen from the alveoli into the blood is also dependent on two factors. The first is the balance between the amount of air getting into alveoli ($\dot{V}$) and the amount of blood perfusing the capillaries around the alveoli ($\dot{Q}$). An abnormal ventilation-perfusion ratio ($\dot{V}/\dot{Q}$) is the most common cause of hypoxemia (Figure 35-2). Normally, alveolocapillary lung units receive almost equal amounts of ventilation and perfusion. The normal $\dot{V}/\dot{Q}$ is 0.8 to 0.9 because perfusion is somewhat greater than ventilation in the lung bases and because some blood is normally shunted to the bronchial circulation. $\dot{V}/\dot{Q}$ mismatch refers to an abnormal distribution of ventilation and perfusion. Hypoxemia can be caused by inadequate ventilation of well-perfused areas of the lung (low $\dot{V}/\dot{Q}$). Mismatching of this type, called **shunting,** occurs in atelectasis, in asthma as a result of bronchoconstriction, and in pulmonary edema and pneumonia when alveoli are filled with fluid. When blood passes through portions of the pulmonary capillary bed that receive no ventilation, right-to-left shunt occurs, resulting in decreased systemic Pa_{O_2} and hypoxemia. Hypoxemia also can be caused by poor perfusion of well-ventilated portions of the lung (high $\dot{V}/\dot{Q}$), resulting in wasted ventilation. The most common cause of high $\dot{V}/\dot{Q}$ is a pulmonary embolus that impairs blood flow to a segment of the lung. An area where alveoli are ventilated but not perfused is termed **alveolar dead space.**

The second factor affecting diffusion of oxygen from the alveoli into the blood is the alveolocapillary barrier. Diffusion of oxygen through the alveolocapillary membrane is impaired if the alveolocapillary membrane is thickened or the surface area available for diffusion is decreased. Abnormal thickness, as occurs with edema (tissue swelling) and fibrosis (formation of fibrous lesions), increases the time required for diffusion across the alveolocapillary membrane. If diffusion is slowed enough, the oxygen in the alveolar gas (P_{AO_2}) and capillary blood does not have time to equilibrate during the fraction of a second that blood remains in the capillary. Destruction of alveoli, such as that which occurs in emphysema, decreases the surface area available for diffusion. Hypercapnia is rarely produced by impaired diffusion, because carbon dioxide diffuses so easily from capillary to alveolus that the individual with impaired diffusion would die from hypoxemia before hypercapnia could occur.

Hypoxemia most often is associated with a compensatory hyperventilation and resultant respiratory alkalosis (i.e., decreased Pa_{CO_2} and increased pH). However, in individuals with associated ventilatory difficulties, hypoxemia may be complicated by hypercapnia and respiratory acidosis. Hypoxemia results in widespread tissue dysfunction and, when severe, can lead to organ infarction. In addition, hypoxic pulmonary vasoconstriction can contribute to increased pressures in the pulmonary artery (pulmonary artery hypertension) and lead to right-sided heart failure and cor pulmonale (see p. 1276). Clinical manifestations of acute hypoxemia may include cyanosis, confusion, tachycardia, edema, and decreased renal output.

Acute Respiratory Failure

Respiratory (lung) failure is defined as inadequate gas exchange, that is, hypoxemia, in which Pa_{O_2} is ≤50 mmHg, or hypercapnia, in which Pa_{CO_2} is ≥50 mmHg with a pH of ≤7.25. Respiratory failure can result from direct injury to the lungs, airways, or chest wall or indirectly because of injury to another body system, such as the brain or liver.[14] It can occur in individuals who have an otherwise normal respiratory system

or in those with underlying chronic pulmonary disease. Most pulmonary diseases can cause episodes of acute respiratory failure. If the respiratory failure is primarily hypercapnic, it is the result of inadequate alveolar ventilation (see Hypercapnia, p. 1251) and the individual must receive ventilatory support, such as with a bag-valve mask, noninvasive positive pressure ventilation, or intubation and placement on mechanical ventilation. If the respiratory failure is primarily hypoxemic, it is the result of inadequate exchange of oxygen between the alveoli and the capillaries (see Hypoxemia, p. 1251) and the individual must receive supplemental oxygen therapy. Many individuals have a combined hypercapnic and hypoxemic respiratory failure and require both kinds of support.

Respiratory failure is an important potential complication of any major surgical procedure, especially those that involve the central nervous system, thorax, or upper abdomen. Smokers are at risk, particularly if they have preexisting lung disease. Limited cardiac reserve, chronic renal failure, chronic hepatic disease, and infection also increase the tendency to develop postoperative respiratory failure. The most common postoperative pulmonary problems are atelectasis, pneumonia, pulmonary edema, and pulmonary emboli (these conditions are discussed later in this chapter).

Prevention of postoperative respiratory failure includes frequent turning and position changes, deep breathing exercises, and early ambulation to prevent atelectasis and accumulation of secretions. Humidification of inspired air can help loosen secretions. Incentive spirometry gives individuals immediate feedback about tidal volumes, which encourages them to breathe deeply. Supplemental oxygen is given for hypoxemia, and antibiotics are given as appropriate to treat infection. If respiratory failure develops, the individual may require conventional mechanical ventilation, high-frequency ventilation, or extracorporeal membrane oxygenation.[15]

DISORDERS OF THE CHEST WALL AND PLEURA

There are many conditions that can affect the chest wall and/or pleura and impact the function of the respiratory system. Chest wall disorders primarily affect tidal volume and therefore result in hypercapnia. Pleural diseases affect ventilation and oxygenation.

Disorders of the Chest Wall

Chest Wall Restriction

If the chest wall is deformed, traumatized, immobilized, or made heavy by fat, the work of breathing is increased and ventilation may be compromised because of a decrease in tidal volume. The degree of ventilatory impairment depends on the severity of the chest wall abnormality. Grossly obese individuals are often dyspneic on exertion or when recumbent. Individuals with severe kyphoscoliosis (lateral bending and rotation of the spinal column with distortion of the thoracic cage) often have dyspnea on exertion that can progress to respiratory failure. Such individuals also are susceptible to lower respiratory tract infections. Obesity and kyphoscoliosis are risk factors for respiratory disease in individuals admitted to a hospital for other problems, particularly those who require surgery. Other

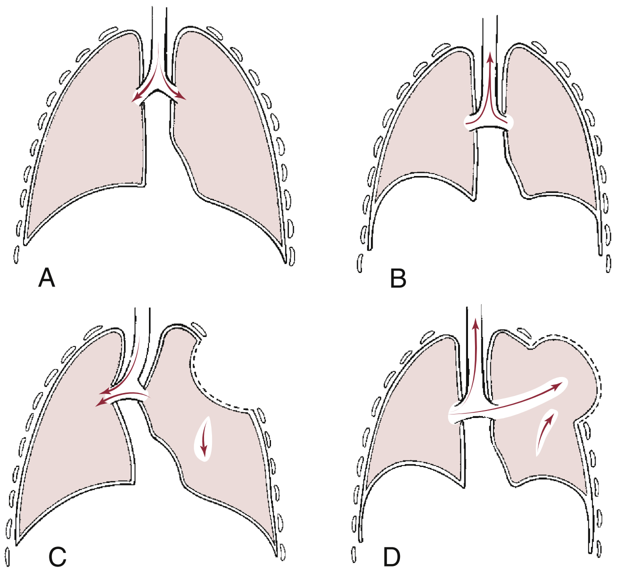

FIGURE 35-3 Flail chest. Normal respiration: **A,** inspiration; **B,** expiration. Paradoxical motion: **C,** inspiration, area of lung underlying unstable chest wall sucks in on inspiration; **D,** expiration, unstable area balloons out. Note movement of mediastinum toward opposite lung during inspiration.

musculoskeletal abnormalities that can impair ventilation are ankylosing spondylitis and pectus excavatum (a deformity characterized by depression of the sternum) (see Chapters 44 and 45, respectively). Pain from chest wall injury, surgery, or disease is also an important cause of restriction and decreased tidal volume. This can cause significant hypoventilation, especially in those with underlying lung disease.

Impairment of respiratory muscle function caused by neuromuscular disease also can restrict the chest wall or impair pulmonary function. Muscle weakness can result in hypoventilation and hypercapnia, inability to remove secretions, and hypoxemia. The most common cause of hospital admission for individuals with neuromuscular diseases, such as muscular dystrophy, myasthenia gravis, and Guillain-Barré syndrome, is respiratory difficulty. (See Unit V for a more complete discussion of these disorders.)
